4 U.S. Environmental Protection Agency policy. Mention of trade names or commercial products  
5 does not constitute endorsement or recommendation for use.  
6

7  
8 **PREFACE**

9  
10 National Ambient Air Quality Standards (NAAQS) are promulgated by the United States  
11 Environmental Protection Agency (EPA) to meet requirements set forth in Sections 108 and 109  
12 of the U.S. Clean Air Act (CAA). Sections 108 and 109 require the EPA Administrator (1) to  
13 list widespread air pollutants that reasonably may be expected to endanger public health or  
14 welfare; (2) to issue air quality criteria for them that assess the latest available scientific  
15 information on nature and effects of ambient exposure to them; (3) to set “primary” NAAQS to  
16 protect human health with adequate margin of safety and to set “secondary” NAAQS to protect  
17 against welfare effects (e.g., effects on vegetation, ecosystems, visibility, climate, manmade  
18 materials, etc.); and (5) to periodically (every 5 years) review and revise, as appropriate, the  
19 criteria and NAAQS for a given listed pollutant or class of pollutants.

20 The original NAAQS for particulate matter (PM), issued in 1971 as “total suspended  
21 particulate” (TSP) standards, were revised in 1987 to focus on protecting against human health  
22 effects associated with exposure to ambient PM less than 10 microns ( $\leq 10 \mu\text{m}$ ) that are capable  
23 of being deposited in thoracic (tracheobronchial and alveolar) portions of the lower respiratory  
24 tract. Later periodic reevaluation of newly available scientific information, as presented in the  
25 last previous version of this “Air Quality Criteria for Particulate Matter” document published in  
26 1996, provided key scientific bases for PM NAAQS decisions published in July 1997. More  
27 specifically, the  $\text{PM}_{10}$  NAAQS set in 1987 ( $150 \mu\text{g}/\text{m}^3$ , 24-h;  $50 \mu\text{g}/\text{m}^3$ , annual average) were  
28 retained in modified form and new standards ( $65 \mu\text{g}/\text{m}^3$ , 24-h;  $15 \mu\text{g}/\text{m}^3$ , annual average) for  
29 particles  $\leq 2.5 \mu\text{m}$  ( $\text{PM}_{2.5}$ ) were promulgated in July 1997.

30 This Fourth External Review Draft of revised Air Quality Criteria for Particulate Matter  
31 assesses new scientific information that has become available mainly between early 1996

1 through April 2002. The present draft is being released for public comment and review by the  
2 Clean Air Scientific Advisory Committee (CASAC) to obtain comments on the organization and  
3 structure of the document, the issues addressed, the approaches employed in assessing and  
4 interpreting the newly available information on PM exposures and effects, and the key findings  
5 and conclusions arrived at as a consequence of this assessment. Public comments and CASAC  
6 review recommendations will be taken into account in making any appropriate further revisions  
7 to this document for incorporation into a final draft. Evaluations contained in the present  
8 document will be drawn on to provide inputs to associated PM Staff Paper analyses prepared by  
9 EPA's Office of Air Quality Planning and Standards (OAQPS) to pose alternatives for  
10 consideration by the EPA Administrator with regard to proposal and, ultimately, promulgation of  
11 decisions on potential retention or revision of the current PM NAAQS.

12 Preparation of this document was coordinated by staff of EPA's National Center for  
13 Environmental Assessment in Research Triangle Park (NCEA-RTP). NCEA-RTP scientific  
14 staff, together with experts from other EPA/ORD laboratories and academia, contributed to  
15 writing of document chapters; and earlier drafts of this document were reviewed by experts from  
16 federal and state government agencies, academia, industry, and non-governmental organizations  
17 (NGOs) for use by EPA in support of decision making on potential public health and  
18 environmental risks of ambient PM. The document describes the nature, sources, distribution,  
19 measurement, and concentrations of PM in outdoor (ambient) and indoor environments. It also  
20 evaluates the latest data on human exposures to ambient PM and consequent health effects in  
21 exposed human populations (to support decision making regarding primary, health-related PM  
22 NAAQS). The document also evaluates ambient PM environmental effects on vegetation and  
23 ecosystems, visibility, and man-made materials, as well as atmospheric PM effects on climate  
24 change processes associated with alterations in atmospheric transmission of solar radiation or its  
25 reflectance from the Earth's surface or atmosphere (to support decision making on secondary  
26 PM NAAQS).

27 The NCEA of EPA acknowledges the contributions provided by authors, contributors, and  
28 reviewers and the diligence of its staff and contractors in the preparation of this document.  
29

# Air Quality Criteria for Particulate Matter

## VOLUME I

EXECUTIVE SUMMARY .....	E-1
1. INTRODUCTION .....	1-1
2. PHYSICS, CHEMISTRY, AND MEASUREMENT OF PARTICULATE MATTER .....	2-1
APPENDIX 2A: Techniques for Measurement of Semivolatile Organic Compounds .....	2A-1
APPENDIX 2B: Analytical Techniques .....	2B-1
3. CONCENTRATIONS, SOURCES, AND EMISSIONS OF ATMOSPHERIC PARTICULATE MATTER .....	3-1
APPENDIX 3A: Spatial and Temporal Variability of the Nationwide AIRS PM <sub>2.5</sub> and PM <sub>10-2.5</sub> Data Sets .....	3A-1
APPENDIX 3B: Aerosol Composition Data from the Speciation Network .....	3B-1
APPENDIX 3C: Organic Composition of Particulate Matter .....	3C-1
APPENDIX 3D: Composition of Particulate Matter Source Emissions .....	3D-1
APPENDIX 3E: Variability Observed in PM <sub>2.5</sub> and PM <sub>10-2.5</sub> Concentrations at IMPROVE Sites .....	3E-1
4. ENVIRONMENTAL EFFECTS OF AIRBORNE PARTICULATE MATTER .....	4-1
APPENDIX 4A: Colloquial and Latin Names .....	4A-1
3. CONCENTRATIONS, SOURCES, AND EMISSIONS OF ATMOSPHERIC PARTICULATE MATTER .....	3-1
4. ENVIRONMENTAL EFFECTS OF AIRBORNE PARTICULATE MATTER .....	4-1
5. HUMAN EXPOSURE TO PARTICULATE MATTER AND ITS CONSTITUENTS .....	5-1

**Air Quality Criteria for Particulate Matter**  
(cont'd)

**VOLUME II**

6.	DOSIMETRY OF PARTICULATE MATTER .....	6-1
7.	TOXICOLOGY OF PARTICULATE MATTER IN HUMANS AND LABORATORY ANIMALS .....	7-1
8.	EPIDEMIOLOGY OF HUMAN HEALTH EFFECTS ASSOCIATED WITH AMBIENT PARTICULATE MATTER .....	8-1
	APPENDIX 8A: Short-Term PM Exposure-Mortality Studies: Summary Tables .....	8A-1
	APPENDIX 8B: Particulate Matter-Morbidity Studies: Summary Tables ...	8B-1
9.	INTEGRATIVE SYNTHESIS .....	9-1
	APPENDIX 9A: Key Quantitative Estimates of Relative Risk for Particulate Matter-Related Health Effects Based on Epidemiologic Studies of U.S. and Canadian Cities Assessed in the 1996 Particulate Matter Air Quality Criteria Document .....	9A-1

## Table of Contents

List of Tables .....	I-xiii
List of Figures .....	I-xix
Authors, Contributors, and Reviewers .....	I-xxxii
U.S. Environmental Protection Agency Project Team for Development of Air Quality Criteria for Particulate Matter .....	I-xxxix
Abbreviations and Acronyms .....	I-xlii
 EXECUTIVE SUMMARY .....	 E-1
 1. INTRODUCTION .....	 1-1
1.1 LEGISLATIVE REQUIREMENTS .....	1-1
1.2 HISTORY OF PREVIOUS PM CRITERIA AND NAAQS REVIEWS .....	1-2
1.2.1 The 1997 PM NAAQS Revision .....	1-3
1.2.2 Coordinated Particulate Matter Research Program .....	1-6
1.3 CURRENT PM CRITERIA AND NAAQS REVIEW .....	1-9
1.3.1 Key Milestones .....	1-9
1.3.2 Methods and Procedures for Document Preparation .....	1-13
1.3.3 Approach .....	1-15
1.4 DOCUMENT ORGANIZATION AND CONTENT .....	1-15
REFERENCES .....	1-17
 2. PHYSICS, CHEMISTRY, AND MEASUREMENT OF PARTICULATE MATTER .....	 2-1
2.1 PHYSICS AND CHEMISTRY OF PARTICULATE MATTER .....	2-2
2.1.1 Basic Concepts .....	2-2
2.1.2 Physical Properties and Processes .....	2-3
2.1.2.1 Definitions of Particle Diameter .....	2-3
2.1.2.2 Aerosol Size Distributions .....	2-5
2.1.2.3 Ultrafine Particles .....	2-20
2.1.3 Chemistry of Atmospheric Particulate Matter .....	2-28
2.1.3.1 Chemical Composition and Its Dependence on Particle Size .....	2-29
2.1.3.2 Primary and Secondary Particulate Matter .....	2-29
2.1.3.3 Particle-Vapor Partitioning .....	2-31
2.1.3.4 Atmospheric Lifetimes and Removal Processes .....	2-34
2.1.4 Comparison of Fine and Coarse Particles .....	2-36
2.2 MEASUREMENT OF PARTICULATE MATTER .....	2-38
2.2.1 Particle Measurements of Interest .....	2-38
2.2.2 Issues in Measurement of Particulate Matter .....	2-40
2.2.2.1 Artifacts Due to Chemical Reactions .....	2-41
2.2.2.2 Treatment of Semivolatile Components of Particulate Matter .....	2-42
2.2.2.3 Upper Cut Point .....	2-43

**Table of Contents**

## List of Figures

<u>Number</u>		<u>Page</u>
1-1	A general framework for integrating particulate-matter research . . . . .	1-7
2-1	Distribution of coarse, accumulation, and nuclei mode particles by three characteristics: (a) number, (b) surface area, and (c) volume for the grand average continental size distribution . . . . .	2-8
2-2	Particle size distributions by number, (a) number concentrations are shown on a logarithmic scale to display the wide range by site and size; (b) number concentrations for the average urban distribution are shown on a linear scale . . . .	2-9
2-3	Size distribution by volume (a) for the averaged rural and urban-influenced rural number distributions shown in Figure 2-2a and a distribution from south central New Mexico, and (b) for the averaged urban and freeway-influenced urban number distributions shown in Figure 2-2a . . . . .	2-10
2-4	Volume size distribution, measured in traffic, showing fine and coarse particles and the nuclei and accumulation modes of fine particles . . . . .	2-11
2-5	Submicron number size distribution observed in a boreal forest in Finland showing the tri-modal structure of fine particles . . . . .	2-12
2-6	Specified particle penetration (size-cut curves) through an ideal (no-particle-loss) inlet for five different size-selective sampling criteria . . . . .	2-15
2-7	An idealized distribution of ambient particulate matter showing fine-mode particles and coarse-mode particles and the fractions collected by size-selective samplers . . . . .	2-16
2-8	Comparison of penetration curves for two PM <sub>10</sub> beta gauge samplers using cyclone inlets . . . . .	2-18
2-9	Typical engine exhaust size distribution . . . . .	2-23
2-10	Number size distributions showing measurement of a nucleation burst made in a boreal forest in Finland . . . . .	2-25
2-11	Examples of the measured one hour average particle number size distributions and the log normal fits to the modes of the data . . . . .	2-26
2-12(a-f)	Fitted multi-model particle size distribution at different sampling distances from Freeway 405 (a) 30 m downwind, (b) 60 m downwind, (c) 90 m downwind, (d) 150 m downwind, (e) 300 m downwind, (f) 300 m upwind . . . . .	2-27

4-38	Relative humidity adjustment factor for ammonium sulfate as a function of relative humidity .....	4-171
4-39a	Aggregate visibility trends for 10 eastern Class 1 areas .....	4-181
4-39b	Aggregate visibility trends for 26 western Class 1 areas .....	4-181
4-40	(a) Eastern class I area aggregate trends in aerosol light extinction on the 20% haziest days, including trends by major aerosol component; (b) Western class I area aggregate trends in aerosol light extinction on the 20% haziest days, including trends by major aerosol component .....	4-183
4-41a	Light extinction trends in Tucson, Arizona from 1993 to 2002 .....	4-185
4-41b	Light extinction trends in Phoenix, Arizona from 1994 to 2001 .....	4-186
4-42	Estimated global mean radiative forcing exerted by gas and various particle phase species for the year 2000, relative to 1750 .....	4-213
5-1	Hypothetical exposure time profile: Pollutant exposure as a function of time showing how the averaged exposure, integrated exposure, and peak exposure relate to the instantaneous exposure .....	5-9
5-2	Distribution of $F_{INF}$ (a) and $\alpha$ (b) for daytime as estimated from PTEAM study data .....	5-23
5-3	Comparison of correlation coefficients for longitudinal analyses of personal exposure versus ambient concentrations for individual subjects for $PM_{2.5}$ and sulfate .....	5-58

**List of Figures**  
(cont'd)

<u>Number</u>		<u>Page</u>
5-4	Personal exposure versus ambient concentrations for PM <sub>2.5</sub> and sulfate . . . . .	5-61
5-5	Regression analyses of aspects of daytime personal exposure to PM <sub>10</sub> estimated using data from the PTEAM study . . . . .	5-62
5-6	Air exchange rates measured in homes throughout the United States . . . . .	5-69
5-7	Box plots of hourly air exchange rates stratified by season in Boston, MA, during 1998 . . . . .	5-70
5-8	Geometric mean infiltration factor (indoor/outdoor ratio) for hourly nighttime, nonsource data for two seasons . . . . .	5-71
5-9	Regression of air exchange rate on absolute indoor-outdoor temperature difference . . . . .	5-73
5-10	Comparison of deposition rates from Long et al., 2001a with literature values . . . . .	5-75
5-11	Penetration efficiencies and deposition rates from models of nightly average data . . . . .	5-76
5-12	Mean hourly indoor/outdoor particle concentration ratio from an unoccupied residence in Fresno, CA, during spring 1999 . . . . .	5-82
5-13	Personal versus outdoor SO <sub>4</sub> <sup>-2</sup> in State College, PA . . . . .	5-97
5-14	Plots of nonambient exposure to PM <sub>10</sub> , (a) daily individual daytime values from PTEAM data and (b) daily-average values from THEES data . . . . .	5-110

USGCRP	U.S. Global Change Research Program
VAPS	Versatile Air Pollution Samplers
VMD	volume mean diameter
VOC	volatile organic compounds
WMO	World Meteorological Organization
VR	visual range
WINS	Well Impactor Ninety-Six
WMO	World Meteorological Organization
WRAC	Wide Range Aerosol Classifier

WTA	willingness to accept
WTP	willingness to pay
XAD	polystyrene-divinyl benzene
XRF	X-ray fluorescence

# EXECUTIVE SUMMARY

## E.1 INTRODUCTION

The purpose of this document, Air Quality Criteria for Particulate Matter (PM AQCD), is to present air quality criteria for particulate matter (PM) in accordance with Clean Air Act (CAA) Sections 108 and 109, which govern establishment, review, and revision of U.S. National Ambient Air Quality Standards (NAAQS) as follows:

- Section 108 directs the U.S. Environmental Protection Agency (EPA) Administrator to list pollutants that may reasonably be anticipated to endanger public health or welfare and to issue air quality criteria for them. The air quality criteria are to reflect the latest scientific information useful in indicating the kind and extent of all identifiable effects on public health and welfare expected from the presence of the pollutant in ambient air.
- Section 109 directs the EPA Administrator to set and periodically revise, as appropriate, (a) primary NAAQS, which in the judgement of the Administrator, are requisite to protect public health, with an adequate margin of safety, and (b) secondary NAAQS which, in the judgement of the Administrator, are requisite to protect the public welfare from any known or anticipated adverse effects (e.g., impacts on vegetation, crops, ecosystems, visibility, climate, man-made materials, etc.).
- Section 109 of the CAA also requires periodic review and, if appropriate, revision of existing criteria and standards. Also, an independent committee of non-EPA experts, the Clean Air Scientific Advisory Committee (CASAC), is to provide the EPA Administrator advice and recommendations regarding the scientific soundness and appropriateness of criteria and NAAQS.

To meet these CAA mandates, this document assesses the latest scientific information useful in deriving criteria as scientific bases for decisions on possible revision of current PM NAAQS. A separate EPA PM Staff Paper will draw upon assessments in this document, together with technical analyses and other information, to identify alternatives for consideration by the EPA Administrator with regard to possible retention or revision of the PM NAAQS.

1           The present document is organized into a set of 10 chapters, as follows:

- 2           • This Executive Summary summarizes key points from the ensuing chapters.
- 3           • Chapter 1 provides a general introduction, including information on legislative requirements  
            and history of the PM NAAQS and an overview of approaches used to prepare this document.
- 4           • Chapters 2, 3 and 5 provide background information on PM atmospheric science, air quality,  
            and human exposure aspects to help place the succeeding discussions of PM health and  
            environmental effects into perspective.
- 5           • Chapter 4 deals with environmental effects of PM on vegetation and ecosystems, visibility,  
            man-made materials, and climate.
- 6           • Human health issues related to PM are addressed in Chapter 6 (Dosimetry); Chapter 7  
            (Toxicology); and Chapter 8 (Community Epidemiology).
- 7           • Chapter 9 provides an integrative synthesis of key points from the preceding chapters.

8

## 9   **E.2   AIR QUALITY AND EXPOSURE ASPECTS**

10           The document's discussion of air quality and exposure aspects considers chemistry and  
11   physics of atmospheric PM; analytical techniques for measuring PM mass, size, and chemical  
12   composition; sources of ambient PM in the United States; temporal/spatial variability and trends  
13   in ambient U.S. PM levels; and ambient concentration-human exposure relationships. Overall,  
14   the atmospheric science and air quality information provides further evidence substantiating the  
15   1996 PM AQCD conclusion that distinctions between fine and coarse mode particles (in terms of  
16   emission sources, formation mechanisms, atmospheric transformation, transport distances, air  
17   quality patterns, and exposure relationships) warrant fine and coarse PM being viewed as  
18   separate subclasses of ambient PM. Key findings are summarized in the next several sections.

19

20

## 1 **E.2.1 Chemistry and Physics of Atmospheric Particles**

- 2 • Airborne PM is not a single pollutant, but rather is a mixture of many subclasses of pollutants with each subclass containing many different chemical species. Particles suspended in the atmosphere originate from a variety of sources and possess a range of morphological, chemical, physical, and thermodynamic properties. A complete description of atmospheric particles would include an accounting of the chemical composition, morphology, and size of each particle, and the relative abundance of each particle type as a function of particle size. Recent developments in single particle analysis techniques are bringing such a description closer to reality.
- 3 • Particle size distributions show that atmospheric particles exist in two classes: fine particles and coarse particles. Fine and coarse particles are defined primarily in terms of their formation mechanisms and size; they also differ in sources, chemical composition, and removal processes (see Table 2-1). Subsequent chapters show that fine and coarse particles also differ in aspects of concentration, exposure, dosimetry, toxicology, and epidemiology. These differences support the setting of separate standards for fine and coarse particles.
- 4 • Fine and coarse particles overlap in the size range between 1 and 3  $\mu\text{m}$  aerodynamic diameter where ambient PM concentrations are at a minimum. Coarse particles are generally larger than this minimum and are generally formed by mechanical processes. Energy considerations limit the break-up of large mineral particles and small particle aggregates generally to a minimum size of about 1  $\mu\text{m}$  in diameter. Coarse particles and coarse-mode particles are equivalent terms.
- 5 • Fine PM is derived primarily from combustion material that has volatilized and then  
6 condensed to form primary PM or from precursor gases reacting in the atmosphere to form secondary PM. New fine particles are formed by the nucleation of gas phase species; they grow by coagulation (existing particles combining) or condensation (gases condensing on existing particles). Fine particles are subdivided into accumulation, Aitkin, and nucleation modes. In earlier texts, nuclei mode referred to the size range now split into the Aitkin and nucleation modes (see Figures 2-4 and 2-5). Particles in the size range below 0.1  $\mu\text{m}$  diameter are called ultrafine or nanoparticles and include the Aitkin and nucleation modes.

- 1
- $PM_{2.5}$  is an indicator for fine particles.  $PM_{10-2.5}$  is an indicator for thoracic coarse particles (coarse particles capable of reaching the thoracic portion of the respiratory system – trachea, bronchi, and alveolar regions).  $PM_{2.5}$  has been selected as the indicator for fine particles to include all accumulation-mode particles during high relative humidity, while recognition that it also includes some coarse-mode particles between 1 and 2.5  $\mu m$ .  $PM_{2.5}$  specifies a sample collected through a size-selective inlet with a specified penetration curve at 50% cut point at 2.5  $\mu m$  aerodynamic diameter.
- 2
- Aerosol scientists use three different approaches or conventions in the classification of particles by size: (1) modes, based on the observed size distributions and formation mechanisms; (2) cut point, usually based on the 50% cut point of the specific sampling device, including legally specified, regulatory sizes for air quality standards; and (3) dosimetry or occupational health sizes, based on the entrance into various compartments of the respiratory system.

3

## 4 **E.2.2 Sources of Airborne Particles in the United States**

- 5
- Because of the complexity of the composition of ambient  $PM_{2.5}$  and  $PM_{10-2.5}$ , sources are best discussed in terms of individual constituents of both primary and secondary  $PM_{2.5}$  and  $PM_{10-2.5}$ . Each of these constituents can have anthropogenic and natural sources as shown in Table 3-8. Major components of fine particles are sulfates, strong acid, ammonium nitrate, organic compounds, trace elements (including metals), elemental carbon, and water.
- 6
- Primary particles are emitted directly from sources. Secondary particles are formed from atmospheric reactions of sulfur dioxide ( $SO_2$ ), nitrogen oxides ( $NO_x$ ), and certain organic compounds. NO reacts with ozone ( $O_3$ ) to form  $NO_2$ .  $SO_2$  and  $NO_2$  react with hydroxy radical (OH) during the daytime to form sulfuric and nitric acid. During the nighttime,  $NO_2$  reacts with ozone and forms nitric acid through a sequence of reactions involving the nitrate radical ( $NO_3$ ). These acids may react further with ammonia to form ammonium sulfates and nitrates. Some types of higher molecular weight organic compounds react with OH radicals, and olefinic compounds also react with ozone to form oxygenated organic compounds,

which nucleate or can condense onto existing particles.  $\text{SO}_2$  also dissolves in cloud and fog droplets, where it may react with dissolved  $\text{O}_3$ ,  $\text{H}_2\text{O}_2$ , or, if catalyzed by certain metals, with  $\text{O}_2$ , yielding sulfuric acid or sulfates, that lead to PM when the droplet evaporates.

- 7
- Organic compounds constitute from 10 to 70% of dry  $\text{PM}_{2.5}$  mass. Whereas the chemistry of particulate nitrate and sulfate formation has been relatively well studied, the chemistry of secondary organic particulate matter formation is especially complex. Although additional sources of secondary organic PM might still be identified, there appears to be a general consensus that biogenic compounds (monoterpenes, sesquiterpenes) and aromatic compounds (e.g., toluene and ethylbenzene) are the most significant precursors. Atmospheric transformations of the compounds, which are formed in the particle phase during the aging of particles, are still not adequately understood.
- 8
- The results of receptor modeling studies throughout the United States indicate that the combustion of fossil and biomass fuels is the major source of measured ambient  $\text{PM}_{2.5}$ . Fugitive dust, found mainly in the  $\text{PM}_{10-2.5}$  range size, represents the largest source of measured ambient  $\text{PM}_{10}$  in many locations in the western United States. The application of any of the source apportionment techniques is still limited by the availability of source profile data. Whereas the Chemical Mass Balance approach relies directly on source profile data, solutions from the Positive Matrix Factorization technique yield profiles for the factors that contribute to PM.
- 9
- The use of organic compounds in source apportionment studies could potentially result in the attribution of PM to many more source categories than is possible using only trace elements. However, in the relatively few studies of the composition of the organic fraction of ambient particles that have been performed, typically only about 10 to 20 % of organic compounds have been quantified. The separation of contributions from diesel- and gasoline-fueled vehicles using organic marker compounds is still somewhat problematic. Additional efforts to develop protocols for extraction and analysis of organic markers are needed.

10

### 1 **E.2.3 Atmospheric Transport and Fate of Airborne Particles**

- 2 • Primary and secondary fine particles have long lifetimes in the atmosphere (days to weeks) and travel long distances (hundreds to thousands of kilometers). They tend to be uniformly distributed over urban areas and larger regions, especially in the eastern United States. As a result, they are not easily traced back to their individual sources.
- 3 • Coarse particles normally have shorter lifetimes (minutes to hours) and generally only travel short distances (<10's of km). Therefore, coarse particles tend to be unevenly distributed across urban areas and tend to have more localized effects than fine particles. However, dust storms occasionally cause long range transport of small coarse-mode particles.

### 4 **E.2.4 Airborne Particle Measurement Methods**

- 5 • Measurements of ambient PM mass and chemical composition are needed to determine attainment of standards; to guide progress towards attainment of a standard (including determination of source categories and validation of air quality models); and to determine health, ecological, and radiative effects. A comprehensive approach requires a combination of analytical techniques to assess (1) mass, (2) crustal and trace elements, (3) water-soluble ionic species including strong acidity, (4) elemental carbon, and (5) organic compounds.
- 6 • There are no calibration standards for suspended particle mass; therefore, the accuracy of particle mass measurements cannot be definitively determined. The precision of particle mass measurements can be determined by comparing results from collocated samplers. Intercomparisons, using different techniques and samplers of different designs, coupled with mass balance studies (relating the sum of components to the measured mass), provide a method for gaining confidence in the reliability of PM measurements.
- 7 • Mass concentration measurements with a precision of 10% or better have been obtained with collocated samplers of identical design. Field studies of EPA PM<sub>10</sub> and PM<sub>2.5</sub> reference methods and reviews of field data from collocated PM<sub>10</sub> and PM<sub>2.5</sub> samplers show high precision (better than ± 10%). The use of more careful techniques, including double

weighing of filters, can provide higher precision and may be needed for precise determination of  $PM_{10-2.5}$  by difference.

- 10 • Analytical techniques exist for measurement of the mass and chemical composition of PM retained on a filter (nonvolatile mass) in terms of elements (except carbon) and certain key ions (sulfate, nitrate, hydrogen, and ammonium). Acceptable measurements can be made of the total carbon retained on a filter. However, the split into organic carbon and elemental carbon depends on the operational details of the analytical methods and varies somewhat among methods. Determination of the various organic compounds in the organic carbon fraction remains a challenge.
- 11 • Important components of atmospheric PM (particle-bound water, ammonium nitrate, and many organic compounds) are termed semivolatile because significant amounts of both the gaseous and condensed phases may exist in the atmosphere in equilibrium. Particle-bound water is not considered a pollutant. Most of the particle-bound water is removed by heating the particles or by equilibration of the collected particles at a low relative humidity (40%) for 24 hours. However, these processes also cause the loss of other semivolatile components. Semivolatile components also evaporate from the filter during sampling due to the pressure drop across the filter or due to a reduction in the atmospheric concentration during the sampling time.
- 12 • Continuous methods must dry the PM to remove particle-bound water. If heating is used to dry the particles, more of the semivolatile components may be removed than are lost in filter sampling. Collection and retention of ammonium nitrate and semivolatile organic compounds represents a major challenge in the effort to move to continuous measurement of PM mass. The use of diffusion dryers, which dehumidify the air stream without heating, represents a promising approach. Uncertainty in the efficiency of retention of ammonium nitrate and organic compounds on filters also affects source category attribution and epidemiologic studies.

- 1
- Semivolatile organic compounds and semivolatile ammonium compounds (such as  $\text{NH}_4\text{NO}_3$ ) may be lost by volatilization during sampling. Such losses may be very important in woodsmoke impacted areas for organic compounds or in agricultural and other areas where low sulfate and high ammonia lead to high  $\text{NH}_4\text{NO}_3$  concentrations. New techniques are now in use for measurement of nitrates and new research techniques are being tested for measurement of mass of semivolatile organic compounds in PM and of the total (semivolatile plus non-volatile) PM mass. The Federal Reference Methods (FRM) for  $\text{PM}_{10}$  and  $\text{PM}_{2.5}$  give precise ( $\pm 10\%$ ) measurements of “equilibrated mass.” However, the loss of semivolatile PM (ammonium nitrate and organic compounds) and the possible retention of some particle-bound water in current PM mass measurements contribute to uncertainty in the measurement of the mass of PM as it exists suspended in the atmosphere.
- 2
- Techniques are available to separate fine particles from coarse particles and collect the fine particles on a filter. No such technique exists for coarse particles. As yet, no consensus exists on the best technique for collecting a coarse particle sample for determination of mass and composition. Candidates include multistage impaction, virtual impaction, and difference (subtracting  $\text{PM}_{2.5}$  mass or composition from  $\text{PM}_{10}$  mass or composition). Advances in the theory and practice of virtual impaction suggest that it should be possible to design virtual impactors with much less than the 10% of fine PM collected in the coarse PM sample, as is now the case for the dichotomous samplers used in air quality studies and with penetration curves as sharp as those used in the current FRM for  $\text{PM}_{2.5}$ .

3

#### 4 **E.2.5 Ambient PM Concentrations in the U.S.**

- 5
- The recently deployed  $\text{PM}_{2.5}$  FRM network has provided data for a large number of sites across the United States. The data are stored in the Aerometric Information Retrieval System (AIRS). Data have also been collected at remote sites as part of the IMPROVE and NESCAUM networks. Annual mean U.S.  $\text{PM}_{2.5}$  concentrations from 1999 to 2000 range from about  $5 \mu\text{g}/\text{m}^3$  to about  $30 \mu\text{g}/\text{m}^3$ . In the eastern United States, the data from 1999 to 2001 indicate that highest quarterly mean concentrations and maximum concentrations most often occur during the summer. In the western United States, highest quarterly mean values

and maximum values occur mainly during the winter at a number of sites although there were exceptions to these general patterns.  $PM_{2.5}$  and  $PM_{10}$  concentrations in many urban areas have generally declined over the past few decades. However, they appear to have leveled off in the past few years.

- 6 • The median  $PM_{2.5}$  concentration across the United States during 1999, 2000, and 2001, the first three years of operation of the  $PM_{2.5}$  FRM network, was  $13 \mu\text{g}/\text{m}^3$ , with a 95<sup>th</sup> percentile value of  $18 \mu\text{g}/\text{m}^3$ . The corresponding median  $PM_{10-2.5}$  concentration was  $10 \mu\text{g}/\text{m}^3$ , with a 95<sup>th</sup> percentile value of  $21 \mu\text{g}/\text{m}^3$ .
- 7 • Although  $PM_{2.5}$  concentrations within a given Metropolitan Statistical Area (MSA) can be highly correlated between sites, there can still be significant differences in their concentrations. The degree of spatial uniformity in  $PM_{2.5}$  concentrations and the strength of site to site correlations in urban areas varies across the country. These factors should be considered in using data obtained by the  $PM_{2.5}$  FRM network to approximate community-scale human exposures, and caution should be exercised in extrapolating conclusions as to spatial uniformity or correlations obtained in one urban area to another. Limited information also suggests that the spatial variability in urban source contributions is likely to be larger than for regional source contributions to  $PM_{2.5}$  and for  $PM_{2.5}$ , itself.
- 8 • Data for  $PM_{10-2.5}$  concentrations are not as abundant as they are for  $PM_{2.5}$ . The difference method used in their derivation is subject to the effects of uncertainties in measuring both  $PM_{10}$  and  $PM_{2.5}$ . As a result, estimates of  $PM_{10-2.5}$  concentrations, at times, come out as negative values, based on currently available data (e.g., in the EPA AIRS Database). In most cities where significant data is available,  $PM_{10-2.5}$  is spatially less uniform than  $PM_{2.5}$ .
- 9 • Ambient PM contains both primary and secondary components. The results of ambient monitoring studies and receptor modeling studies indicate that  $PM_{2.5}$  is dominated by secondary components in the eastern United States. General statements about the origin of OC in ambient  $PM_{2.5}$  samples cannot yet be made and so the contribution of secondary components throughout the rest of the United States is still highly uncertain. Primary constituents represent a smaller but still important component of  $PM_{2.5}$ . Crustal materials,

which are primary constituents, constitute the largest measured fraction of  $PM_{10-2.5}$  throughout the United States. Data for the concentration of bioaerosols in both the  $PM_{2.5}$  and  $PM_{10-2.5}$  size ranges are sparse.

- 10
- Recent but limited information about policy-relevant background concentrations have not provided sufficient evidence to warrant any changes in estimates of the annual average background concentrations given in the 1996 PM AQCD. These are: 1 to 4  $\mu\text{g}/\text{m}^3$  in the West and 2 to 5  $\mu\text{g}/\text{m}^3$  in the East for  $PM_{2.5}$ ; and approximately 3  $\mu\text{g}/\text{m}^3$  in both the East and the West for  $PM_{10-2.5}$ , with a range of 0 to 9  $\mu\text{g}/\text{m}^3$  in the West and 0 to 7  $\mu\text{g}/\text{m}^3$  in the East. Such concentrations are likely to be highly variable both spatially and temporally. Further information regarding the frequency distribution of 24-hour concentrations based on analyses of observations at relatively remote monitoring sites and on source apportionment analyses has become available and can be used for selected sites.

11

## 12 **E.2.6 Human Exposure to PM**

- 13
- Personal exposure to PM mass or its constituents results when individuals come in contact with particulate pollutant concentrations in locations or microenvironments that they frequent during a specific period of time. Various PM exposure metrics can be defined according to its source (i.e., ambient, nonambient) and the microenvironment where exposure occurs.
- 14
- Most people spend most of their time indoors where they are exposed to indoor-generated PM and ambient PM that has infiltrated indoors.
- 15
- Indoor-generated and ambient PM differ in sources, sizes, chemical composition, and toxicity.
- 16
- The ambient PM concentration and the indoor PM concentration can be measured by outdoor and indoor monitors. The total personal exposure can be measured by a personal exposure monitor carried by the person. However, the concentrations of indoor-generated PM and

ambient PM that has infiltrated indoors and the related values of ambient and nonambient PM exposures must be estimated.

- 17
- The intercept of a regression of individual, daily values of total personal exposure on daily PM concentrations, gives the average nonambient PM exposure; and the slope gives the average attenuation factor (the ratio of ambient PM exposure to ambient PM concentration).
- 18
- Similarly, the intercept of a regression of individual, daily values of indoor PM concentration on daily ambient concentrations, gives the average concentration of indoor-generated PM; and the slope gives the average infiltration factor (concentrations of ambient PM that has infiltrated indoors/ambient PM concentration).
- 19
- The attenuation factor and the infiltration factor depend on the penetration coefficient, the fraction of ambient PM that penetrates through the walls, doors, windows, etc.; the deposition or removal rate, a measure of how rapidly PM within the indoor microenvironment is removed by deposition to surfaces or by filtration in a heating/cooling system; and the air exchange rate, a measure of how rapidly indoor air is replaced by outdoor air. The attenuation factor also depends on the fraction of time spent outdoors.
- 20
- The air exchange rate is an important variable for determining the concentration of ambient PM found indoors. It can be measured by release and measurement of an inert tracer gas indoors. The air exchange rate increases with opening of windows or doors or operation of window or attic fans. It also increases as the indoor/outdoor temperature difference increases. For closed homes, i.e., no open windows or doors, the air exchange rate does not appear to be a function of wind speed or direction.
- 21
- The penetration coefficient and the deposition rate can be estimated from measurements of outdoor and indoor concentrations under conditions when there are no indoor sources (night time or unoccupied home). These parameters are functions of particle size. The penetration coefficient is high and the deposition rate is low for accumulation mode particles (0.1 to 1.0  $\mu\text{m}$ ). The penetration coefficient is lower and the deposition rate is higher for ultrafine particles ( $< 0.1 \mu\text{m}$ ) and coarse mode particles ( $> 1.0 \mu\text{m}$ ). The attenuation factor and the

infiltration factor are higher for particles in the accumulation mode than for ultrafine or coarse particles.

- 22
- The attenuation factor and the infiltration factor will vary as the air exchange rate does, and, therefore, will vary with season and housing characteristics. These factors will increase with increased opening of windows and doors. For closed homes, these factors will increase with an increase of the indoor/outdoor temperature difference; but they do not appear to be affected by wind speed or direction.
- 23
- The regression technique is useful for finding average values of the attenuation factor and the nonambient exposure and possibly for estimating the distribution of individual, daily values of the nonambient PM exposure.
- 24
- Individual, daily values of the ambient PM exposure, the nonambient PM exposure, and the attenuation factor may be determined from individual, daily values of the total PM personal exposure and daily ambient PM concentrations by several techniques:
- 25
- *Mass balance technique.* Direct measurement of the air exchange rate, measurement of the fraction of time spent outdoors by a diary of the subject's activity pattern, and use of the equilibrium mass balance equation for the attenuation factor with estimated values of the penetration coefficient and the deposition rate.
- 26
- *Sulfate ratio technique.* Individual, daily values of the attenuation factor (for  $PM_{2.5}$ ) will be given by individual, daily values of personal exposure to sulfate / the daily ambient sulfate concentration provided there are no indoor sources of sulfate and sulfate and  $PM_{2.5}$  have similar particle size distributions.
- 27
- *Recursive technique.* Indoor-generated emissions, which tend to be episodic, can be removed from a continuous record of indoor PM concentration, allowing separation of indoor-generated PM and ambient PM that has infiltrated indoors.
- 28
- In pooled studies (different subjects measured on different days), individual, daily values of total PM exposure are usually not well correlated with daily ambient PM concentrations.

In longitudinal studies (each subject measured for multiple days), individual, daily values of total PM personal exposure and daily ambient PM concentrations are highly correlated for some, but not all subjects.

- 29
- Only one study has reported estimated individual, daily values of ambient and nonambient PM exposure. Individual, daily values of total PM personal exposure and daily ambient PM concentrations were poorly correlated. However, individual, daily values of ambient PM exposure and daily ambient PM concentrations were highly correlated. Individual daily values of ambient and nonambient PM exposure were not well correlated. Individual daily values of nonambient PM exposure and daily ambient PM concentrations were also not well correlated.
- 30
- As long as the nonambient PM exposure is not correlated with the ambient PM exposure, it will not bias the estimated health effect of PM. However, the effect per  $\mu\text{g}/\text{ambient PM concentration}$  will be biased low compared to the health effect per  $\mu\text{g}/\text{ambient PM exposure}$  by the attenuation factor. This effect probably explains some of the heterogeneity in  $\text{PM}_{10}$  effects observed in multicity epidemiology studies, as indicated by a correlation of PM effects in different cities with air conditioning use in those cities (i.e., the higher the air conditioning use, the lower the health effect estimate per  $\mu\text{g}/\text{m}^3$  of ambient PM).
- 31
- Exposure relationships also provide some insight into the issue of confounding. While the data base is small, concentrations of gaseous co-pollutants,  $\text{NO}_2$ ,  $\text{O}_3$ , and  $\text{SO}_2$  (and probably  $\text{CO}$ ) are likely poorly correlated, and sometimes not significantly correlated, with personal exposure to the respective co-pollutant. However, they are frequently significantly correlated with both the ambient PM concentration and the ambient PM exposure. Thus, in a regression, where associations are found between gaseous co-pollutants and a health effect, it may be because they are a surrogate for PM rather than a confounder. That is, the health effect due to PM is transferred to the gaseous pollutant because of the positive correlation between the ambient concentration of the gas and the ambient PM exposure.

32

33

### 1 **E.3 DOSIMETRY OF PARTICULATE MATTER**

- 2 • Dosimetry establishes the relationship between PM exposure and the dose of inhaled PM delivered to and retained at the target site. Deposition, clearance, translocation, and retention comprise the essential elements of dosimetry.
- 3 • Dosimetric information is critical to extrapolating effects found in controlled exposure studies of laboratory animals to those observed in human exposure studies and for relating effects in normal healthy persons to those in potentially susceptible persons.
- 4 • Dosimetry separates the respiratory tract into three regions, extrathoracic (ET), tracheobronchial (TB), and alveolar (A), based on anatomical features and particle deposition and clearance phenomena that occur within each region.
- 5 • Particles in the accumulation mode size range (0.1 to 1.0  $\mu\text{m D}_p$ ) have the lowest deposition fraction in all three regions.
- 6 • Coarse and ultrafine particles have higher fractional deposition. For coarse particles, fractional deposition peaks between 5 and 10  $\mu\text{m D}_p$  for the TB region and 2.5 and 5  $\mu\text{m D}_p$  for the A region.
- 7 • For ultrafine particles, fractional deposition peaks between 0.0025 and 0.005  $\mu\text{m D}_p$  for the TB region and between 0.01 and 0.05 for the A region.
- 8 • A significant fraction of ultrafine and coarse particles, but not particles in the accumulation-mode size range, are deposited in the ET region.
- 9 • Such transport could provide a mechanism whereby particles could affect cardiovascular function as reported in the epidemiologic studies
- 10 • Fractional deposition, as a function of particle size, depends on lung size, tidal volume, and breathing rate. Exercising subjects receive higher doses of particles per  $\text{cm}^2$  of lung surface than subjects at rest.

- 1 • Airway structure and physiological function vary with age. Such variations may alter the deposition patterns for inhaled particles. Airflow distribution is very uneven in diseased lungs, and deposition can be enhanced locally in areas of active ventilation. Total lung deposition is generally increased by obstructed airways so that particle deposition can be enhanced in people with chronic lung disease. Unfortunately, deposition studies in another susceptible population, the elderly, are still lacking.
- 2 • Particles depositing on airway surfaces may be completely cleared from the respiratory tract or translocated to other sites within this system by regionally specific clearance mechanisms. Clearance is either absorptive (dissolution) or nonabsorptive (transport of intact particles). Deposited particles may be dissolved in body fluids, taken up by phagocytic cells, or transported by the mucociliary system. Retained particles tend to be small ( $< 2.5 \mu\text{m}$ ) and poorly soluble (e.g., silica, metals). Ultrafine particles can be rapidly cleared from the lungs into the systemic circulation where they can be transported to extrapulmonary regions.
- 3 • Tracheobronchial clearance has both a fast and a slow component. In the fast phase particles deposited in the TB region clear out rapidly during the first several hours and continue to clear out for 24 hours. A small remaining portion may clear out over several days (slow phase). Translocation of poorly soluble PM to the lymph nodes takes a few days and is more rapid for smaller ( $< 2 \mu\text{m}$ ) particles; elimination rates of these retained particles are on the order of years. People with COPD have increased particle retention partly because of increased initial deposition and impaired mucociliary clearance and use cough to augment mucociliary clearance.
- 4 • Alveolar clearance takes months to years. Particles may be taken up by alveolar macrophages within 24 hours, but some phagocytosed macrophages translocate into the interstitium or lymphatics whereas some remain on the alveolar surface. Penetration of uningested particles into the interstitium increases with increasing particle load and results in increased translocation to lymph nodes.
- 5 • Acute effects of PM are probably best related to deposited dose; whereas chronic effects may be related to cumulative or retained dose. Retention of particles is a function of deposition

site, clearance of particles by macrophages or the mucociliary system, and particle characteristics, especially solubility. Chronic effects may also arise from recurring cycles of pulmonary injury and repair.

- 6
- Computational models allow calculation of fractional deposition and dose per cm<sup>2</sup> of lung surface as a function of particle size and respiratory parameters for humans and some animals (including the laboratory rat). Such calculations can be used to predict the exposures needed to produce comparable doses for animal to human extrapolation. Computational models have been improved in recent years but experimental validation of model predictions is still required.

7

## 8 **E.4 TOXICOLOGY OF PARTICULATE MATTER IN HUMANS AND** 9 **LABORATORY ANIMALS**

### 10 **E.4.1 Health Effects of Specific PM Components**

- 11
- There is relatively little new information on the effects of acid aerosols, and the conclusions of the 1996 PM AQCD, i.e., Air Quality Criteria for Particulate Matter (U.S. Environmental Protection Agency, 1996a), are unchanged. It was previously concluded that acid aerosols cause little or no change in pulmonary function in healthy subjects, but asthmatics may develop small changes in pulmonary function. Although pulmonary effects of acid aerosols have been the subject of extensive research in past decades, the cardiovascular effects of acid aerosols have received little attention and should not be ruled out as possible mediators of PM health effects.
- 12
- Health effects of particle-associated soluble metals have been demonstrated by in vivo and in vitro studies using residual oil fly ash (ROFA) or soluble transition metals. Although there are some uncertainties about differential effects of one transition metal versus another, water soluble metals leached from ROFA or ambient filter extracts have been shown consistently (albeit at high concentrations) to cause cell injury and inflammatory changes in vitro and in vivo.

- 1 • Even though it is clear that combustion particles that have a high content of soluble metals can cause lung injury and even death in compromised animals and correlate well with epidemiologic findings in some cases (e.g., Utah Valley Studies), it has not been fully established that the small quantities of metals associated with ambient PM are sufficient to cause health effects. Moreover, it cannot be assumed that metals are the only or the primary toxic component of ambient PM, rather than there possibly being many different toxic agents contributing to ambient PM health effects.
- 2 • There is growing toxicological evidence that diesel exhaust particles exacerbate the allergic response to inhaled antigens. The organic fraction of diesel exhaust has been linked to eosinophil degranulation and induction of cytokine production, suggesting that the organic constituents of diesel PM are the responsible part for the immune effects. It is not known whether the adjuvant-like activity of diesel PM is unique or whether other combustion particles have similar effects. It is important to compare the immune effects of other source-specific emissions, as well as concentrated ambient PM, to diesel PM to determine the extent to which exposure to diesel exhaust may contribute to the incidence and severity of allergic rhinitis and asthma.
- 3 • Published research on the acute effects of particle-associated organic carbon constituents is conspicuous by its relative absence, except for diesel exhaust particles.
- 4 • Studies with ultrafine particles have demonstrated a significantly greater inflammatory response than that seen with fine particles of the same chemical composition at similar mass doses. In other more limited studies, ultrafines also have generated greater oxidative stress in experimental animals. However, when the particle surface area is used as a dose metric, the inflammatory response to both fine and ultrafine particles may be basically the same. Thus, it may be the higher surface area of ultrafine particles is the important factors contributing to health effects.
- 5 • Concentrated ambient particle (CAPS) studies should be among the most relevant in helping to understand the characteristics of PM producing toxicity, susceptibility of individuals to PM, and the underlying mechanisms. Studies have used collected urban PM for intratracheal administration to healthy and compromised animals. Despite the difficulties in extrapolating

from the bolus delivery used in such studies, they have provided strong evidence that the chemical composition of ambient particles can have a major influence on toxicity.

- 6 • Ambient particle concentrators, that concentrate particles in situ, provide particles for inhalation studies. The concentration of particles without collection avoids the changes in size and composition that occur during collection during collection and resuspension. Studies with inhaled CAPs have observed cardiopulmonary changes in rodents and dogs at high concentrations of PM between 0.15 and 2.5  $\mu\text{m}$  diameter. A new generation of ambient particle concentrators that allow separation and concentration of coarse-mode, accumulation-mode, and ultrafine particle separately will permit the direct toxicological comparison of these various ambient particle sizes.
- 7 • Recent studies support the conclusion of the 1996 PM AQCD, which stated that bioaerosols, at concentrations present in the ambient environment, cannot account for the reported health effects of ambient PM. However, it is possible that bioaerosols could contribute to the health effects of PM.

8

## 9 **E.4.2 Mechanisms of Action**

### 10 **E.4.2.1 Cardiovascular Effects**

- 11 • Changes in heart rate, heart rate variability, and conductance associated with ambient PM exposure have been reported in animal studies, in several human panel studies, and in a reanalysis of data from the MONICA study. Some of these studies included endpoints related to respiratory effects but few significant adverse respiratory changes were detected. This raises the possibility that ambient PM may have effects on the heart that are independent of adverse changes in the lung.
- 12 • Inhaled particulate matter affects the heart by uptake of particles into the circulation or release of a soluble substances into the circulation.
- 13 • Inhaled particulate matter affects autonomic control of the heart and cardiovascular system.

14

15

#### 1 E.4.2.2 Respiratory Effects

- 2
- Particularly compelling evidence pointing towards ambient PM causing lung injury and inflammation derives from the study of ambient PM materials on filter extracts collected from community air monitors before, during the temporary closing of a steel mill in Utah Valley, and after its reopening. Intratracheal instillation of filter extract materials in human volunteers provoked greater lung inflammatory responses for materials obtained before and after the temporary closing versus that collected during the plant closing. Further, the instillation in rats of extract materials from before and after the plant closing resulted in a 50% increase in air way hyperresponsiveness to acetylcholine compared to 17 or 25% increases with saline or extract materials for the period when the plant was closed, respectively. Analysis of the extract materials revealed notably greater quantities of metals for when the plant was opened suggesting that such metals (e.g., Cu, Zn, Fe, Pb, As, Mn, Ni) may be important contributors to the pulmonary toxicity observed in the controlled exposure studies, as well as to health effects shown epidemiologically to vary with PM exposures of Utah Valley residents before, during, and after the steel mill closing.
- 3
- Still other toxicological studies point towards lung injury and inflammation being associated with exposure of lung tissue to complex combustion-related PM materials, with metals again being likely contributors. Rats with SO<sub>2</sub>-induced bronchitis and monocrotaline-treated rats have been reported to have a greater inflammatory response to concentrated ambient PM than normal rats. These studies suggest that exacerbation of respiratory disease by ambient PM may be caused in part by lung injury and inflammation.
- 4
- Particulate air pollution causes increased susceptibility to respiratory infections. Exposure of rats to ROFA and *L. monocytogenes*, a bacterial pathogen, led rats treated with saline or *L. monocytogenes* in the absence of ROFA. Preexposure of rats to ROFA significantly enhanced injury and delayed the pulmonary clearance of a subsequent challenge of *L. monocytogenes*, when compared to saline-treated control rats. Acute exposure to ROFA appeared to slow pulmonary clearance of *L. monocytogenes* and to alter AM function. Such changes could lead to increased susceptibility to lung infection in exposed populations.

- 1 • Particulate air pollution increases airway reactivity and exacerbates asthma. Diesel  
particulate matter (DPM) has been shown to increase production of antigen-specific IgE in  
mice and humans. In vitro studies have suggested that the organic fraction of DPM is  
involved in the increased IgE production. ROFA leachate also has been shown to enhance  
antigen-specific airway reactivity in mice, indicating that soluble metals can also enhance an  
allergic response.

2

### 3 **E.4.2.3 Systemic Effects Secondary to Lung Injury**

- 4 • Lung injury from inhaled PM causes impairment of oxygenation and increased work of  
breathing that adversely affects the heart.
- 5 • Lung inflammation and cytokine production cause adverse systemic hemodynamic effects.
- 6 • Lung inflammation from inhaled PM causes increased blood coagulability that increases the  
risk of heart attacks and strokes.
- 7 • Interaction of PM with the lung affects hematopoiesis.

8

### 9 **E.4.3 Susceptibility**

- 10 • Older animals or animals with certain types of compromised health, either genetic or  
induced, are more susceptible to instilled or inhaled particles, although the increased animal-  
to-animal variability in these models has created greater uncertainty for the interpretation of  
the findings. Moreover, because PM seems to affect broad categories of disease states,  
ranging from cardiac arrhythmias to pulmonary infection, it can be difficult to know what  
disease models to use in evaluating the biological plausibility of adverse health effects of  
PM. Nevertheless, particularly interesting new findings point toward ambient PM  
exacerbation of allergic airway hyperresponsiveness and/or antigen-induced immune  
responses. Both metals and diesel particles have been implicated, with an expanding array of  
new studies showing DPM in particular as being effective in exacerbating allergic asthma  
responses.

## **E.5 EPIDEMIOLOGY OF HUMAN HEALTH EFFECTS ASSOCIATED WITH AMBIENT PARTICULATE MATTER**

Chapter 8 of this document assesses the extensive PM epidemiologic data base that has become newly available since the 1996 PM AQCD. The most important types of additions to the epidemiologic database beyond that assessed in the 1996 PM AQCD include the following:

- New multi-city studies on a variety of endpoints which provide more precise estimates of the average PM effect sizes than most smaller-scale individual city studies;
- More studies of various health endpoints using ambient  $PM_{10}$  and/or closely related mass concentration indices (e.g.,  $PM_{13}$  and  $PM_7$ ), which substantially lessen the need to rely on non-gravimetric indices (e.g., BS or CoH);
- New studies evaluating relationships of a variety of health endpoints to the ambient PM coarse fraction ( $PM_{10-2.5}$ ), the ambient fine-particle fraction ( $PM_{2.5}$ ), and even ambient ultrafine particles measures ( $PM_{0.1}$  and smaller), using direct mass measurements and/or estimated from site-specific calibrations;
- A few new studies in which the relationship of some health endpoints to ambient particle number concentrations were evaluated;
- Many new studies which evaluated the sensitivity of estimated PM effects to the inclusion of gaseous co-pollutants in the model;
- Preliminary attempts to evaluate the effects combinations or mixtures of air pollutants including PM components, based on factor analysis or source profiles;
- Numerous new studies of cardiovascular endpoints, with particular emphasis on assessment of cardiovascular risk factors as well as symptoms;
- Additional new studies on asthma and other respiratory conditions potentially exacerbated by PM exposure;
- New analyses of lung cancer associations with long-term exposures to ambient PM;

- 1
- New studies of infants and children as a potentially susceptible population.

2 In addition, Chapter 8 discusses statistical issues posed by use of General Additive Mode  
3 (GAM) analyses involving default convergence criteria in widely used commercially-available  
4 software employed in time-series analyses of ambient PM-health effects relationship reported in  
5 a few published studies assessed in the 1996 PM AQCD and in numerous more recent studies  
6 assessed in the present PM AQCD. This includes discussion of the following key points:

- 7
- Use of GAM analyses with default convergence criteria (GAM default) has variable impacts  
on PM effect size estimates from study to study, depending on many factors (numbers of  
observations, numbers of potential effect modifiers or potential confounders included,  
specific “smoothing” approaches used to control for their effects, numbers of degrees of  
freedom used, etc.). The effect of GAM (default) use tends most often to be some  
(unusually only slight) overestimation of the PM effect size compared to results obtained  
with use of GAM with stringent convergence criteria or other appropriate modeling  
approaches, e.g., general linear models (GLM).
- 8
- The results of EPA-encouraged reanalyses of a number of (> 35) of important PM time-  
series analyses comparing PM effect sizes and standard error (confidence interval) estimates  
from GAM (default) analyses versus GAM (stringent) or other appropriate statistical  
approaches (GLM). These reanalyses appear in a Health Effects Institute Special Report  
(HEI, 2003) that includes not only short communications on the GAM reanalyses by the  
original investigators, but also commentaries on the reanalyses and their implications for  
interpreting the PM time-series analyses results by a special peer-review panel convened by  
HEI at EPA’s request.

9

## 10 **E.5.2 Key Epidemiologic Findings**

11 The epidemiologic studies discussed in Chapter 8 demonstrate biologically-plausible  
12 responses in humans exposed at ambient concentrations. These observational study findings are  
13 further enhanced by supportive findings of causal studies from other scientific disciplines  
14 (dosimetry, toxicology, etc.), in which other factors could be experimentally controlled, as

1 discussed in Chapters 6 and 7. The most salient findings derived from the PM epidemiologic  
2 studies include the following:

- 3 • A large and reasonably convincing body of epidemiology evidence confirms earlier  
associations between short- and long-term ambient  $PM_{10}$  exposures (inferred from stationary  
community air monitor measures) and mortality/morbidity effects and suggest that  $PM_{10}$   
(or one or more  $PM_{10}$  components) is a probable contributing cause of adverse human health  
effects.
  
- 4 • There appears to be some spatial heterogeneity in city-specific excess risk estimates for the  
relationships between short-term ambient  $PM_{10}$  concentrations and acute health effects. The  
reasons for such variation in effects estimates are not well understood at this time but do not  
negate ambient PM's likely causative contribution to observed PM-mortality and/or  
morbidity associations in many locations. Possible factors contributing to the apparent  
heterogeneity include geographic differences in air pollution mixtures, composition of PM  
components, and personal and sociodemographic factors affecting PM exposure (such as use  
of air conditioners, education, and so on).
  
- 5 • A growing body of epidemiologic studies confirm associations between short- and long-term  
ambient  $PM_{2.5}$  exposures (inferred from stationary air monitor measures) and adverse health  
effects and suggest that  $PM_{2.5}$  (or one or more  $PM_{2.5}$  components) is a probable contributing  
cause of observed PM-associated health effects. Some new epidemiologic findings also  
suggest that health effects are associated with mass or number concentrations of ultrafine  
(nuclei-mode) particles, but not necessarily more so than for other ambient fine PM  
components.
  
- 6 • A smaller body of evidence appears to support an association between short-term ambient  
thoracic coarse fraction ( $PM_{10-2.5}$ ) exposures (inferred from stationary air monitor measures)  
and short-term health effects in epidemiologic studies. This suggests that  $PM_{10-2.5}$ , or some  
constituent component(s) of  $PM_{10-2.5}$ , may be a contributory cause of adverse health effects  
in some locations. Reasons for differences among findings on coarse-particle health effects  
reported for different cities are still poorly understood, but several of the locations where

significant PM<sub>10-2.5</sub> effects have been observed (e.g., Phoenix, Mexico City, Santiago) tend to be in drier climates and may have contributions to observed effects due to higher levels of organic particles from biogenic processes (endotoxins, molds, etc.) during warm months. Other studies suggest that particles of crustal origin are generally unlikely to exert notable health effects under most ambient exposure conditions. Also, in some western U.S. cities where PM<sub>10-2.5</sub> is a large part of PM<sub>10</sub>, the relationship between hospital admissions and PM<sub>10</sub> may be an indicator of response to coarse thoracic particles from wood burning.

- 7 • Long-term PM exposure durations, on the order of months to years, as well as on the order of a few days, are statistically associated with serious human health effects (indexed by mortality, hospital admissions/medical visits, etc.). More chronic PM exposures, on the order of years or decades, appear to be associated with life shortening well beyond that accounted for by the simple accumulation of the more acute effects of short-term PM exposures (on the order of a few days). Substantial uncertainties remain regarding the magnitude of and mechanisms underlying chronic health effects of long-term PM exposures and the relationship between chronic exposure and acute responses to short-term exposure.
- 8 • Recent investigations of the public health implications of such chronic PM exposure-mortality effect estimates were also reviewed. Life table calculations by Brunekreef (1997) found that relatively small differences in long-term exposure to airborne PM of ambient origin can have substantial effects on life expectancy. For example, a calculation for the 1969-71 life table for U.S. white males indicated that a chronic exposure increase of 10 µg/m<sup>3</sup> PM was associated with a reduction of 1.3 years for the entire population's life expectancy at age 25. Also, new evidence of associations of PM exposure with infant mortality and/or intrauterine growth retardation and consequent increase risk for many serious health conditions associated with low birth weight, if further substantiated, would imply that life shortening in the entire population from long-term PM exposure could well be significantly larger than that estimated by Brunekreef (1997).
- 9 • Considerable coherence exists among effect size estimates for ambient PM health effects. For example, results derived from several multi-city studies, based on pooled analyses of

data combined across multiple cities (thought to yield the most precise estimates of mean effect size), show the percent excess total (non-accidental) deaths estimated per 50  $\mu\text{g}/\text{m}^3$  increase in 24-h  $\text{PM}_{10}$  to be  $\sim 1.4\%$  in the 90 largest U.S. cities with the estimate for the Northeast being the largest (approximately twice the nationwide estimate);  $\sim 3.4\%$  in 10 large U.S. cities;  $\sim 3.6\%$  in the 8 largest Canadian cities; and  $\sim 3.0\%$  in western European cities. These combined estimates are consistent with the range of  $\text{PM}_{10}$  estimates previously reported in the 1996 PM AQCD. These and excess risk estimates from many other individual-city studies, generally falling in the range of ca. 1.5 to 8.0% per 50  $\mu\text{g}/\text{m}^3$  24-h  $\text{PM}_{10}$  increment, also comport well with numerous new studies confirming increased cause-specific cardiovascular- and respiratory-related mortality. They are also coherent with larger effect sizes reported for cardiovascular and respiratory hospital admissions and visits, as would be expected for these morbidity endpoints versus those for  $\text{PM}_{10}$ -related mortality.

- 10
- Several independent panel studies (but not all) that evaluated temporal associations between PM exposures and measures of heart beat rhythm in elderly subjects provide generally consistent indications of decreased heart rate variability (HRV) being associated with ambient PM exposure (decreased HRV being an indicator of increased risk for serious cardiovascular outcomes, e.g., heart attacks). Other studies point toward changes in blood characteristics (e.g., C-reactive protein levels) related to increased risk of ischemic heart disease also being associated with ambient PM exposures. However, these heart rhythm and blood characteristics findings should currently be viewed as providing only limited or preliminary support for PM-related cardiovascular effects.
- 11
- Notable new evidence now exists which substantiates positive associations between ambient PM concentrations and increased respiratory-related hospital admissions, emergency department, and other medical visits, particularly in relation to  $\text{PM}_{10}$  levels. Of much interest are new findings tending to implicate not only fine particle components but also coarse thoracic (e.g.,  $\text{PM}_{10-2.5}$ ) particles as likely contributing to exacerbation of asthma conditions. Also of much interest are emerging new findings indicative of likely increased occurrence of chronic bronchitis in association with (especially chronic) PM exposure. Also of particular interest are reanalyses or extensions of earlier prospective cohort studies of

long-term ambient PM exposure effects which demonstrate substantial evidence for association of increased lung cancer risk with such PM exposures, especially exposure to fine PM or its subcomponents.

- 12
- One major methodological issue affecting epidemiologic studies of both short-term and long-term PM exposure effects is that ambient PM of varying size ranges is typically found in association with other air pollutants, including gaseous criteria pollutants (e.g. O<sub>3</sub>, NO<sub>2</sub>, SO<sub>2</sub>, CO), air toxics, and/or bioaerosols. Available statistical methods for assessing potential confounding arising from these associations may not yet be fully adequate. The inclusion of multiple pollutants often produces statistically unstable estimates. Omission of other pollutants may incorrectly attribute their independent effects to PM. Second-stage regression methods may have certain pitfalls that have not yet been fully evaluated. Much progress in sorting out relative contributions of ambient PM components versus other co-pollutants is nevertheless being made and, overall, tends to substantiate that observed PM effects are at least partly due to ambient PM acting alone or in the presence of other covarying gaseous pollutants. However, the statistical association of health effects with PM acting alone or with other pollutants should not be taken as an indicator of a lack of effect of the other pollutants.
- 13
- It is possible that differences in observed health effects will be found to depend on site-specific differences in chemical and physical composition characteristics of ambient particles and on factors affecting exposure (such as air conditioning) as well as on differences in PM mass concentration. For example, epidemiologic Utah Valley studies showed that PM<sub>10</sub> particles, known to be richer in metals during exposure periods while the steel mill was operating, were more highly associated with adverse health effects than was PM<sub>10</sub> during the PM exposure reduction while the steel mill was closed. In contrast, PM<sub>10</sub> or PM<sub>2.5</sub> was relatively higher in crustal particles during windblown dust episodes in Spokane and in three central Utah sites than at other times, but was not associated with higher total mortality. These differences require more research that may become more feasible as the PM<sub>2.5</sub> sampling network produces air quality data related to speciated samples.

- 1 • The above reasons suggest it is inadvisable to pool PM epidemiologic studies for different locations or time periods, with different population sub-groups, or different health endpoints (as is often done in “meta-analyses”), without careful assessment of potential causes and consequences of these differences and appropriate caveating of results. Published multi-city analyses using common data bases, measurement methods, analytical strategies, and extensive independent external review (as carried out in the APHEA and NMMAPS studies) are useful. Pooled analyses of more diverse collections of independent studies of different cities, using varying methodology and/or data quality or representativeness, are likely less credible and should not, in general, be used without careful assessment of their underlying scientific comparability.
- 2 • It may be possible that different PM size components or particles with different composition or sources produce effects by different mechanisms manifested at different lags or that different preexisting conditions may lead to different delays between exposure and effect. Thus, although maximum effect sizes for PM effects have often been reported for 0-1 day lags, evidence is also beginning to suggest that more consideration should be given to lags of several days. Also, if it is considered that all health effects occurring at different lag days are all real effects, so that the risks for each lag day should be additive, then overall risks may exist that are higher than implied by maximum estimates for any particular single or two-day lags. In that case, multi-day averages or distributed lag models may provide more accurate estimate of the total impact of PM on the population.
- 3 • Certain classes of ambient particles may be distinctly less toxic than others and may not exert human health effects at typical ambient exposure concentrations or only under special circumstances. Coarse thoracic particles of crustal origin, for example, may be relatively non-toxic under most circumstances compared to those of combustion origin such as wood burning. However, crustal particles may be sufficiently toxic to cause human health effects under some conditions; resuspended crustal particles, for example, may carry toxic trace elements and other components from previously deposited fine PM, e.g., metals from smelters (Phoenix) or steel mills (Steubenville, Utah Valley), PAH’s from automobile exhaust, or pesticides from administration to agricultural lands. Likewise, fine particles

from different sources have different effect sizes. More research is needed to identify conditions under which one or another class of particles may cause little or no adverse health effects, as well as conditions under which different classes of particles may cause relatively more notable effects.

- 4 • Certain epidemiologic evidence from “intervention studies” suggests that reducing ambient PM<sub>10</sub> concentrations may reduce a variety of health effects on a time scale from a few days to a few months, as found in epidemiologic studies of “natural experiments” such as in the Utah Valley, and supported by toxicology studies using particles extracts from ambient community sampling filters from the Utah Valley. Recent studies in Germany and in the Czech Republic also tend to support a hypothesis that reductions in particle-related air pollution are associated with reductions in the incidence of adverse health effects.
- 5 • Studies that combine the features of cross-sectional and cohort studies provide the best evidence for chronic effects of PM exposure. Gauderman et al. (2000; 2002) have found significant decreases in lung function growth related to PM<sub>10</sub> levels using these techniques.
- 6 • Adverse health effects in children reported in a limited number of more recent studies are emerging as an important area of more concern than was the case in the 1996 PM AQCD. Unfortunately, relatively little is known about the relationship of PM to the most serious health endpoints, neonatal and infant mortality, emergency hospital admissions and mortality in older children, as well as low birth weight and preterm birth.
- 7 • Little is yet known about involvement of PM exposure in the progression from less serious childhood conditions, such as asthma and respiratory symptoms, to more serious disease endpoints later in life. This is an important health issue because childhood illness or death may cost a very large number of productive life-years.
- 8 • Lastly, new epidemiologic studies of ambient PM associations with increased non-hospital medical visits (physician visits) and asthma effects suggest likely much larger health effects and costs to society due to ambient PM than just those indexed by mortality and/or hospital admissions/visits.

## 1 **E.6 ENVIRONMENTAL EFFECTS OF PM**

### 2 **E.6.1 Vegetation and Ecosystem Effects**

- 3 • Deposition of particulate matter from the atmosphere has the potential to alter ecosystem structure and function. Human existence on this planet depends on the essential life-support services that ecosystem structure and functions provide. Concern has risen in recent years regarding the consequences of changing the biological diversity of ecosystems because human activities are creating disturbances that are altering the structure (complexity and stability) and functioning (producing changes in the processes of energy and water flow and nutrient cycling) of ecosystems.
- 4 • Human-induced changes in biotic diversity and alterations in the structure and ecosystems processes are the two most dramatic ecological trends in the past century. Biodiversity encompasses all levels of biological organization, including individuals, populations, species, and ecosystems. For this reason, there is a need to understand the effects of PM deposition on vegetation and ecosystems and biodiversity.
- 5 • Ecosystem functions maintain clean water, pure air, biodiversity, and impart the following benefits: fixation of solar energy, absorption and breakdown of pollutants, cycling of nutrients, binding of soil, degradation of organic wastes, maintenance of a balance of atmospheric gases, regulation of radiation balance, and climate.
- 6 • The deposition of PM onto vegetation and soil, depending on its chemical composition (acid/base, trace metal, or nutrients, e.g., nitrates or sulfates), can produce direct or indirect responses within an ecosystem.
- 7 • Ecosystem response to pollutant deposition is a direct function of the level of sensitivity of the ecosystem and its ability to ameliorate resulting changes. Changes in ecosystem structural patterns and the functioning of ecological processes must be scaled in both time and space and propagated to the more complex levels of community interaction to produce observable ecosystem changes.

- 1 • The major effect of atmospheric PM on ecosystems is indirect and occurs through the deposition of nitrates and sulfates and the acidifying effects of the associated  $H^+$  ion in wet and dry deposition in the soil environment. In the soil, they have the potential to inhibit nutrient uptake, alter the ecological processes of energy flow and nutrient cycling, change ecosystem structure, and affect ecosystem biodiversity. Most nitrate is not deposited or measured as PM but is a combination of wet and dry deposition.
- 2 • The soil environment, one of the most dynamic sites of biological interaction, is inhabited by communities of bacteria, fungi, and actinomycetes. Bacteria, as essential components of the nitrogen and sulfur cycles, and fungi in the uptake of mineral nutrients play an important role in plant nutrition. Their actions make these elements available for plant uptake. Fungi form mycorrhizae, a mutualistic symbiotic relationship with plant roots that is integral to the uptake of mineral nutrients. Changes in the soil environment resulting from deposition of nitrates and sulfates that alter the role of the bacteria in the nutrient cycles and mycorrhizal fungi in making minerals available for plant utilization, determine plant and, ultimately, ecosystem response.
- 3 • Although nitrogen as molecular nitrogen ( $N_2$ ) is the most abundant element in the atmosphere, it only becomes available to support plant growth after its conversion into reactive forms. In nature, nitrogen may be divided into two groups: reactive (Nr) and nonreactive ( $N_2$ ). Reactive nitrogen or Nr includes the inorganic reduced forms of nitrogen (e.g., ammonia [ $NH_3$ ] and ammonium [ $NH_4^+$ ]), inorganic oxidized forms (e.g., nitrogen oxides [ $NO_x$ ], nitric acid [ $HNO_3$ ], nitrous oxide [ $N_2O$ ], and nitrate [ $NO_3^-$ ]), and organic compounds (e.g., urea, amine, proteins, and nucleic acids).
- 4 • Reactive nitrogen can be widely dispersed and accumulate in the environment when the rates of its formation exceed the rates of removal via denitrification. As a result of human food production, it is now accumulating in the environment on all spatial scales – local, regional and global; and its creation and accumulation is projected to increase as per capita use of resources by human populations increases.

- 1 • The major changes in the nitrogen cycle can be both beneficial and detrimental to the health and welfare of humans and ecosystems. The cascade of environmental effects resulting from reactive nitrogen accumulation include the following: (1) production of tropospheric ozone and aerosols that induce human health and ecosystem problems; (2) increases in the productivity in forests and grasslands followed by decreases wherever Nr deposition increases significantly and exceeds critical thresholds; (3) reactive nitrogen additions probably decrease biodiversity in many natural habitats; (4) in association with sulfur is responsible for acidification and loss of biodiversity in lakes and streams in many regions of the world; (5) eutrophication, hypoxia, loss of biodiversity, and habitat degradation in coastal ecosystems. [Eutrophication is now considered the biggest pollution problem in coastal waters.], and (6) contributes to global climate change and stratospheric ozone depletion, which can in turn affect ecosystems and human health.
  
- 2 • “Nitrogen saturation” results when reactive nitrogen concentrations exceed the capacity of a system to utilize it. Saturation implies that some resource other than nitrogen is limiting biotic function. Water and phosphorus for plants and carbon for microorganisms are most likely to be the secondary limiting factors. The appearance of nitrogen in soil solution is an early symptom of excess nitrogen. In the final stage, disruption of ecosystem structure becomes visible.
  
- 3 • Possible ecosystem responses to nitrogen saturation include (1) a permanent increase in foliar nitrogen and reduced foliar phosphorus and lignin caused by the lower availability of carbon, phosphorus, and water; (2) reduced productivity in conifer stands because of disruptions of physiological function; (3) decreased root biomass and increased nitrification and nitrate leaching; (4) reduced soil fertility, resulting from increased cation leaching and increased nitrate and aluminum concentrations in streams, (5) decreased water quality, and (6) changes in soil microbial communities from predominantly fungal (mycorrhizal) communities to those dominated by bacteria during saturation.

- 1 • Intensive research over nearly a decade indicates that, although the soils of most North American forests are nitrogen limited, severe symptoms of nitrogen saturation have been observed in the high-elevation, non-aggrading spruce-fir ecosystems in the Appalachian Mountains; the eastern hardwood watersheds at the Fernow Experimental Forest near Parsons, WV; forests in southern California; the southwestern Sierra Nevada in Central California; and the Front Range in northern Colorado. The mixed conifer forest and chaparral watershed with high smog exposure in the Los Angeles Air Basin exhibit the highest stream water  $\text{NO}_3^-$  concentrations in wilderness areas of North America.
- 2 • Increases in soil nitrogen play a selective role in ecosystems. Plant succession patterns and biodiversity are affected significantly by chronic nitrogen additions in some North American ecosystems. Long-term nitrogen fertilization studies in both New England and Europe suggest that some forests receiving chronic inputs of nitrogen may decline in productivity and experience greater mortality. Declining coniferous forest stands with slow nitrogen cycling may be replaced by deciduous fast-growing forests that rapidly cycle nitrogen.
- 3 • In experimental studies nitrogen deposition over a 12-year period Minnesota grasslands dominated by native warm-season grasses shifted to low-diversity mixtures dominated by cool-season grasses.
- 4 • Excess nitrogen inputs to unmanaged heathlands in the Netherlands has resulted in nitrophilous grass species replacing slower growing heath species. Over the past several decades the composition of plants in the forest herb layers has been shifting toward species commonly found in nitrogen-rich areas. It also was observed that the fruiting bodies of mycorrhizal fungi had decreased in number, indicating that formation of mycorrhizae were affected.
- 5 • Soil nitrogen enrichment of the soil significantly alters the composition and richness of the arbuscular mycorrhizal fungal community and markedly decreases overall diversity of the mycorrhizal community. Decline in the coastal sage scrub in southern California was directly linked to the decline of arbuscular mycorrhizal fungal community.

- 1 • The effects of excessive deposition of nitrogen, particularly  $\text{NH}_3$  and  $\text{NH}_4^+$ , have led to changes in Dutch heathlands via: (1) acidification of the soil and the loss of cations of  $\text{K}^+$ ,  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ ; and (2) nitrogen enrichment, which results in increased plant growth rates and altered competitive relationships. Alteration of any of a number of parameters (e.g., increased nitrogen) can alter ecosystem structure and function.
- 2 • Notable effects of excess nitrogen deposition have been observed with regard to aquatic systems. Atmospheric nitrogen deposition onto soils in watershed areas feeding into estuarine sound complexes (e.g., the Pamlico Sound of North Carolina) appear to contribute to excess nitrogen flows in runoff (especially during and after heavy rainfall events such as hurricanes) from agricultural practices or other uses (e.g., fertilization of lawns or gardens). Massive influxes of such nitrogen into watersheds and sounds can lead to algae blooms, which, upon degradation, deplete oxygen and cause extensive fish kills and damage to commercial fish and sea food harvesting.
- 3 • Acidic precipitation, a critical environmental stress that affects forest landscapes and aquatic ecosystems in North America, Europe, and Asia, is linked to the effects associated with the deposition of Nr and sulfates and the associated hydrogen ion. The resulting soil acidity can lead to nutrient deficiencies and to high aluminum-to-nutrient ratios that limit uptake of calcium and magnesium and create a nutrient deficiency adversely affect tree growth. Calcium is essential in the formation of wood and the maintenance of the primary plant tissues necessary for tree growth.
- 4 • The critical loads concept is useful for estimating the amounts of pollutants (e.g., reactive nitrogen and acidic precipitation) that sensitive ecosystems can absorb on a sustained basis without experiencing measurable degradation. The estimation of ecosystem critical loads requires an understanding of how an ecosystem will respond to different loading rates in the long term and can be of special value for ecosystems receiving chronic deposition of Nr and sulfur independently and as acidic deposition when in combination.

- 1 • The biological effect of PM is determined by the amount deposited during the wet and dry deposition onto the plant surfaces or soil in the vicinity of the roots. The three major routes involved are (1) precipitation scavenging in which particles are deposited in rain and snow; (2) occult (fog, cloud water, and mist interception); and (3) dry deposition, a much slower, yet more continuous removal to place surfaces.
- 2 • Few heavy metals (e.g., copper, nickel, zinc) have been documented to have direct phytotoxicity under field conditions. Ecosystems immediately downwind of major emissions sources such as power generating, industrial, or urban complexes can receive locally heavy inputs. Heavy metal accumulation in the richly organic forest floor where biological activity is greatest by affecting litter decomposition present the greatest potential for influencing nutrient cycling. The presence of cadmium, copper and nickel have been observed to affect the symbiotic activity of fungi, bacteria, and actinomycetes.
- 3 • Phytochelatins produced by plants as a response to sublethal concentrations of heavy metals, are indicators of metal stress and can be used to indicate that heavy metals are involved in forest decline. Increasing concentrations of phytochelatins with increasing altitude, and their increases across regions that show increased levels of forest injury, have implicated them in forest decline.
- 4 • Secondary organics formed in the atmosphere have been variously subsumed under the following terms: toxic substances, pesticides, hazardous air pollutants (HAPS), air toxics, semivolatile organic compounds (SOCs), and persistent organic pollutants (POPS). Such substances are controlled under CAA Sect.112, Hazardous Air Pollutants (not as criteria pollutants controlled by NAAQS under CAA Sections 108 and 109). Their possible effects on humans and ecosystems are discussed in many other government documents and publications. They are noted in this document because, in the atmosphere, many of the chemical compounds are partitioned between gas and particle phases and are deposited as particulate matter. As particles, they become airborne and can be distributed over a wide area and affect remote ecosystems. Some are also of concern to humans because they may reach toxic levels in food chains of both animals and humans; whereas others may tend to maintain or decrease some toxicity as they move through the food chain.

5

## 1 E.6.2 Visibility

2 Chapter 4 of this document includes information supplementary to several other significant  
3 reviews of the science of visibility, including the 1991 report of the National Acid Precipitation  
4 Assessment Program, the National Research Council's *Protecting Visibility in National Parks  
5 and Wilderness Areas* (1993), and EPA's 1995 *Interim Findings on the Status of Visibility  
6 Research*. The following points are made in Chapter 4 and/or in the above referenced  
7 documents.

- 8 • The relationships between air quality and visibility are well understood. Ambient fine  
particles are the major cause of visibility impairment. Significant scientific evidence exists  
showing that reducing fine particle concentrations will improve visibility.
- 9 • The National Research Council defines visibility qualitatively as “the degree to which the  
atmosphere is transparent to visible light.” This definition may be expressed quantitatively in  
terms of contrast transmittance. The EPA has defined visibility impairment as a reduction in  
visual range (the farthest distance at which a large black object can be distinguished against  
the horizontal sky is the visual range) and/or atmospheric discoloration.
- 10 • Light, as it passes through the atmosphere from a scene to an observer, is both scattered and  
absorbed. The rate of loss of transmitted light intensity with distance is measured by the  
light-extinction coefficient, which may be expressed as the sum of the coefficients for:  
(a) light scattering due to gases; (b) light scattering due to particles; (c) light absorption by  
gases, and; (d) light absorption by particles. Light scattering by particles is the major  
component of light extinction. Light absorption by gases is almost entirely due to NO<sub>2</sub>, and is  
typically significant only near NO<sub>2</sub> sources. Light absorption by particles is primarily caused  
by elemental carbon.
- 11 • Light scattering efficiency depends on particle size, falling off rapidly for particles below  
0.3 or above 1.0 μm in diameter. Therefore, particles in the accumulation mode (of the fine  
particle mode) are most effective in scattering light and are more important in visibility  
degradation than either nuclei-mode or coarse-mode particles. Light absorption is not a  
strong function of particle size. Under exceptional circumstances, such as dust storms, coarse  
particles can dominate scattering.

- 1 • In addition to reducing the intensity of light carrying information about a scene (transmitted radiance), particles also scatter light into the observer's view. This extraneous light, called air light or path radiance, carries no information about the scene. The competition between these two sources of light, expressed as the ratio of transmitted radiance from the scene to path radiance, determines the contrast transmittance and the visual quality of the view.
- 2 • Visibility at any location is affected by air quality and non-air quality related effects. The visibility effects of atmospheric constituents are dependant upon not just the mass of pollutants, but on the size distribution and refractive index of particles, which are strongly influenced by relative humidity. Non-air quality effects include the angle between the sun and the observer's sight path, location of clouds, and reflectivity of the ground. These effects are independent of effects due to changes in atmospheric constituents. Lighting and scene effects can be accounted for by defining a range of these effects when estimating visibility changes due to air quality influences.
- 3 • The relationship between air pollution and the appearance of a scenic view is well understood. Models exist that, given an adequate description of the air quality and non-air quality variables, can produce a simulated photograph that accurately depicts a cloud-free scene as it would appear to a human observer.
- 4 • There are several potential quantitative indicators of visibility, including: (a) fine particle mass and composition (fine particle mass alone provides less of both types of information); (b) scattering by dried ambient particles; (c) scattering by particles under ambient conditions; (d) extinction (calculated from measurements of scattering plus absorption); (e) light extinction measured directly; and (f) contrast transmittance.
- 5 • A new index, the deciview ( $dv$ ), is now being used as a quantitative measure of haziness. It is related to the light extinction coefficient,  $b_{ext}$ , by *Haziness* ( $dv$ ) =  $10 \ln(b_{ext}/10 Mn)$ . The deciview is more nearly linearly related to perceived changes in haze level than either visual range or light extinction. A change of 1 or 2  $dv$  in uniform haze under many viewing conditions will be seen as a small but noticeable change in the appearance of a scene regardless of the initial haze condition.

- 1 • Visibility in the United States is best in the western, intermountain region. Visibility  
impairment or haziness is greatest in the eastern United States and southern California.  
Haziness in the eastern United States is caused primarily by atmospheric sulfate. Haziness in  
southern California is primarily caused by nitrate and organic PM. Nitrates contribute about  
40% to the total light extinction in southern California. Nitrates account for 10 to 20% of the  
total extinction in other areas of the United States.
- 2 • Organics are the second largest contributors to light extinction in most areas in the United  
States. Organic carbon is the greatest cause of light extinction in the Pacific Northwest,  
Oregon, Idaho, and Montana, accounting for 40 to 45% of the total extinction. Organic  
carbon contributes between 15 to 20% to the total extinction in most of the western United  
States and 20 to 30% in the remaining areas of the United States.
- 3 • Light absorption by carbon is relatively insignificant but is highest in the Pacific Northwest  
(up to 15%) and in the eastern United States (3%).
- 4 • High dust concentrations transported from southern California and the subtropics have  
contributed to regional haze in the Grand Canyon and other Class I areas in the southwestern  
United States.

5

### 6 **E.6.3 Particulate Matter-Related Effects on Materials**

7 Atmospheric PM and SO<sub>2</sub> exert effects on materials that are related both to aesthetic appeal  
8 and physical damage. Studies have demonstrated particles, primarily consisting of carbonaceous  
9 compounds, cause soiling of commonly used building materials and culturally important items  
10 such as statues and works of art. Physical damage from the dry deposition of SO<sub>2</sub>, particles, and  
11 the absorption or adsorption of corrosive agents on deposited particles can also result in the  
12 acceleration of the weathering of manmade building and naturally occurring cultural materials.

- 13 • The natural process of metal corrosion from exposure to environmental elements (wind,  
moisture, sun, temperature fluctuations, etc.) is enhanced by exposure to anthropogenic  
pollutants, in particular SO<sub>2</sub>.

- 1 • Dry deposition of SO<sub>2</sub> enhances the effects of environmental elements on calcereous stones (limestone, marble, and carbonated cemented) by converting the calcium carbonate (calcite) in the stone to calcium sulphate dihydrate (gypsum). The rate of deterioration is determined by the SO<sub>2</sub> concentration, the stone's permeability and moisture content, and the deposition rate.
- 2 • Sulfur dioxide limits the life expectancy of paints by causing discoloration, loss of gloss, and loss of thickness of the paint film layer.
- 3 • A significant detrimental effect of particulate pollution is the soiling of painted surfaces and other building materials. Soiling is a degradation process requiring remediation by cleaning or washing, and depending on the soiled surface, repainting. Soiling decreases the reflectance of a material and reduces the transmission of light through transparent materials. Soiling may reduce the life usefulness of the material soiled.

4

#### 5 **E.6.4 Effects of Atmospheric Particulate Matter on Global Warming** 6 **Processes and Transmission of Solar Ultraviolet Radiation**

- 7 • The physical processes (i.e., scattering and absorption) responsible for airborne particle effects on transmission of solar visible and ultraviolet radiation are the same as those responsible for visibility degradation. Scattering of solar radiation back to space and absorption of solar radiation determine the effects of an aerosol layer on solar radiation.
- 8 • Atmospheric particles greatly complicate projections of future trends in global warming processes because of emissions of greenhouse gases; consequent increases in global mean temperature; resulting changes in regional and local weather patterns; and mainly deleterious (but some beneficial) location-specific human health and environmental effects. The body of available evidence, ranging from satellite to in situ measurements of aerosol effects on radiation receipts and cloud properties, is strongly indicative of an important role in climate for aerosols. This role, however, is poorly quantified. No significant advances have been made in reducing the uncertainties assigned to forcing estimates provided by the IPCC for aerosol-related forcing, especially for black carbon-containing aerosol. The IPCC

characterizes the scientific understanding of greenhouse gas-related forcing as “high” in contrast to that for aerosol, which it describes as “low” to “very low.”

- 9 • Quantification of the effect of anthropogenic aerosol on hydrological cycles requires more information than is presently available regarding ecosystems responses to reduced solar radiation and other changes occurring in the climate system. However, several global scale studies indicate that aerosol cooling alone can slow down the hydrological cycle, while cooling plus the nucleation of additional cloud droplets can dramatically reduce precipitation rates.
- 10 • In addition to direct climate effects through the scattering and absorption of solar radiation, particles also exert indirect effects on climate by serving as cloud condensation nuclei, thus affecting the abundance and vertical distribution of clouds. The direct and indirect effects of particles appear to have significantly offset global warming effects caused by the buildup of greenhouse gases on a globally-averaged basis. However, because the lifetime of particles is much shorter than that required for complete mixing within the Northern Hemisphere, the climate effects of particles generally are felt much less homogeneously than are the effects of long-lived greenhouse gases.
- 11 • Any effort to model the impacts of local alterations in particle concentrations on projected global climate change or consequent local and regional weather patterns would be subject to considerable uncertainty.
- 12 • Atmospheric particles also complicate estimation of potential future impacts on human health and the environment projected as possible to occur because of increased transmission of solar ultraviolet radiation (UV-B) through the Earth’s atmosphere, secondary to stratospheric ozone depletion due to anthropogenic emissions of chlorofluorocarbons (CFCs), halons, and certain other gases. The transmission of solar UV-B radiation is affected strongly by atmospheric particles. Measured attenuations of UV-B under hazy conditions range up to 37% of the incoming solar radiation. Measurements relating variations in PM mass directly to UV-B transmission are lacking.

- 1
- Particles also can affect the rates of photochemical reactions occurring in the atmosphere, e.g., those involved in catalyzing tropospheric ozone formation. Depending on the amount of absorbing substances in the particles, photolysis rates either can be increased or decreased. Thus, atmospheric particle effects on UV-B radiation, which vary depending on size and composition of particles, can differ substantially over different geographic areas and from season to season over the same area. Any projection of effects of location-specific airborne PM alterations on increased atmospheric transmission of solar UV radiation (and associated potential human health or environmental effects) due to stratospheric ozone-depletion would, therefore, also be subject to considerable uncertainty.

2

## 3 **E.7 KEY CONCLUSIONS**

- 4
- Epidemiologic studies show consistent positive associations of exposure to ambient PM with health effects, including mortality and morbidity. The observed associations of ambient PM exposure with health effects must take into account the effects of other environmental or demographic factors, depending on whether the effects are acute or chronic. Effect-size estimates for PM-attributable excess relative risk for a given health outcome vary somewhat depending on specific analytic models used, but nevertheless have shown reasonable quantitative consistency across different studies.
- 5
- Issues surrounding potential bias in PM risk estimates from time-series studies using generalized additive models analyses and default convergence criteria were recently raised. Reanalyses of some important studies were included in an HEI Special Report (2003) that generally confirmed that PM effect estimates generally decline somewhat when using more stringent convergence criteria, as compared to the default GAM analyses, with the new estimates being well within confidence intervals of the original estimates. Overall, the absolute effect was relatively small, and the basic direction of effect and conclusions regarding the significance of the PM effect on mortality and hospital admissions remained unchanged in these analyses when the GAM convergence requirement was made more stringent. A modeling issue of particular importance highlighted by HEI (2003) is the

sensitivity of all models to the degrees of freedom allotted to potentially confounding weather variables and time. The HEI panel recommended further exploration of the sensitivity of these studies to a wider range of alternative degrees of smoothing and to alternative specifications of weather variables in time-series models.

- 6 • Individuals with cardiovascular or pulmonary disease, especially if they are elderly, are more likely to suffer severe health effects (mortality or hospitalization) related to PM exposure than are healthy young adults. Children and asthmatics are also susceptible to certain PM effects, e.g., increased respiratory symptoms and decreased lung function. Smokers also constitute a population group at increased risk for ambient PM exposure effects.
- 7 • Daily ambient fine particle concentrations measured at a community air-monitoring site are useful surrogates for daily personal exposures to ambient fine particles. This is consistent, for example, with observed high correlations of personal sulfate exposures with ambient sulfate concentrations. The relationship between personal exposure to thoracic coarse particles and the ambient concentration of thoracic coarse fraction particles is not as strong, making effects due to coarse fraction particles harder to detect in epidemiologic studies.
- 8 • Development of a comprehensive biologically based exposure-dose-response model to aid health risk assessment requires further dosimetry data characterizing differences among species in percent deposition and regional deposition patterns including differences in inhalability, airway geometry, and clearance rates. More information is also needed on mechanism(s) of clearance, pathological processes affecting deposition and clearance of particles, and factors influencing the response(s) of respiratory tract tissues to particle burden.
- 9 • The percent deposition and regional patterns of deposition depend strongly on particle size. Percent deposition is higher in smaller lungs (children; women), during exercise, and in the functioning parts of the lungs in people with compromised lungs (e.g., those with chronic obstructive lung disease).
- 10 • Estimation of public health impacts of ambient airborne particle exposures in the United States would most credibly combine information on exposure-response relationships derived

for particular U.S. urban areas, in combination with estimates of exposures to ambient particle concentrations for the general population and/or specific susceptible subgroups (e.g., the elderly) those particular areas. At this time, risk assessment is necessarily limited to use of available information from concentration-response relationships relating ambient concentrations to health effects in populations. In view of geographic differences in ambient PM mixtures and demographics, broad generalization of some single “best estimate” of relative risk for a given increment in concentration of a given particle indicator (e.g., PM<sub>10</sub>, PM<sub>2.5</sub>, etc.) would be subject to much uncertainty.

- 11 • Toxicological studies of PM using controlled inhalation exposure of humans and laboratory animals, intratracheal instillation in humans and animals, and exposure of human and animal cells grown in culture find numerous biological effects which may be related to adverse health effects. Newer studies are finding different biological effects for a variety of different particle components. Newer studies also are beginning to identify biological mechanisms whereby PM deposited in the lung can produce adverse effects on the cardiovascular and respiratory systems.
- 12 • Epidemiologic studies indicate increased health risks associated with exposure to PM, alone or in combination with other air pollutants. PM-related increases in individual health risks are small, but likely significant from an overall public health perspective because of the large numbers of individuals in susceptible risk groups that are exposed to ambient PM.
- 13 • Numerous new studies, including multicity studies, continue to show a consistent association of PM<sub>10</sub> exposure with mortality and various morbidity endpoints, thus substantiating the relationship of PM exposure with various health effects. However, some new studies using PM<sub>2.5</sub> as an indicator find higher statistical significance and higher excess risk for PM<sub>2.5</sub> compared to PM<sub>10</sub>. Several studies have also observed statistically associations of PM<sub>10-2.5</sub> with health effects.
- 14 • Epidemiologic studies, in which factors identified with source categories or individual chemical components of PM have been used as indicators, also show significant associations

with nitrates, sulfates, various indicators of elemental carbon, the organic component of PM, and some elements. PM-related source category factors, such as regional sulfate, vehicular traffic, fossil fuel combustion, vegetative combustion, and oil burning have also been found to be significantly associated with mortality.

- 15 • Data from multicity studies, comparisons of effects found in single and multiple regressions, exposure relationships, and toxicity suggest that the gaseous co-pollutants (CO, NO<sub>3</sub>, SO<sub>2</sub>, O<sub>3</sub>) are not responsible for the relationships observed with PM indicators in community, time-series epidemiology. This does not, however, necessarily imply lack of an independent association of gaseous co-pollutants with health effects.
- 16 • Fine and thoracic coarse PM, indexed respectively by PM<sub>2.5</sub> and PM<sub>10-2.5</sub>, should be considered as separate subclasses of PM. Considerations of emissions sources, atmospheric chemistry, physical behavior, exposure relationships, respiratory deposition, toxicologic findings, and epidemiologic observations argue for monitoring fine and thoracic coarse particles separately.
- 17 • Assessment of health risk in epidemiologic studies of ambient air pollutants, including PM, has relied largely on studies that focus on changes in health risks that occur in relation to normal changes in ambient air pollutant concentrations. Further evidence of the effects of air pollution on health may be deduced from intervention studies, i.e, studies of changes in health effects that occur when air pollution concentrations have been temporarily or permanently reduced through regulatory action, industrial shutdown, or other intervening factor(s). Only a few epidemiologic intervention studies are available; however, taken together, these studies lend confidence that further reduction of ambient air pollution exposures in the U.S. would reduce both respiratory and cardiovascular health effects. Available studies also give reason to expect that further reductions in both particulate and gaseous air pollutants would benefit health. Furthermore, experimental studies of Utah Valley filter extracts points to PM-associated metals as a likely cause or promoter of at least some of the health disorders associated with ambient PM.

- 1 • The overall weight of evidence, based on information concerning PM exposure, dosimetry, toxicology, and epidemiology, supports the conclusion that PM, especially fine PM, is the primary contributor to a variety of adverse health effects associated with air pollution. However, difficult technical issues still remain in further separating the effects of fine and coarse particles and in delineating respective contributions of PM acting along or in combination with gaseous co-pollutants in increasing risks of health effects anticipated to occur in response to exposures to contemporary particle-containing ambient air mixes in the United States.

# 1. INTRODUCTION

This document is an update of “Air Quality Criteria for Particulate Matter” published by the U.S. Environmental Protection Agency (EPA) in 1996, and it will serve as the basis for Congressionally-mandated periodic review of the National Ambient Air Quality Standards (NAAQS) for particulate matter (PM). The present document critically assesses the latest scientific information relative to determining the health and welfare effects associated with the presence of various concentrations of PM in ambient air. The document builds upon the assessment in the previous 1996 EPA Air Quality Criteria Document for Particulate Matter (PM AQCD) by focusing on assessment and integration of information most relevant to PM NAAQS criteria development, based on pertinent peer-reviewed literature published or accepted for publication mainly through April 2002. This introductory chapter presents a brief summary of legislative requirements and history of the PM NAAQS, provides an overview of issues addressed and procedures utilized in the preparation of the present document, and provides orientation to the general organizational structure of the document.

## 1.1 LEGISLATIVE REQUIREMENTS

As indicated in U.S. Code (1991), the U.S. Clean Air Act (CAA), Sections 108 and 109 (42 U.S.C. Sections 7408 and 7409) govern the establishment, review, and revision of National Ambient Air Quality Standards (NAAQS). Section 108(a) directs the EPA Administrator to list pollutants, which, in the Administrator’s judgement, cause or contribute to air pollution which may reasonably be anticipated to endanger either public health or welfare and to issue air quality criteria for them. The air quality criteria are to reflect the latest scientific information useful in indicating the kind and extent of all identifiable effects on public health and welfare that may be expected from the presence of the pollutant in ambient air.

Section 109 directs the Administrator of EPA to propose and promulgate “primary” and “secondary” NAAQS for pollutants identified under Section 108. Section 109(b)(1) defines a primary standard as a level of air quality, the attainment and maintenance of which, in the judgement of the Administrator, based on the criteria and allowing for an adequate margin of

1 safety, is requisite to protect the public health. Section 109(b)(2) defines a secondary standard as  
2 one which, in the judgement of the Administrator, based on the criteria, is requisite to protect  
3 public welfare from any known or anticipated adverse effects associated with the presence of  
4 such pollutants. Welfare effects, defined in Section 302(h), include, but are not limited to,  
5 effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather,  
6 visibility and climate, damage to and deterioration of property, and hazards to transportation, as  
7 well as effects on economic values and personal comfort and well-being. Section 109(d)(1)  
8 requires periodic review and, as appropriate, revision of existing criteria and standards.  
9 Section 109(d)(2) requires an independent committee of non-EPA experts, the Clean Air  
10 Scientific Advisory Committee (CASAC), to provide advice and recommendations to the EPA  
11 Administrator regarding the scientific soundness and appropriateness of criteria and NAAQS for  
12 PM and other “criteria air pollutants” (i.e., ozone, nitrogen dioxide, sulfur oxides, carbon  
13 monoxide, lead) regulated under CAA Sections 108-109.  
14  
15

## 16 **1.2 HISTORY OF PREVIOUS PM CRITERIA AND NAAQS REVIEWS**

17 “Particulate matter” is the generic term for a broad class of physically and chemically  
18 diverse substances that exist in ambient air as discrete particles (liquid droplets or solids) over a  
19 wide range of sizes. These airborne particles originate from a variety of stationary and mobile  
20 sources. Primary particles are emitted directly into ambient air; whereas secondary particles are  
21 formed in the atmosphere by transformation of gaseous emissions such as sulfur oxides (SO<sub>x</sub>),  
22 nitrogen oxides (NO<sub>x</sub>), and volatile organic compounds (VOCs). The physical and chemical  
23 properties of PM vary greatly with time, region, meteorology, and source category, thus  
24 complicating assessment of ambient PM health and welfare effects. Particles in ambient air are  
25 usually distributed bimodally in two somewhat overlapping size categories: (1) fine (diameter  
26 generally less than 2.5 μm) and (2) coarse (diameter generally greater than 1.0 μm). Particles in  
27 these two size fractions tend to differ in terms of formation mechanisms, sources of origin,  
28 composition, and behavior in the atmosphere and human respiratory tract.

29 EPA first promulgated primary and secondary NAAQS for PM on April 30, 1971 (Federal  
30 Register, 1971). These standards measured PM as “total suspended particulate” (TSP), which  
31 refers to ambient PM up to a nominal size of 25 to 45 micrometers (μm). The primary standards

1 for PM (measured as TSP) were 260  $\mu\text{g}/\text{m}^3$  (24-h average), not to be exceeded more than once  
2 per year, and 75  $\mu\text{g}/\text{m}^3$  (annual geometric mean). The secondary standard (measured as TSP)  
3 was 150  $\mu\text{g}/\text{m}^3$  (24-h average), not to be exceeded more than once per year.

4 EPA completed the next review of PM air quality criteria and standards in July 1987,  
5 revising the 1971 standards to protect against adverse health effects of inhalable airborne  
6 particles which can be deposited in the lower (thoracic) regions of the human respiratory tract,  
7 with “PM<sub>10</sub>” as the indicator (i.e., those particles collected by a sampler with a specified  
8 penetration curve yielding an upper 50% cut-point of 10- $\mu\text{m}$  aerodynamic diameter (Federal  
9 Register, 1987). EPA established identical primary and secondary PM<sub>10</sub> standards for two  
10 averaging times: 150  $\mu\text{g}/\text{m}^3$  (24-h average), with no more than one expected exceedance per  
11 year and 50  $\mu\text{g}/\text{m}^3$  (expected annual arithmetic mean), averaged over three years.  
12

### 13 **1.2.1 The 1997 PM NAAQS Revision**

14 The last previous review of the air quality criteria and standards for PM was initiated in  
15 April 1994 by EPA announcing its intention to develop revised Air Quality Criteria for  
16 Particulate Matter. Several workshops were held by EPA’s Environmental Criteria and  
17 Assessment Office in Research Triangle Park, NC (ECAO-RTP) in November 1994 and January  
18 1995 to discuss important new health effects information useful in preparing initial PM AQCD  
19 draft materials. Also, plans for review of the PM criteria and standards under a highly  
20 accelerated, court-ordered schedule were presented by EPA at a public meeting of the CASAC in  
21 December 1994. A court order entered in *American Lung Association v. Browner*, CIV-93-643-  
22 TUC-ACM (U.S. District Court of Arizona, 1995), as subsequently modified, required  
23 publication of EPA’s final decision on the review of the PM NAAQS by July 19, 1997.

24 Several external review drafts of the revised PM AQCD were prepared by the RTP  
25 Division of EPA’s newly created National Center for Environmental Assessment (i.e., by  
26 NCEA-RTP, the successor office to ECAO-RTP), and each were made available for public  
27 comment followed by CASAC review (at public meetings held in August 1995, December 1995,  
28 and February 1996). The CASAC came to closure on its review of the PM AQCD in early 1996,  
29 advising the EPA Administrator in a March 15, 1996 closure letter (Wolff, 1996) that “although  
30 our understanding of the health effects of PM is far from complete, a revised Criteria Document  
31 which incorporates the Panel’s latest comments will provide an adequate review of the available

1 scientific data and relevant studies of PM.” Revisions made in response to public and CASAC  
2 comments were then incorporated by NCEA-RTP, as appropriate, into the final 1996 PM AQCD  
3 (U.S. Environmental Protection Agency, 1996a). A PM Staff Paper (SP), prepared by the Office  
4 of Air Quality Planning and Standards (OAQPS) within EPA’s Office of Air and Radiation  
5 (OAR), drew upon the 1996 PM AQCD and other exposure and risk assessments to pose options  
6 for PM NAAQS decisions. Drafts of the PM SP also underwent public comment and CASAC  
7 review, with consequent revision into the final 1996 PM SP (U.S. Environmental Protection  
8 Agency, 1996b).

9 The 1996 PM AQCD and the 1997 PM SP (U.S. Environmental Protection Agency,  
10 1997a,b) provide detailed information on atmospheric formation, ambient concentrations, and  
11 health effects of ambient air PM, as well as quantitative estimates of human health risks  
12 associated with exposure to ambient PM. The principal focus of these documents was on recent  
13 epidemiologic evidence reporting associations between ambient concentrations of PM and a  
14 range of serious health effects. Special attention was given to several size-specific classes of  
15 particles, including PM<sub>10</sub> and the principal fractions of PM<sub>10</sub>, referred to as the fine (PM<sub>2.5</sub>) and  
16 coarse (PM<sub>10-2.5</sub>) fractions. PM<sub>2.5</sub> refers to those particles collected by samplers having  
17 penetration curves yielding an upper 50% cut point of 2.5 µm aerodynamic diameter. PM<sub>10-2.5</sub>  
18 refers to those particles in an aggregate sample having an upper 50% cut point of 10 µm and a  
19 lower 50% cut point of 2.5 µm aerodynamic diameter. In other words, the coarse fraction  
20 (PM<sub>10-2.5</sub>) refers to the inhalable particles that remain if fine (PM<sub>2.5</sub>) particles are removed from a  
21 sample of PM<sub>10</sub> particles. As discussed in the 1996 PM AQCD, fine and coarse fraction particles  
22 can be differentiated by their sources and formation processes and by their chemical and  
23 physical properties, including behavior in the atmosphere.

24 Taking into account information and assessments presented in the 1996 PM AQCD and  
25 PM SP, advice and recommendations of CASAC, and public comments received on proposed  
26 revisions to the PM NAAQS published in December 1996 (Federal Register, 1996), the EPA  
27 Administrator promulgated significant revisions to the PM NAAQS in July 1997 (Federal  
28 Register, 1997). In that decision, the PM NAAQS were revised in several respects. While it was  
29 determined that the PM NAAQS should continue to focus on particles less than or equal to  
30 10 µm in diameter, it was also determined that the fine and coarse fractions of PM<sub>10</sub> should be  
31 considered separately. New standards were added, using PM<sub>2.5</sub> as the indicator for fine particles,

1 and PM<sub>10</sub> standards were retained for the purpose of regulating coarse-fraction particles. Two  
2 new PM<sub>2.5</sub> standards were set: an annual standard of 15 µg/m<sup>3</sup>, based on the 3-year average of  
3 annual arithmetic mean PM<sub>2.5</sub> concentrations from single or multiple community-oriented  
4 monitors; and a 24-hour standard of 65 µg/m<sup>3</sup>, based on the 3-year average of the 98<sup>th</sup> percentile  
5 of 24-hour PM<sub>2.5</sub> concentrations at each population-oriented monitor within an area. To continue  
6 to address coarse-fraction particles, the annual PM<sub>10</sub> standard was retained, and the form, but not  
7 the level, of the 24-hour PM<sub>10</sub> standard was revised to be based on the 99<sup>th</sup> percentile of 24-hour  
8 PM<sub>10</sub> concentrations at each monitor in an area. The secondary standards were revised by  
9 making them identical in all respects to the primary standards.

10 Following promulgation of the revised PM NAAQS, legal challenges were filed by a large  
11 number of parties, addressing a broad range of issues. In May 1998, the U.S. Court of Appeals  
12 for the District of Columbia Circuit issued an initial opinion that upheld EPA's decision to  
13 establish fine particle standards, holding that such standards were amply justified by the growing  
14 body of empirical evidence demonstrating a relationship between fine particle pollution and  
15 adverse health effects. American Trucking Associations v. Browner, 175 F. 3d 1027, 1055-56  
16 (D.C. Cir. 1999) (rehearing granted in part and denied in part, 195 F. 3d 4 (D.C. Cir. 1999b),  
17 affirmed in part and reversed in part, Whitman v. American Trucking Associations, 531 U.S. 457  
18 (2001). Further, the court found "ample support" for EPA's decision to regulate coarse fraction  
19 particles, although it vacated the revisions to the 1987 PM<sub>10</sub> standards on the basis of PM<sub>10</sub> being  
20 a "poorly matched indicator for coarse particulate pollution" because PM<sub>10</sub> includes fine  
21 particles. Id. at 1053-55. As a result of this aspect of the court's ruling, which EPA did not  
22 appeal, the 1987 PM<sub>10</sub> standards remain in effect.

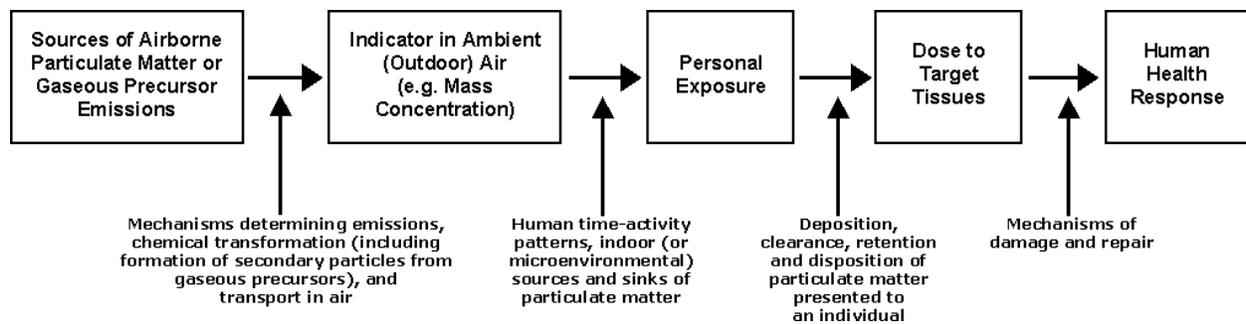

23 In addition, the court broadly held that EPA's approach to establishing the level of the  
24 standards in its 1997 decisions on both the PM and ozone NAAQS (which were promulgated on  
25 the same day and considered together by the court in this aspect of its opinion) effected "an  
26 unconstitutional delegation of legislative authority." Id. at 1034-40. EPA appealed this aspect of  
27 the court's ruling to the United States Supreme Court. In February 2001, the U.S. Supreme  
28 Court unanimously reversed the Court of Appeals' ruling on the constitutional issue, and sent the  
29 case back to the Court of Appeals for resolution of any remaining issues that had not been  
30 addressed in that court's earlier rulings. Whitman v. American Trucking Associations, 531 U.S.  
31 457, 475-76 (2001). In March 2002, the Court of Appeals rejected all remaining challenges to

1 the standards, finding that the 1997 PM<sub>2.5</sub> standards were reasonably supported by the record and  
2 were not “arbitrary or capricious.” American Trucking Associations v. EPA, 283 F. 3d 355,  
3 369-72 (D.C. Cir. 2002). Thus, the 1997 PM<sub>2.5</sub> standards are in effect.  
4

### 5 **1.2.2 Coordinated Particulate Matter Research Program**

6 Shortly after promulgation of the 1997 PM NAAQS decisions, NCEA-RTP published a  
7 PM Health Risk Research Needs Document (U.S. Environmental Protection Agency, 1998a) that  
8 identified research needed to improve scientific information supporting future reviews of the PM  
9 NAAQS. The document provided a foundation for PM research coordination among Federal  
10 agencies and other research organizations and also provided input to later National Research  
11 Council (NRC) deliberations on PM research. The Office of Research and Development (ORD)  
12 of EPA also moved quickly to broaden its ongoing PM research activities by developing, in  
13 partnership with other Federal agencies, a coordinated interagency PM research program. This  
14 interagency program has and continues to focus mainly on expanding scientific knowledge of  
15 ambient PM exposure and health effects, as well as including development of improved  
16 monitoring methods and cost-effective mitigation strategies. The interagency effort also  
17 promotes substantially expanded coordination with other research organizations, including the  
18 Health Effects Institute (HEI) and other state-, university-, and industry-sponsored research  
19 groups. Beginning in the fall of 1997, public participation was and continues to be encouraged  
20 through workshops and review of EPA’s PM Research Program documentation.

21 In response to Congressional requirements in EPA’s Fiscal Year 1998 Appropriation, the  
22 NRC established its Committee on Research Priorities for Airborne Particulate Matter in January  
23 1998. This NRC PM Research Committee’s charge is to identify the most important research  
24 priorities relevant to setting PM NAAQS, to develop a conceptual plan for PM research, and to  
25 monitor EPA’s research progress toward improved understanding of the relationship between  
26 PM and public health. The Committee issued its first report in early 1998 (National Research  
27 Council, 1998), a second one in 1999 (National Research Council, 1999), and a third one in 2001  
28 (National Research Council, 2001). In the above-noted series of reports, the NRC PM Research  
29 Committee recommended that expanded PM research efforts be planned and carried out in  
30 relation to a general conceptual framework as shown in Figure 1-1. That framework essentially  
31 calls for research aimed at: (a) identifying sources of airborne particles or gaseous precursor

**Figure 1-1. A general framework for integrating particulate-matter research. Note that this figure is not intended to represent a framework for research management. Such a framework would include multiple pathways for the flow of information.**

Source: National Research Council (2001).

1 emissions and characterization of processes involved in atmospheric transformation, transport,  
 2 and fate of ambient PM; (b) delineation of temporal and spatial patterns of air quality indicators  
 3 (e.g., PM<sub>2.5</sub>, PM<sub>10-2.5</sub>, PM<sub>10</sub> mass concentrations) of ambient PM and apportionment of observed  
 4 variations in such ambient PM indicators to various emission sources; (c) characterization of  
 5 human exposures to ambient PM as one important component of total personal exposure to  
 6 particles, as modified by time-activity patterns and varying microenvironmental exposure to  
 7 particles of indoor or ambient origin; (d) characterization of resulting respiratory tract  
 8 deposition, clearance, retention, and disposition of inhaled particles, as determinants of dose to  
 9 target tissues (e.g., locally in the lungs or via systemic translocation to the heart or other organs);  
 10 (e) delineation of mechanisms of damage and repair plausibly leading to (f) human health  
 11 responses, as extrapolated from or quantified by experimental animal or human exposure  
 12 (toxicology) studies and/or observational (epidemiology) studies.

13 Research conducted under a PM Research Program structured in relation to the conceptual  
 14 framework shown in Figure 1-1 would be expected (a) to reduce key scientific uncertainties  
 15 regarding interrelationships between PM sources, ambient concentrations, exposures, dose to  
 16 target tissues, and resulting health effects and (b) thereby improve the scientific underpinnings  
 17 for both current and future periodic PM NAAQS reviews. Table 1-1 highlights some types of  
 18 key uncertainties identified by the NRC PM Research Committee in relation to elements of the

Source: National Research Council (2001).

1 source-to-response conceptual framework illustrated in Figure 1-1. The NRC Committee went  
2 on to delineate a series of 10 research topics that they recommended be addressed in an  
3 expanded PM research program aimed at answering a set of broadly stated questions, as shown  
4 in Table 1-2.

5 The EPA PM Research Program, structured to address topics shown in Table 1-2 includes,  
6 for example, studies to improve understanding of the formation and composition of fine PM,  
7 improved measurements and estimation of population exposures to ambient PM, the  
8 characteristics or components of PM that are responsible for its health effects, factors increasing  
9 susceptibility to PM effects in some subpopulations, and mechanisms by which these effects are  
10 produced. The results from these efforts, and related efforts by other Federal agencies and the  
11 general scientific community during the past several years, have substantially enhanced the  
12 scientific and technical bases for future decisions on the PM NAAQS.

### 15 **1.3 CURRENT PM CRITERIA AND NAAQS REVIEW**

#### 16 **1.3.1 Key Milestones**

17 As with other NAAQS reviews, rigorous assessment of relevant scientific information is  
18 presented in this updated, revised PM AQCD. As shown in Table 1-3, development of the  
19 document has involved substantial external peer review through (a) public workshops involving  
20 the general aerosol scientific community, (b) iterative reviews of successive drafts by CASAC,  
21 and (c) comments from the public. The final document will reflect input received through these  
22 reviews and will serve to evaluate and integrate the latest available scientific information to  
23 ensure that the review of the PM standards is based on rigorous evaluation of the available  
24 science.

25 An earlier (October 1999) First External Review Draft of this updated document was  
26 released in the fall of 1999 for public comment and CASAC review. A Second External Review  
27 Draft (March 2001) took into account earlier public comments and the December 1999 CASAC  
28 review and was reviewed by CASAC in July 2001. A Third External Review Draft similarly  
29 took into account prior public comments and CASAC recommendations and was released in  
30 early May 2002 for a 60-day public comment period; CASAC reviewed it at a public meeting in  
31 July 2002.

**TABLE 1-2. RESEARCH TOPICS AND QUESTIONS RECOMMENDED BY  
NATIONAL RESEARCH COUNCIL (NRC) TO BE ADDRESSED BY EXPANDED  
PM RESEARCH PROGRAM**

<b>RESEARCH TOPIC 1.</b>	<b>OUTDOOR MEASURES VERSUS ACTUAL HUMAN EXPOSURES</b>
	<i>• What are the quantitative relationships between concentrations of particulate matter and gaseous co-pollutants measured at stationary outdoor air monitoring sites and the contributions of these concentrations to actual personal exposures, especially for subpopulations and individuals?</i>
<b>RESEARCH TOPIC 2.</b>	<b>EXPOSURES OF SUSCEPTIBLE SUBPOPULATIONS TO TOXIC PARTICULATE MATTER COMPONENTS</b>
	<i>• What are the exposures to biologically important constituents and specific characteristics of particulate matter that cause responses in potentially susceptible subpopulations and the general population?</i>
<b>RESEARCH TOPIC 3.</b>	<b>CHARACTERIZATION OF EMISSION SOURCES</b>
	<i>• What are the size distribution, chemical composition, and mass-emission rates of particulate matter emitted from the collection of primary-particle sources in the United States, and what are the emissions of reactive gases that lead to secondary particle formation through atmospheric chemical reactions?</i>
<b>RESEARCH TOPIC 4.</b>	<b>AIR-QUALITY MODEL DEVELOPMENT AND TESTING</b>
	<i>• What are the linkages between emission sources and ambient concentrations of the biologically important components of particulate matter?</i>
<b>RESEARCH TOPIC 5.</b>	<b>ASSESSMENT OF HAZARDOUS PARTICULATE MATTER COMPONENTS</b>
	<i>• What is the role of physicochemical characteristics of particulate matter in eliciting adverse health effects?</i>
<b>RESEARCH TOPIC 6.</b>	<b>DOSIMETRY: DEPOSITION AND FATE OF PARTICLES IN THE RESPIRATORY TRACT</b>
	<i>• What are the deposition patterns and fate of particles in the respiratory tract of individuals belonging to presumed susceptible subpopulations?</i>
<b>RESEARCH TOPIC 7.</b>	<b>COMBINED EFFECTS OF PARTICULATE MATTER AND GASEOUS POLLUTANTS</b>
	<i>• How can the effects of particulate matter be disentangled from the effects of other pollutants? How can the effects of long-term exposure to particulate matter and other pollutants be better understood?</i>
<b>RESEARCH TOPIC 8.</b>	<b>SUSCEPTIBLE SUBPOPULATIONS</b>
	<i>• What subpopulations are at increased risk of adverse health outcomes from particulate matter?</i>
<b>RESEARCH TOPIC 9.</b>	<b>MECHANISMS OF INJURY</b>
	<i>• What are the underlying mechanisms (local pulmonary and systemic) that can explain the epidemiologic findings of mortality/morbidity associated with exposure to ambient particulate matter?</i>
<b>RESEARCH TOPIC 10.</b>	<b>ANALYSIS AND MEASUREMENT</b>
	<i>• To what extent does the choice of statistical methods in the analysis of data from epidemiologic studies influence estimates of health risks from exposures to particulate matter? Can existing methods be improved? What is the effect of measurement error and misclassification on estimates of the association between air pollution and health?</i>

**TABLE 1-3. SCHEDULE FOR DEVELOPMENT OF THE CURRENT REVISED PARTICULATE MATTER AIR QUALITY CRITERIA DOCUMENT (PM AQCD)**

Major Milestones	Target Dates
PM NAAQS Review Plan to CASAC	October 1997
Prepare AQCD Development Plan	November 1997 to January 1998
Begin Literature Search	February 1998
Federal Register Call for Information/Sources Sought	April 1998
CASAC Meeting on AQCD Development Plan	May 1998
Prepare Workshop Drafts of Chapters	May to December 1998
Peer Review Workshop	April 1999
Prepare External Review Draft AQCD	March to September 1999
First External Review Draft	October 1999
Public Comment Period on Draft AQCD	October 1999 to January 2000
CASAC Meeting on First Draft AQCD	December 1999
Second External Review Draft	March 2001
Public Comment Period on Second Draft	April to July 2001
CASAC Meeting on Second Draft	July 2001
Third External Review Draft	April 2002
Public Comment Period on Third Draft	May to July 2002
CASAC Meeting on Third Draft	July 2002
Final PM AQCD	Oct/Nov 2002

1            Shortly after EPA released the Third External Review Draft in May 2002, the Health  
2            Effects Institute (HEI) announced that researchers at Johns Hopkins University had discovered  
3            problems with applications of statistical software used in a number of important studies on links  
4            between ambient air particulate matter (PM) and death and disease. In response to the surfacing  
5            of such statistical issues, which affected numerous PM time-series studies that used General  
6            Additive Models (GAM) and were published post-1995, EPA took steps in consultation with  
7            CASAC to encourage researchers to reanalyze affected studies and to submit them expeditiously

1 for peer review by a special expert panel convened by HEI. The results of reanalyses for more  
2 than 30 studies of likely importance in informing U.S. standard setting decisions for ambient PM  
3 have now been peer-reviewed and are included, along with commentary by the HEI expert peer-  
4 review panel, in a recently released HEI Special Report (Health Effects Institute, May 2003).  
5 The subject statistical issues and reanalyses results are discussed in more detail in Chapter 8 of  
6 this document. After a 60-day public comment period, starting in June 2003, and CASAC  
7 review of this Fourth Draft, the final version of this PM AQCD is targeted for issuance by  
8 December 31, 2003.

9 After CASAC review of the First External Review Draft of this revised PM AQCD in  
10 December 1999, EPA's OAQPS started to prepare the associated PM Staff Paper (SP).  
11 A preliminary draft SP was made available to the public and was discussed at a July 2001  
12 CASAC meeting; and additional consultations have been held via teleconference with CASAC  
13 to obtain feedback on proposed approaches to be used in conducting analyses to be included in  
14 the First External Review Draft of the PM SP due to be released in the summer of 2003. The  
15 draft PM SP will draw on the updated findings and conclusions from this draft PM AQCD and  
16 will also undergo public comment and CASAC review (now being scheduled for November,  
17 2003). Ultimately drawing on information in the final version of this newly revised PM AQCD,  
18 the PM SP will evaluate policy implications of the key studies and scientific findings contained  
19 in the AQCD, present related staff analyses of air quality and human health risk, and identify  
20 critical elements that EPA staff believes should be considered in reviewing the PM standards.  
21 The PM SP is intended to bridge the gap between the scientific review in the AQCD and the  
22 public health and welfare policy judgements required of the Administrator in reviewing the PM  
23 NAAQS. In doing so, the PM SP will include staff conclusions and recommendations of options  
24 for the Administrator's consideration.

25 Based on the final versions of the PM AQCD and the PM SP, and on the advice of  
26 CASAC, the Administrator will propose decisions as to whether to retain or revise the current  
27 PM NAAQS and provide opportunities for public and CASAC comments on the proposed  
28 decisions. Taking into account comments on the proposed decisions, the Administrator will then  
29 make final decisions on the PM NAAQS, which are now expected to be published around the  
30 end of 2005.

### 1.3.2 Methods and Procedures for Document Preparation

The procedures for developing this revised PM AQCD build on the experience and methods derived from the most recent previous PM, Ozone, and CO AQCD preparation efforts. Briefly, the respective responsibilities for production of the present PM AQCD are as follows. An NCEA-RTP PM Team was formed and is responsible for developing and implementing the project plan for preparation of the PM AQCD, taking into account inputs from individuals in other EPA program and policy offices identified as part of the EPA PM Work Group. The resulting project plan (i.e., the PM Document Development Plan) was discussed with CASAC in May 1998 and was appropriately revised. An ongoing literature search has continued to be conducted to identify, to the extent possible, all pertinent PM literature published since early 1996. Additionally, EPA published in the Federal Register (1) a request for information asking for recently available research information on PM that may not yet be published and (2) a request for individuals with the appropriate type and level of expertise to contribute to the writing of PM AQCD materials to identify themselves (U.S. Environmental Protection Agency, 1998b). The specific authors of chapters or sections of the proposed document were selected on the basis of their expertise on the subject areas and their familiarity with the relevant literature; these include both EPA and non-EPA scientific experts. The project team defined critical issues and topics to be addressed by the authors and provided direction in order to emphasize evaluation of those studies most clearly identified as important for standard setting. It should be noted that materials contributed by non-EPA authors are incorporated and, at times, modified by EPA PM team staff to reflect internal and/or external review comments, e.g., by the public or CASAC, and that EPA is responsible for the ultimate content of the PM AQCD.

The main focus of this revised criteria document is the evaluation and interpretation of pertinent atmospheric science information, air quality data, human exposure information, and health and welfare effects information newly published since that assessed in the 1996 PM AQCD and likely to be useful in deriving criteria for U.S. EPA PM NAAQS decisions. Initial draft versions of AQCD chapters were evaluated via expert peer-review workshop discussions and/or written peer reviews that focused on the selection of pertinent studies included in the chapters, the potential need for additional information to be added to the chapters, and the quality of the summarization and interpretation of the literature. The authors of the draft chapters then revised them on the basis of workshop and/or written expert review

1 recommendations. These and other integrative summary materials were incorporated into the  
2 First External Review Draft of the PM AQCD (October 1999), which underwent public  
3 comment and was the subject of consultation with CASAC at a December 1999 public meeting.

4 In order to foster timely presentation and publication of newly emerging PM research  
5 findings, EPA co-sponsored an Air and Waste Management Association International Speciality  
6 Conference, entitled “PM 2000: Particulate Matter and Health,” held in January 2000 in  
7 Charleston, SC. The conference was co-sponsored in cooperation with several other government  
8 agencies and/or private organizations that also fund PM research. Topics covered included new  
9 research results concerning the latest advances in PM atmospheric sciences (e.g., PM formation,  
10 transport, transformation), PM exposure, PM dosimetry and extrapolation modeling, PM  
11 toxicology (e.g., mechanisms, laboratory animal models, human clinical responses), and PM  
12 epidemiology. The main purpose of the conference was to facilitate having the latest scientific  
13 information available in time for incorporation as quickly as possible into the Second External  
14 Review Draft of this revised PM AQCD. Hence, arrangements were made for scientists to  
15 submit written manuscripts on papers or posters presented at the PM 2000 Conference for  
16 expedited peer-review by several major journals, so that decisions on acceptance for publication  
17 could be made by mid-2000. The evaluations and findings set forth in the Second External  
18 Review Draft (March 2001) of the revised PM AQCD included consideration of such published  
19 PM 2000 papers and extensive additional information published elsewhere since the previous  
20 First External Review Draft; and the Second Draft was reviewed by CASAC in July 2001.

21 Further revisions were then incorporated into the Third External Review Draft (April 2002)  
22 to reflect both public comment and CASAC review of the Second Draft, as well as assessment of  
23 additional extensive new information published since that addressed in the Second Draft. This  
24 Fourth Draft AQCD incorporates changes made in response to earlier public comments and  
25 CASAC reviews; and it includes pertinent peer-reviewed literature published or accepted for  
26 publication mainly through April 2002. The final PM AQCD will include revisions made in  
27 response to public comment and CASAC review of this draft document.

### 1 **1.3.3 Approach**

2 An initial step in development of this revised PM AQCD was to focus on selection of  
3 pertinent issues to include in the document as the basis for the derivation of PM NAAQS criteria.  
4 Preliminary issues were identified by the NCEA PM Team via inputs from other EPA program  
5 and policy offices, as derived from the 1996 PM AQCD and SP, their CASAC and public  
6 reviews, from the 1997 standard promulgation process, and from the 1998 PM Research Needs  
7 Document (alluded to in Section 1.2.2). Still further identification and refinement of issues  
8 resulted from NRC review and reports on PM research priorities (also discussed in Section 1.2.2  
9 above). The CASAC review of the PM AQCD Development Plan and public comments on  
10 earlier draft AQCD materials at various stages of their development also provided important  
11 inputs regarding issue identification.

12 In developing draft materials for inclusion in the revised PM AQCD, detailed review of  
13 key new research was undertaken as a first step. However, instead of presenting a  
14 comprehensive review of all the literature, emphasis in this revised AQCD is placed on (1) first,  
15 the concise summary of key findings derived from previous PM criteria reviews (especially the  
16 1996 PM AQCD) and, then, (2) evaluation of the most pertinent new key information, with  
17 greater emphasis on more interpretive assessment — an approach reflecting CASAC  
18 recommendations. To aid in the development of a more concise document than the 1996 PM  
19 AQCD, compilation of summary tables of relevant new literature published since completion of  
20 that previous document and selective text discussion of such new literature has been undertaken,  
21 with increased emphasis being placed in text discussions on interpretive evaluation and  
22 integration of key points derived from the newly summarized research results.

## 23 24 25 **1.4 DOCUMENT ORGANIZATION AND CONTENT**

26 The present draft document attempts to critically review and assess relevant scientific  
27 literature on PM published, since early 1996, including materials accepted for publication mainly  
28 through April 2002 (and thus appearing mostly during 2002). Limited coverage of some more  
29 recent studies is also included as deemed appropriate in light of its special importance. For  
30 example, information derived from the recently released HEI Special Report (Health Effects  
31 Institute, May 2003), discussed above in Section 1.3.1, is being integrated into this assessment.

1 Literature discussed in detail in the 1996 EPA PM AQCD (U.S. Environmental Protection  
2 Agency, 1996a) generally is not discussed in depth in this document; rather key findings from  
3 that 1996 review are summarized as appropriate. Limited treatment is included, however, for  
4 some earlier studies judged to be of particular importance in the review of the PM NAAQS.  
5 Key literature is mainly summarized in tables; and the text mainly attempts to integrate and  
6 discuss overall interpretive points. An attempt is made to present alternative points of view  
7 where scientific controversy exists.

8       Emphasis is placed in the document on studies conducted at or near PM pollutant  
9 concentrations found in ambient air. However, although emphasis has been placed on studies in  
10 the range of current ambient levels, studies examining effects of higher concentrations have been  
11 included if they contain unique data or documentation of a previously unreported effect or  
12 mechanism.

13       The present document, basically organized to assess information related to topics along the  
14 same flow of issues presented in the NRC conceptual framework shown in Figure 1-1, includes  
15 an Executive Summary and nine chapters presented in two volumes. Volume I contains the  
16 Executive Summary, this general introduction (Chapter 1), and Chapters 2 through 5. Chapters 2  
17 and 3 provide background information on physical and chemical properties of PM and related  
18 compounds; sources and emissions; atmospheric transport, transformation, and fate of PM;  
19 methods for the collection and measurement of PM; and U.S. ambient air PM concentrations.  
20 Chapter 4 assesses PM environmental effects on vegetation and ecosystems, visibility, man-  
21 made materials, and climate-related effects (including effects on atmospheric transmission of  
22 solar radiation), and includes limited information on economic impacts of some welfare effects.  
23 Chapter 5 discusses factors affecting exposure of the general population to ambient PM.

24       The second volume contains Chapters 6 through 9. Chapter 6 evaluates information  
25 concerning dosimetry of inhaled particles in the respiratory tract. Chapter 7 assesses the  
26 toxicology of specific types of PM constituents and potential mechanisms of action, based on  
27 both laboratory animal studies and controlled human exposure studies. Chapter 8 discusses  
28 observational, i.e., epidemiologic, studies. Lastly, Chapter 9 integrates key information on  
29 exposure, dosimetry, and critical health risk issues derived from studies reviewed in the prior  
30 chapters, as well as highlighting key points regarding important welfare effects associated with  
31 ambient PM.

## 2. PHYSICS, CHEMISTRY, AND MEASUREMENT OF PARTICULATE MATTER

Chapter 3 of the 1996 EPA document Air Quality Criteria for Particulate Matter (1996 PM AQCD; U.S. Environmental Protection Agency, 1996a) contained an extensive review of the physics and chemistry of airborne particulate matter (PM). Chapter 2 of this revised version of the PM AQCD also provides background information on the physics and chemistry of atmospheric particles, information useful in aiding the understanding of subsequent chapters. Those subsequent chapters are basically organized to follow the sequence of key elements comprising the risk assessment framework described in Chapter 1 (Section 1.2.2), beginning with sources and continuing to effects as shown in Figure 1-1. Thus, this chapter provides new information useful in evaluating PM effects of PM on human health and welfare and in preparing related risk assessments used to support PM standard-setting decisions. Information important for implementation of PM standards, but not essential to the standard setting process, is not the focus in this chapter. The reader is referred to the NARSTO Fine Particle Assessment (NARSTO, 2003) for information relevant to air quality management for PM.

Unlike other criteria pollutants ( $O_3$ , CO,  $SO_2$ ,  $NO_2$ , and Pb), PM is not a specific chemical entity but is a mixture of particles from different sources and of different sizes, compositions, and properties. Emphasis is placed here on discussion of differences between fine and coarse particles and differences between ultrafine particles and accumulation-mode particles within fine particles.

PM is defined quantitatively by the measurement techniques employed. Therefore, it will be useful to discuss our understanding of the relationship between PM suspended in the atmosphere, PM inhaled by people, and PM measured by various sampling and analytical techniques. Chapter 4 of the 1996 PM AQCD (U.S. Environmental Protection Agency, 1996a) contained a review of the state-of-the-art of PM measurement technology. Since that time, considerable progress has been made in understanding problems in the measurement of PM mass, chemical composition, and physical parameters. There also has been progress in developing new and improved measurement techniques, especially for continuous measurements. Therefore, a more extensive survey on measurement problems and on newly

1 developed measurement techniques is included in Section 2.2. For more detail and older  
2 references, the reader is referred to Chapters 3 and 4 of the 1996 PM AQCD (U.S.  
3 Environmental Protection Agency, 1996a).

## 6 **2.1 PHYSICS AND CHEMISTRY OF PARTICULATE MATTER**

### 7 **2.1.1 Basic Concepts**

8 Atmospheric particles originate from a variety of sources and possess a range of  
9 morphological, chemical, physical, and thermodynamic properties. Examples of atmospheric  
10 particles include combustion-generated particles, such as diesel soot or fly ash; photochemically  
11 produced particles, such as those found in urban haze; salt particles formed from sea spray; and  
12 soil-like particles from resuspended dust. Some particles are liquid; some are solid. Others may  
13 contain a solid core surrounded by liquid. Atmospheric particles contain inorganic ions, metallic  
14 compounds, elemental carbon, organic compounds, and crustal compounds. Some atmospheric  
15 particles are hygroscopic and contain particle-bound water. The organic fraction is especially  
16 complex, containing hundreds (probably thousands) of organic compounds. (See Appendix 3C  
17 for information on the composition of the organic fraction and the concentration of specific  
18 organic compounds.) Primary particles are emitted directly from sources; whereas secondary  
19 particles are formed from gases through chemical reactions in the atmosphere involving  
20 atmospheric oxygen ( $O_2$ ) and water vapor ( $H_2O$ ); reactive species such as ozone ( $O_3$ ); radicals  
21 such as the hydroxyl ( $\bullet OH$ ) and nitrate ( $\bullet NO_3$ ) radicals; and pollutants such as sulfur dioxide  
22 ( $SO_2$ ), nitrogen oxides ( $NO_x$ ), and organic gases from natural and anthropogenic sources. The  
23 particle formation process includes nucleation of particles from low-vapor pressure gases  
24 emitted from sources or formed in the atmosphere by chemical reactions, condensation of  
25 low-vapor pressure gases on existing particles, and coagulation of particles. Thus, any given  
26 particle may contain PM from many sources. Because a particle from a given source is likely to  
27 be composed of a mixture of chemical components and particles from different sources may  
28 coagulate to form a new particle, atmospheric particles may be considered a mixture of mixtures.

29 The composition and behavior of particles are fundamentally linked with those of the  
30 surrounding gas. An aerosol may be defined as a suspension of solid or liquid particles in air.  
31 The term aerosol includes both the particles and all vapor or gas phase components of air.

1 However, the term aerosol is sometimes used to refer to the suspended particles only. In this  
2 document, “particulate” is used only as an adjective, as in particulate matter.

3 A complete description of the atmospheric aerosol would include an accounting of the  
4 chemical composition, morphology, and size of each particle and the relative abundance of each  
5 particle type as a function of particle size (Friedlander, 1970). However, the physical and  
6 chemical characteristics of particles are usually measured separately. Size distributions by  
7 particle number, used to calculate surface area and volume distributions, often are determined by  
8 physical means, such as electrical mobility, aerodynamic behavior, or light scattering. Chemical  
9 composition usually is determined by analysis of collected samples although some species can  
10 be measured in situ. The mass and average chemical composition of particles, segregated  
11 according to aerodynamic diameter by cyclones or impactors, can also be determined. However,  
12 recent developments in single particle analysis techniques by electron microscopy with X-ray  
13 analysis of single particles (but not agglomerates) collected on a substrate or by mass  
14 spectroscopy of individual suspended particles provide elemental composition of individual  
15 particles by particle size and, thus, are bringing the description envisioned by Friedlander closer  
16 to reality.

## 17 18 **2.1.2 Physical Properties and Processes**

### 19 **2.1.2.1 Definitions of Particle Diameter**

20 The diameter of a spherical particle may be determined by optical or electron microscopy,  
21 by light scattering and Mie theory, by its electrical mobility, or by its aerodynamic behavior.  
22 However, atmospheric particles often are not spherical. Therefore, their diameters are described  
23 by an “equivalent” diameter (i.e., the diameter of a sphere that would have the same physical  
24 behavior). An optical diameter is the diameter of a spherical particle, with the same refractive  
25 index as the particle used to calibrate the optical particle sizer, that scatters the same amount of  
26 light into the solid angle measured. Diffusion and gravitational settling are important physical  
27 behaviors for particle transport, collection, and removal processes, including deposition in the  
28 respiratory tract. Different equivalent diameters are used depending on which process is more  
29 important. For smaller particles diffusion is more important and the Stokes diameter is often  
30 used. For larger particles gravitational setting is more important and the aerodynamic diameter  
31 is often used.

1 The Stokes diameter,  $D_p$ , describes particle size based on the aerodynamic drag force  
2 imparted on a particle when its velocity differs from that of the surrounding fluid. For a smooth,  
3 spherically shaped particle,  $D_p$  exactly equals the physical diameter of the particle. For  
4 irregularly shaped particles,  $D_p$  is the diameter of an equivalent sphere that would have the same  
5 aerodynamic resistance. Electrical mobility analyzers classify particles according to their  
6 electrical mobility. Particles of equal Stokes diameters that carry the same electric charge will  
7 have the same electrical mobility. Hence, for spherical particles, the electrical mobility diameter  
8 would equal the Stokes diameter. The mobility diameter can be considered the diameter of a  
9 spherical particle that would have the same electrical mobility. The particle mobility can be  
10 related to the particle diffusion coefficient and Brownian diffusion velocity through the Stokes-  
11 Einstein equation. Thus, the Stokes diameter is the appropriate parameter for particle behavior  
12 governed by diffusion. The Stokes diameter,  $D_p$ , is used in size distributions based on light  
13 scattering and mobility analysis. The Stokes diameter is independent of density.

14 The aerodynamic diameter,  $D_a$ , however, depends on particle density. It is defined as the  
15 diameter of a spherical particle with an equal gravitational settling velocity but a material density  
16 of  $1 \text{ g/cm}^3$ . Cascade impactors separate particles based on their aerodynamic diameter and  
17 aerodynamic particle sizers measure the aerodynamic diameter. Respirable, thoracic, and  
18 inhalable sampling and  $\text{PM}_{2.5}$  and  $\text{PM}_{10}$  sampling are based on particle aerodynamic diameter.  
19 For particles greater than about  $0.5 \text{ }\mu\text{m}$ , the aerodynamic diameter is generally the quantity of  
20 interest. For smaller particles, the Stokes diameter may be more useful. Particles with the same  
21 physical size and shape but different densities will have the same Stokes diameter but different  
22 aerodynamic diameters.

23 Aerodynamic diameter,  $D_a$ , is related to the Stokes diameter,  $D_p$ , by:  
24

$$D_a = \left( \frac{\rho C_p}{C_a} \right)^{1/2} D_p \quad (2-1)$$

25  
26 where  $\rho$  is the particle density, and  $C_p$  and  $C_a$  are the Cunningham slip factors evaluated for the  
27 particle diameters  $D_p$  and  $D_a$  respectively. The slip factor is a function of the ratio between  
28 particle diameter and mean free path of the suspending gas ( $0.066 \text{ }\mu\text{m}$  for air at one atmosphere

1 pressure and 20 °C). C is an empirical factor that accounts for the reduction in the drag force on  
2 particles due to the “slip” of the gas molecules at the particle surface. It is important for  
3 particles less than 1 μm in diameter, for which the surrounding air cannot be modeled by a  
4 continuous fluid. For large particles ( $D_p > 5 \mu\text{m}$ )  $C = 1$ ; while for smaller particles  $C > 1$ .

5 For particles with diameters greater than the mean free path,  $\lambda$ , the aerodynamic diameter  
6 given by equation (2-1) is approximated by:  
7

$$D_a = (\rho)^{1/2} D_p \quad (D_p \gg \lambda) \quad (2-2)$$

8  
9 This expression, which shows that aerodynamic diameter is directly proportional to the square  
10 root of the particle density, is often used for particles as small as 0.5 μm. For particles with  
11 diameters much smaller than the mean free path, the slip factor must be taken into account.  
12 In this case the aerodynamic diameter is directly proportional to the particle density,  
13

$$D_a = (\rho) D_p \quad (D_p \ll \lambda) \quad (2-3)$$

14  
15 Detailed definitions of the various sizes and their relationships are given in standard aerosol  
16 textbooks (e.g., Friedlander [2000], Reist [1984, 1993], Seinfeld and Pandis [1998], Hinds  
17 [1999], Vincent [1989, 1995], Willeke and Baron [1993], Baron and Willeke [2002], and Fuchs  
18 [1964, 1989]).

#### 20 **2.1.2.2 Aerosol Size Distributions**

21 Particle size as indexed by one of the “equivalent” diameters is an important parameter in  
22 determining the properties, effects, and fate of atmospheric particles. The atmospheric  
23 deposition rates of particles and therefore their residence times in the atmosphere are a strong  
24 function of their Stokes and aerodynamic diameters. The diameter also influences deposition  
25 patterns of particles within the lung. Because light scattering is strongly dependent on the  
26 optical particle size, the amount of light scattering per unit PM mass will be dependent on the  
27 size distribution of atmospheric particles. Therefore, the effects of atmospheric particles on

1 visibility, radiative balance, and climate will be influenced by the size distribution of the  
2 particles. Studies using cascade impactors or cyclones measure the particle-size distribution  
3 directly in aerodynamic diameter. The diameters of atmospheric particles range from 1 nm to  
4 100  $\mu\text{m}$ , spanning 5 orders of magnitude. A variety of different instruments, measuring a variety  
5 of equivalent diameters, are required to cover this range.

6 Older particle counting studies used optical particle counters to cover the range of 0.3 to  
7 30  $\mu\text{m}$  diameter. Diameters of particles below 0.5  $\mu\text{m}$  were measured as mobility diameters.  
8 The particle diameters used in size distribution graphs from these studies usually are given as  
9 physical or Stokes diameters rather than aerodynamic diameters. In recent years, aerodynamic  
10 particle sizers have been developed that give a direct measurement of the aerodynamic diameter  
11 in the range of approximately 0.7 to 10  $\mu\text{m}$  diameter. These instruments have been used with  
12 electrical mobility analyzers that measure the mobility diameter of particles from 3 nm to  
13 approximately 0.5  $\mu\text{m}$  (McMurry, 2000). Unfortunately, there is no agreed-upon technique for  
14 combining the various equivalent diameters. Some workers use various assumptions to combine  
15 the various measurements into one presentation; others report each instrument separately.  
16 Therefore, the user of size distribution data should be careful to determine exactly which  
17 equivalent diameter is reported.

### 18 19 ***Particle Size Distribution Functions***

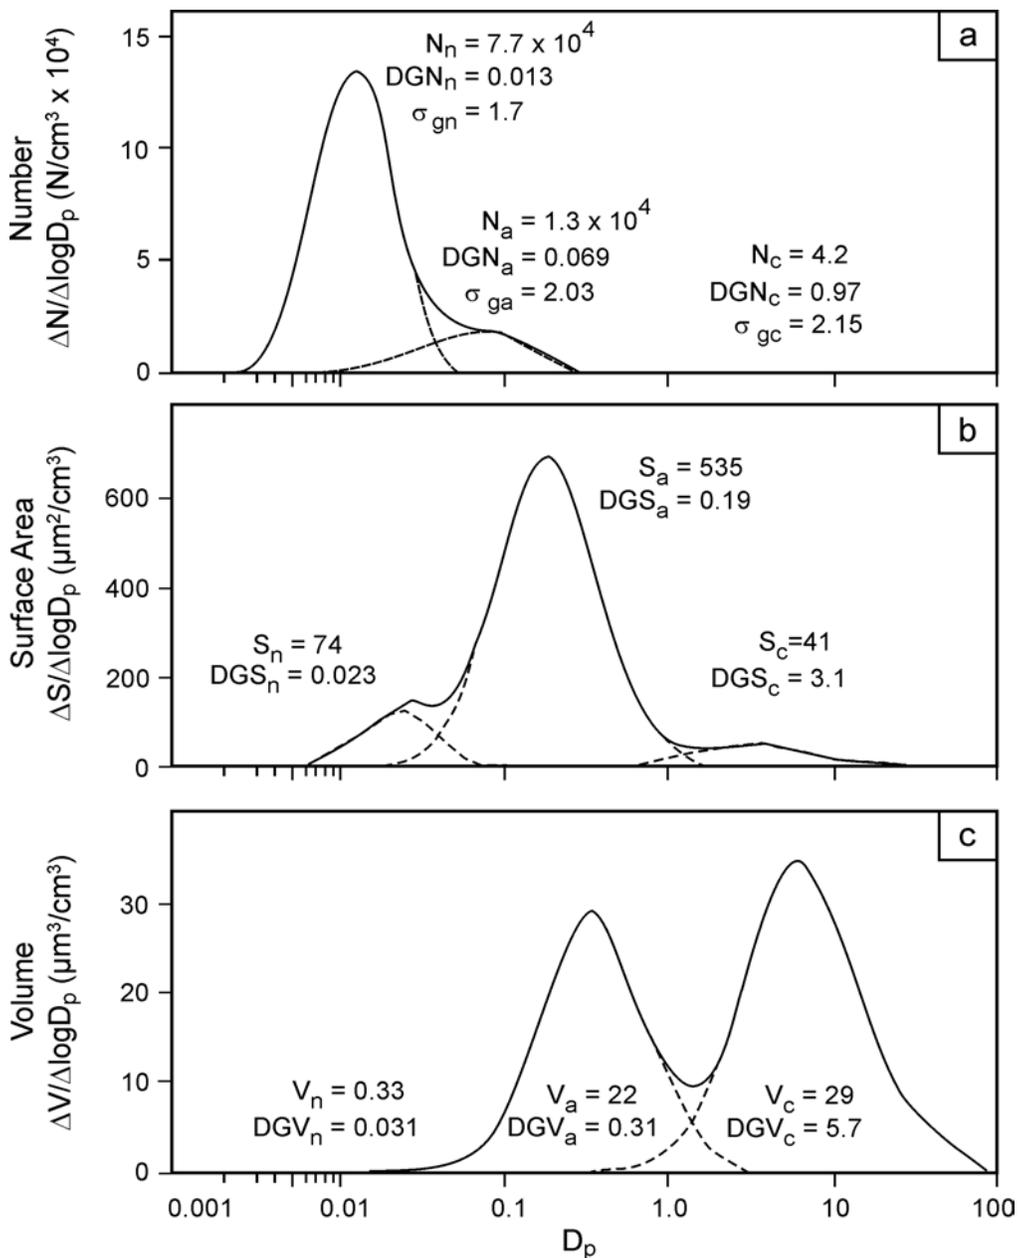

20 The distribution of particles with respect to size is an important physical parameter  
21 governing their behavior. Because atmospheric particles cover several orders of magnitude in  
22 particle size, size distributions often are expressed in terms of the logarithm of the particle  
23 diameter on the X-axis and the measured differential concentration on the Y-axis:  $\Delta N/\Delta(\log D_p)$   
24 = the number of particles per  $\text{cm}^3$  of air having diameters in the size range from  $\log D_p$  to  $\log(D_p$   
25  $+ \Delta D_p)$ . Because logarithms do not have dimensions, it is necessary to think of the distribution  
26 as a function of  $\log(D_p/D_{p0})$ , where the reference diameter  $D_{p0} = 1 \mu\text{m}$  is not explicitly stated. If  
27  $\Delta N/\Delta(\log D_p)$  is plotted on a linear scale, the number of particles between  $D_p$  and  $D_p + \Delta D_p$  is  
28 proportional to the area under the curve of  $\Delta N/\Delta(\log D_p)$  versus  $\log D_p$ . Similar considerations  
29 apply to distributions of surface, volume, and mass. When approximated by a function, the  
30 distributions are usually given as  $dN/d(\log D_p)$  rather than  $\Delta N/\Delta(\log D_p)$ .

## *Atmospheric Aerosol Size Distributions*

In 1978, Whitby (1978) published an analysis of over 1000 particle size distributions measured at various locations in the U.S. Figure 2-1 shows the number, surface area, and volume distributions for the grand average continental size distribution. Volume, surface area, and number distributions are plotted on an arithmetic scale such that the volume, surface area, or number of particles in any specified size range is proportional to the corresponding area under the curve. These distributions show that most of the particles are quite small, below 0.1  $\mu\text{m}$ ; whereas most of the particle volume (and therefore most of the mass) is found in particles  $> 0.1 \mu\text{m}$ . Other averaged atmospheric size distributions are shown in Figure 2-2 and 2-3 (Whitby, 1978; Whitby and Sverdrup, 1980). Figure 2-2a and b describe the number of particles as a function of particle diameter for rural, urban-influenced rural, urban, and freeway-influenced urban aerosols. For some of the same data, the particle volume distributions are shown in Figure 2-3a and b. Whitby (1978) observed that the size distributions typically had three peaks which he called “modes.” The entire size distribution could be characterized well by a trimodal model consisting of three additive log-normal distributions. The mode with a peak between 5 and 30  $\mu\text{m}$  diameter, formed by mechanical processes, was named the coarse particle mode; the mode with a peak between 0.15 and 0.5  $\mu\text{m}$ , formed by condensation and coagulation, was called the accumulation mode; and the mode with a peak between 0.015 and 0.04  $\mu\text{m}$ , whose size was influenced by nucleation as well as by condensation and coagulation, was called the transient nuclei or Aiken nuclei range, subsequently shortened to the nuclei mode. The nuclei mode could be seen in the number and surface distribution but only in special situations was it noticeable in the mass or volume distributions. The accumulation and nuclei modes taken together were called fine particles. An idealized size distribution showing modes and formation mechanisms is shown in Figure 2-4.

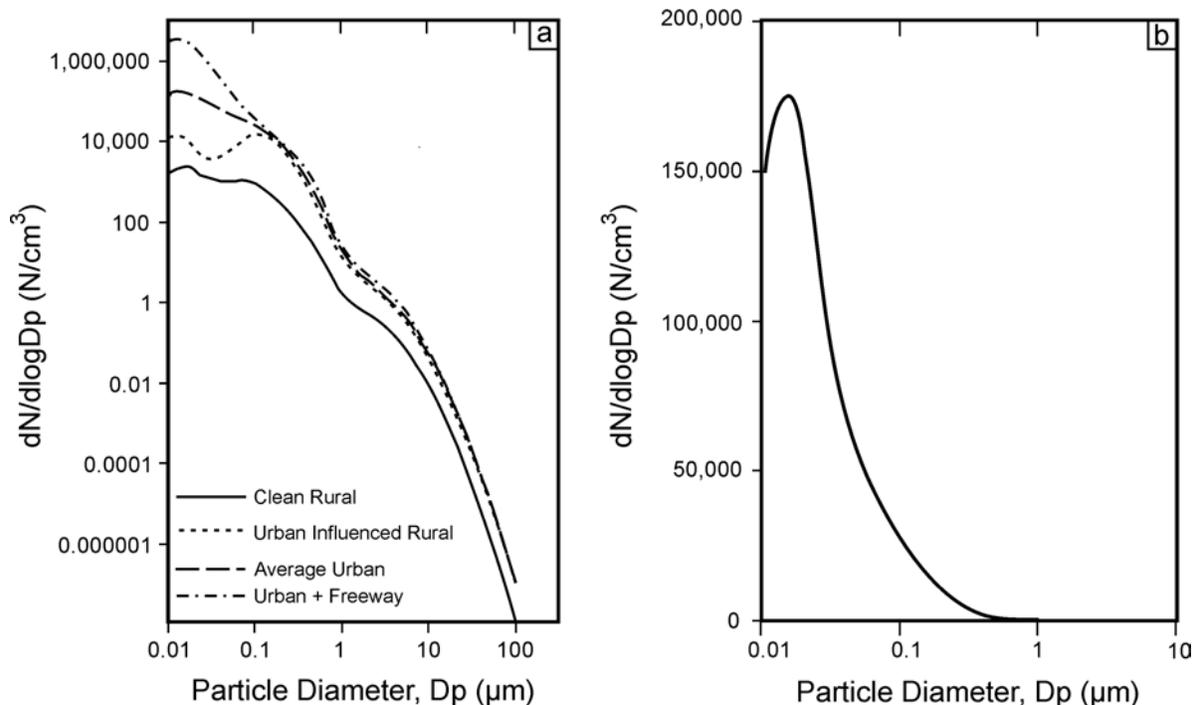

Whitby (1978) concluded

The distinction between “fine particles” and “coarse particles” is a fundamental one. There is now an overwhelming amount of evidence that not only are two modes in the mass or volume distribution usually observed, but that these fine and coarse modes are usually chemically quite different. The physical separation of the fine and coarse modes originates because condensation produces fine particles while mechanical processes produce mostly coarse particles . . . the dynamics of fine particle growth ordinarily operate to prevent the fine

**Figure 2-1. Distribution of coarse (c), accumulation (a), and nuclei (n) mode particles by three characteristics, a) number (N), b) surface area (S) and c) volume (V) for the grand average continental size distribution. DGV = geometric mean diameter by volume; DGS = geometric mean diameter by surface area; DGN = geometric mean diameter by number;  $D_p$  = particle diameter.**

1 particles from growing larger than about 1 μm. Thus, the fine and coarse modes originate  
 2 separately, are transformed separately, are removed separately, and are usually chemically  
 3 different . . . practically all of the sulfur found in atmospheric aerosol is found in the fine  
 4 particle fraction. Thus, the distinction between fine and coarse fractions is of fundamental  
 5 importance to any discussion of aerosol physics, chemistry, measurement, or aerosol air quality  
 6 standards.

7

8 Whitby's (1978) conclusions were based on extensive studies of size distributions in a  
 9 number of western and midwestern locations during the 1970s (Whitby et al., 1974; Willeke  
 10 and Whitby, 1975; Whitby, 1978; Wilson et al., 1977; Whitby and Sverdrup, 1980).

11 No size-distribution studies of similar scope have been published since then. Newer results

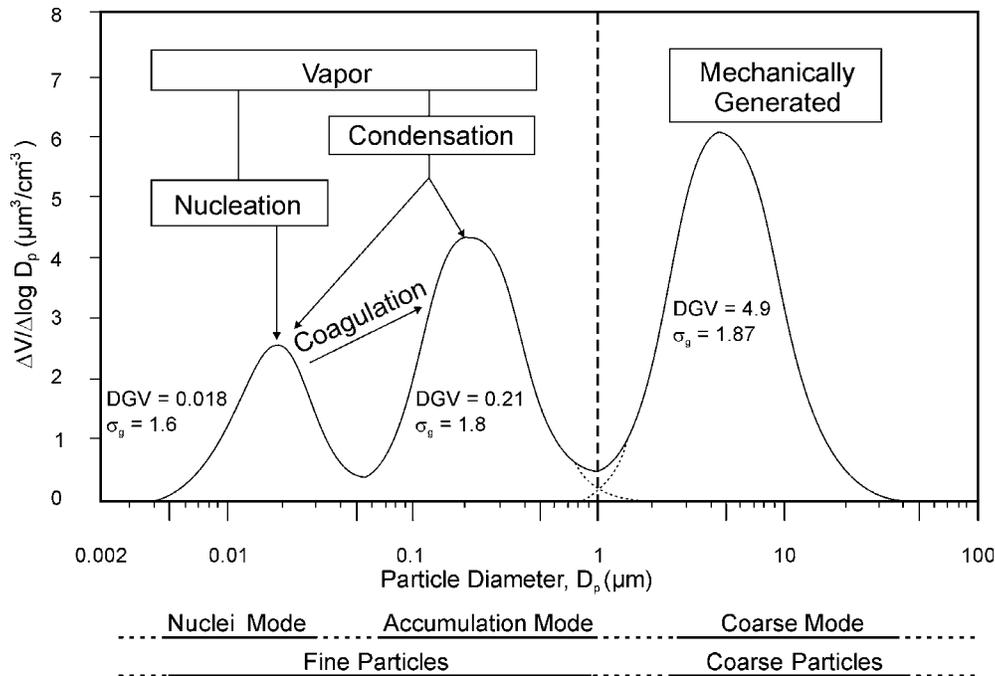

**Figure 2-3. Size distribution by volume (a) for the averaged rural and urban-influenced rural number distributions shown in Figure 2-2a and a distribution from south central New Mexico, and (b) for the averaged urban and freeway-influenced urban number distributions shown in Figure 2-2a.**

Source: Whitby and Sverdrup (1980); Kim et al. (1993) south central New Mexico.

1 from particle counting and impactor techniques, including data from Europe (U.S.  
 2 Environmental Protection Agency, 1996a) and Australia (Keywood et al., 1999, 2000), show  
 3 similar results for the accumulation and coarse modes. Extensive measurements of particle size  
 4 distributions, as part of EPA's Supersites program, are providing much new data for analysis.

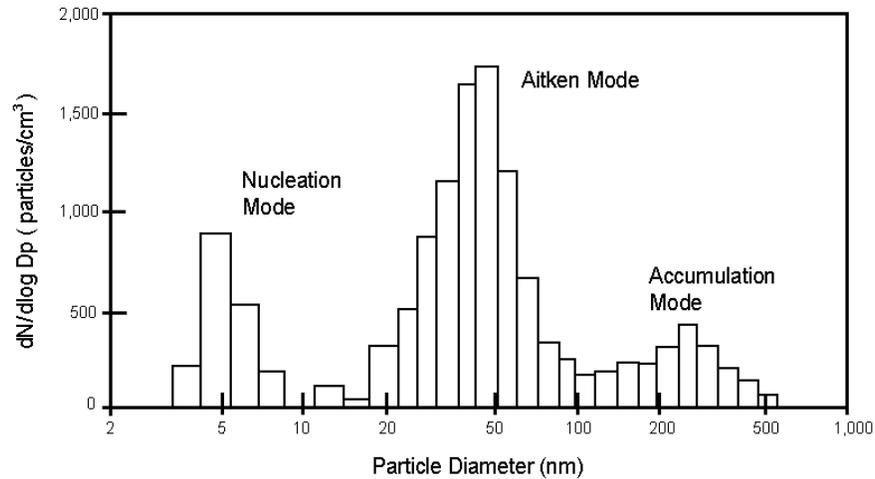

5 Whitby's (1978) conclusions have held up remarkably well. However, ideas about the  
 6 sub-0.1  $\mu\text{m}$  diameter range have changed somewhat as newer instruments provided  
 7 measurements extending to smaller sizes and with greater resolution in size and time (McMurry  
 8 et al., 2000). Depending on the source, temperature, saturated vapor pressure of the components,  
 9 and the age of the aerosol, size distributions have been observed with peaks (including multiple  
 10 peaks) throughout the sub-0.1  $\mu\text{m}$  diameter size range. Sub-0.1  $\mu\text{m}$  diameter peaks have been

**Figure 2-4. Volume size distribution, measured in traffic, showing fine and coarse particles and the nuclei and accumulation modes of fine particles. DGV (geometric mean diameter by volume, equivalent to volume median diameter) and  $\sigma_g$  (geometric standard deviation) are shown for each mode. Also shown are transformation and growth mechanisms (e.g., nucleation, condensation, and coagulation).**

Source: Adapted from Wilson and Suh (1997).

1 observed in rural areas (O'Dowd, 2002) as well as for brief periods (nucleation bursts) in urban  
 2 areas (Woo et al., 2001a). Based on these and other observations, discussed in detail in  
 3 Section 2.1.2.3, aerosol scientists now classify particles in the sub-0.1  $\mu\text{m}$  size range as ultrafine  
 4 particles and divide this size range into a nucleation region ( $< 10$  nm) and an Aitkin (nuclei)  
 5 region (10-100 nm), as shown in Figure 2-5. Other studies, discussed in detail in the 1996 PM  
 6 AQCD (U.S. Environmental Protection Agency, 1996a), have shown that in fog or clouds or at  
 7 very high relative humidities the accumulation mode may split into a larger size (more  
 8 hygroscopic or droplet) submode and a smaller size (less hygroscopic or condensation) submode.  
 9

1 ***Definitions of Particle Size Fractions***

2 In the preceding discussion several subdivisions of the aerosol size distribution were  
 3 identified. Aerosol scientists use three different approaches or conventions in the classification  
 4 of particles by size: (1) modes, based on the observed size distributions and formation  
 5 mechanisms; (2) cut point, usually based on the 50% cut point of the specific sampling device,  
 6 including legally specified, regulatory sizes for air quality standards; and (3) dosimetry or  
 7 occupational health sizes, based on the entrance into various compartments of the respiratory  
 8 system.

9  
 10 **Modal.** The modal classification as first proposed by Whitby (1978) is shown in  
 11 Figures 2-1 and 2-4. New modes introduced since 1978 are shown in Figure 2-5. The  
 12 nucleation and Aitkin modes are best observed in the number distribution. However, the Aitkin  
 13 mode can be seen in the volume distribution in traffic or near traffic or other sources of ultrafine  
 14 particles (Figures 2-3b and 2-4). The observed modal structure is frequently approximated by

1 several log-normal distributions. Definitions of terms used to describe size distributions in  
2 modal terms are given below.

3  
4 *Nucleation Mode:* Freshly formed particles with diameters below 10 nm, observed during  
5 active nucleation events. The lower limit, where particles and large molecules overlap, is  
6 uncertain. Current techniques limit measurements to particles 3 nm or greater.

7  
8 *Aitkin Mode:* Larger particles with diameters between 10 and 100 nm. The Aitken mode  
9 may result from growth of smaller particles or nucleation from higher concentrations of  
10 precursors. Nucleation and Aitkin nuclei modes are normally observed in the number  
11 distribution.

12  
13 *Accumulation Mode:* Particles with diameters from about 0.1  $\mu\text{m}$  to just above the  
14 minimum in the mass or volume distributions which usually occurs between 1 and 3  $\mu\text{m}$ .  
15 Accumulation-mode particles normally do not grow into the coarse mode. Nucleation-  
16 mode and Aitkin-mode particles grow by coagulation (two particles combining to form  
17 one) or by condensation (low-equilibrium vapor pressure gas molecules condensing on a  
18 particle) and “accumulate” in this size range.

19  
20 *Coarse Mode or Coarse Particles:* Particles with diameters mostly greater than the  
21 minimum in the particle mass or volume distributions, which generally occurs between  
22 1 and 3  $\mu\text{m}$ . These particles are usually formed by mechanical breakup of larger particles  
23 or bulk material.

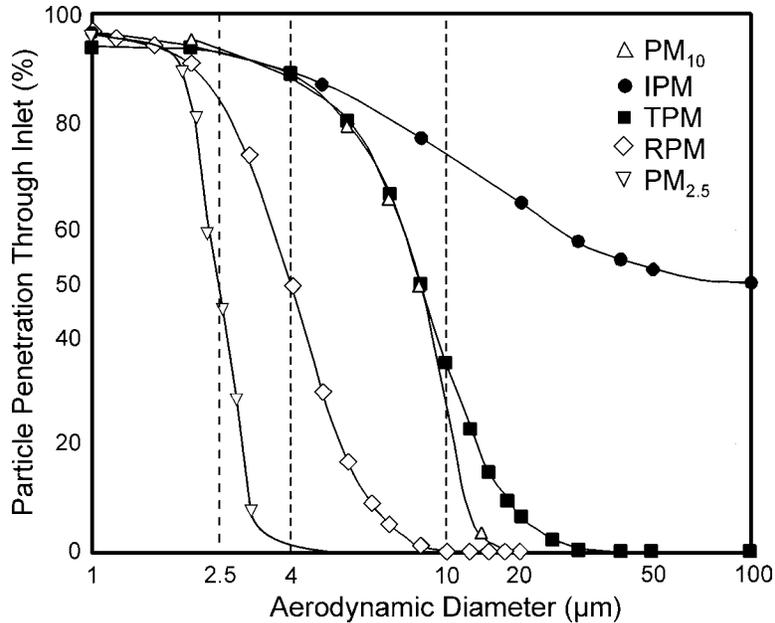

24  
25 *Fine Particles:* Fine particles include the nucleation, Aitkin, and accumulation modes, i.e.,  
26 particles from the lowest measurable size, currently about 3 nm, to just above the minimum  
27 in the mass or volume distribution which generally occurs between 1 and 3  $\mu\text{m}$ . These  
28 particles are generated during combustion or formed from gases.

29  
30 *Ultrafine Particles:* That portion of fine particles with diameters below about 0.1  $\mu\text{m}$   
31 (100 nm), i.e., the Aitkin and nucleation modes.

1 Modes are defined primarily in terms of their formation mechanisms but also differ in  
2 terms of sources, composition, age, and size. Nucleation mode applies to newly formed particles  
3 which have had little chance to grow by condensation or coagulation. Aitkin mode particles are  
4 also recently formed particles that are still actively undergoing coagulation. However, because  
5 of higher concentrations of precursors or more time for condensation and coagulation, the  
6 particles have grown to larger sizes. Accumulation mode applies to the final stage as particles,  
7 originally formed as nuclei, grow to a point where growth slows down. These three modes,  
8 which together are called fine particles, are formed primarily by combustion or chemical  
9 reactions of gases yielding products with low saturated vapor pressures. Fine particles include  
10 metals and elemental and organic carbon (primary PM) and sulfate, nitrate, ammonium ions, and  
11 organic compounds (secondary PM).

12 The coarse mode refers to particles formed by mechanical breakdown of minerals, crustal  
13 material, and organic debris. The composition includes primary minerals and organic material.  
14 The accumulation mode and the coarse mode overlap in the region between 1 and 3  $\mu\text{m}$  (and  
15 occasionally over an even larger range). In this region, chemical composition of individual  
16 particles can usually, but not always, allow identification of a source or formation mechanism  
17 and so permit identification of a particle as belonging to the accumulation or coarse mode.

18  
19 ***Sampler Cut Point.*** Another set of definitions of particle size fractions arises from  
20 considerations of size-selective sampling. Size-selective sampling refers to the collection of  
21 particles below or within a specified aerodynamic size range. Size fractions are usually specified  
22 by the 50% cut point size; e.g.,  $\text{PM}_{2.5}$  refers to particles collected by a sampling device that  
23 collects 50% of 2.5  $\mu\text{m}$  particles and rejects 50% of 2.5  $\mu\text{m}$  particles. However, size fractions  
24 are defined, not merely by the 50% cut point, but by the entire penetration curve. Examples of  
25 penetration curves are given in Figure 2-6. Thus, as shown by Figure 2-6, a  $\text{PM}_{2.5}$  sampler, as  
26 defined by the Federal Reference Method, rejects 94% of 3  $\mu\text{m}$  particles, 50% of 2.5  $\mu\text{m}$   
27 particles, and 16% of 2  $\mu\text{m}$ . Samplers with the same 50% cut point but differently shaped  
28 penetration curves would collect different fractions of PM. Size-selective sampling has arisen in  
29 an effort to measure particle size fractions with some special significance (e.g., health, visibility,  
30 source apportionment, etc.), to measure mass size distributions, or to collect size-segregated  
31 particles for chemical analysis. Dichotomous samplers split the particles into smaller and larger

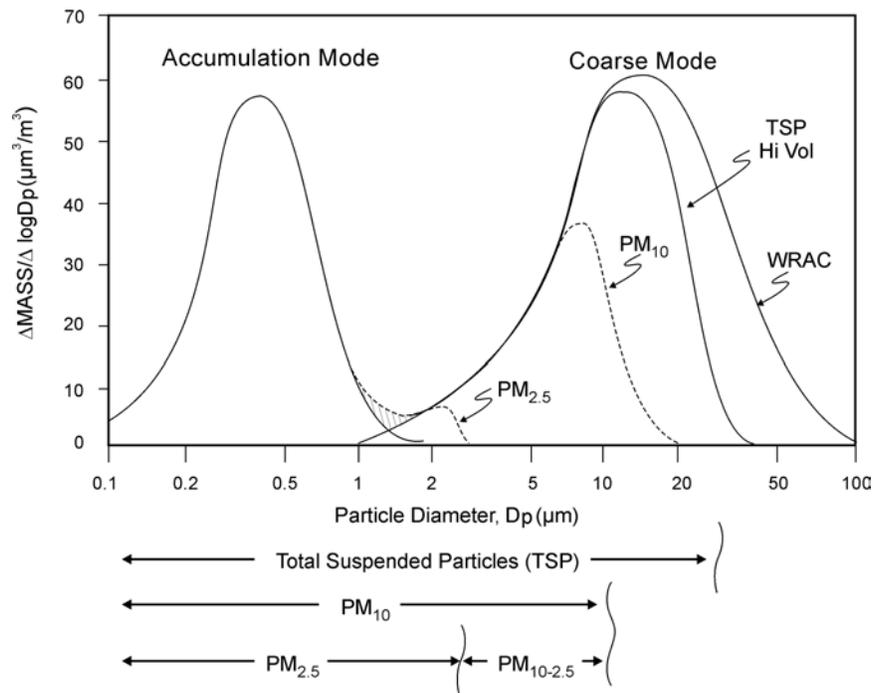

**Figure 2-6. Specified particle penetration (size-cut curves) through an ideal (no-particle-loss) inlet for five different size-selective sampling criteria. Regulatory size cuts are defined in the Code of Federal Regulations; PM<sub>2.5</sub> (2001c), PM<sub>10</sub> (2001a). PM<sub>2.5</sub> is also defined in the Federal Register (1997). Size-cut curves for inhalable particulate matter (IPM), thoracic particulate matter (TPM) and respirable particulate matter (RPM) size cuts are computed from definitions given by American Conference of Governmental and Industrial Hygienists (1994).**

1 fractions that may be collected on separate filters. However, some fine particles ( $\approx 10\%$ ) are  
 2 collected with the coarse particle fraction. Cascade impactors use multiple size cuts to obtain a  
 3 distribution of size cuts for mass or chemical composition measurements. One-filter samplers  
 4 with a variety of upper size cuts are also used, e.g., PM<sub>2.5</sub>, PM<sub>10</sub>.

5 Regulatory size cuts are a specific example of size-selective sampling. In 1987, the  
 6 NAAQS for PM were revised to use PM<sub>10</sub>, rather than total suspended particulate matter (TSP),  
 7 as the indicator for the NAAQS for PM (Federal Register, 1987). The use of PM<sub>10</sub> as an  
 8 indicator is an example of size-selective sampling based on a regulatory size cut (Federal  
 9 Register, 1987). The selection of PM<sub>10</sub> as an indicator was based on health considerations and  
 10 was intended to focus regulatory concern on those particles small enough to enter the thoracic  
 11 region of the human respiratory tract. The PM<sub>2.5</sub> standard set in 1997 is also an example of

1 size-selective sampling based on a regulatory size cut (Federal Register, 1997). The  $PM_{2.5}$   
 2 standard was based primarily on epidemiologic studies using concentrations measured with  
 3  $PM_{2.5}$  samplers as an exposure index. However, the  $PM_{2.5}$  sampler was not designed to collect all  
 4 respirable particles; it was designed to collect fine particles because of their different sources and  
 5 properties (Whitby et al., 1974). Thus, the need to attain a  $PM_{2.5}$  standard will tend to focus  
 6 regulatory concern on control of sources of fine particles.

7 Prior to 1987, the indicator for the NAAQS for PM was TSP. TSP is defined by the design  
 8 of the High Volume Sampler (hivol) that collects all of the fine particles but only part of the  
 9 coarse particles (Figure 2-7). The upper cut-off size of the hivol depends on the wind speed and  
 10 direction and may vary from 25 to 40  $\mu m$ . The Wide Range Aerosol Classifier (WRAC) was  
 11 designed specifically to collect the entire coarse mode using an impaction system designed by  
 12 Lundgren to collect particles up to 100  $\mu m$  in diameter (Lundgren and Burton, 1995).  
 13

**Figure 2-7. An idealized distribution of ambient particulate matter showing fine-mode particles and coarse-mode particles and the fractions collected by size-selective samplers. (WRAC is the Wide Range Aerosol Classifier which collects the entire coarse mode [Lundgren and Burton, 1995].)**

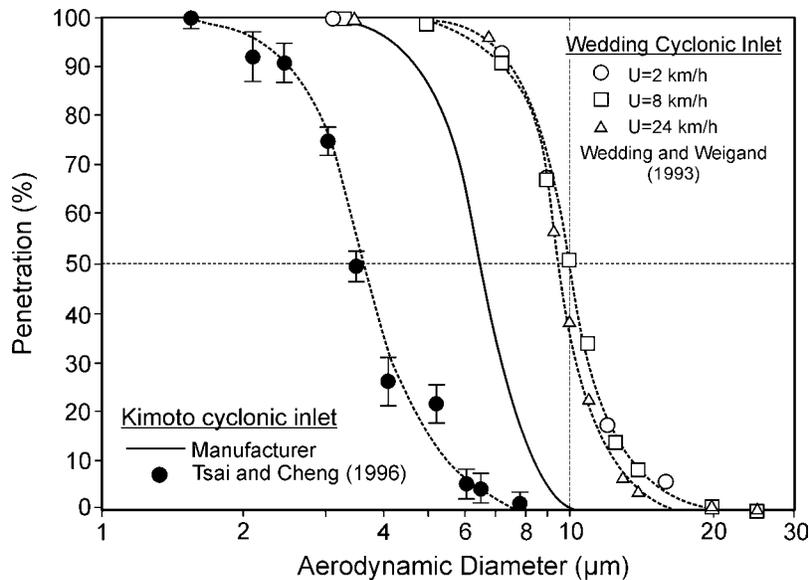

Source: Adapted from Wilson and Suh (1997) and Whitby (1978).

1 An idealized distribution with the normally observed division of ambient aerosols into  
2 fine-mode particles and coarse-mode particles and the size fractions collected by the WRAC,  
3 TSP, PM<sub>10</sub>, PM<sub>2.5</sub> and PM<sub>10-2.5</sub> samplers is shown in Figure 2-7. PM<sub>10</sub> samplers, as defined in  
4 Appendix J to Title 40 Code of Federal Regulations (40 CFR) Part 50 (Code of Federal  
5 Regulations, 2001a; Federal Register, 1987), collect all of the fine-mode particles and part of the  
6 coarse-mode particles. The upper cut point is defined as having a 50% collection efficiency at  
7 10 ± 0.5 μm aerodynamic diameter. The slope of the collection efficiency curve is defined in  
8 amendments to 40 CFR, Part 53, (Code of Federal Regulations, 2001b). An example of a PM<sub>10</sub>  
9 size-cut curve is shown in Figure 2-6.

10 An example of a PM<sub>2.5</sub> size-cut curve is also shown in Figure 2-6. The PM<sub>2.5</sub> size-cut  
11 curve, however, is defined by the design of the Federal Reference Method (FRM) Sampler. The  
12 basic design of the FRM sampler is given in the Federal Register (1997, 1998) and as 40 CFR  
13 Part 50, Appendix L (Code of Federal Regulations, 2001c). Additional performance  
14 specifications are given in 40 CFR Parts 53 and 58 (Code of Federal Regulations, 2001b,d).  
15 In order to be used for measurement of PM<sub>2.5</sub> to determine compliance with the PM<sub>2.5</sub> NAAQS,  
16 each specific sampler design and its associated manual of operational procedures must be  
17 designated as a reference method under 40 CFR Part 53 in Section 1.2 of Appendix L (Code of  
18 Federal Regulations, 2001c). Thus PM<sub>2.5</sub> FRM samplers may have somewhat different designs  
19 (see Table 2-4 in Section 2.2.4.1.2).

20 Papers discussing PM<sub>10</sub> or PM<sub>2.5</sub> frequently insert an explanation such as “PM<sub>x</sub> (particles  
21 less than x μm diameter)” or “PM<sub>x</sub> (nominally, particles with aerodynamic diameter ≤ x μm).”  
22 While these explanations may seem easier than “PM<sub>x</sub>, (particles collected with an upper 50% cut  
23 point of x μm aerodynamic diameter and a specified penetration curve),” they are not entirely  
24 correct and may be misleading since they suggest an upper 100% cut point of x μm. Some  
25 countries use PM<sub>10</sub> to refer not to samplers with a 50% cut at 10 μm D<sub>a</sub> but to samplers with  
26 100% rejection of all particles greater than 10 μm D<sub>a</sub>. Such samplers miss a fraction of coarse  
27 thoracic PM. An example is shown in Figure 2-8.

28 PM<sub>10</sub>, as defined by EPA, refers to particles collected by a sampler with an upper 50% cut  
29 point of 10 μm D<sub>a</sub> and a specific, fairly sharp, penetration curve. PM<sub>2.5</sub> is analogously defined.  
30 Although there is not yet an FRM, PM<sub>10-2.5</sub> refers either to particles collected by a sampler with  
31 an upper 50% cut point of 10 μm D<sub>a</sub> and a lower 50% cut point of 2.5 μm D<sub>a</sub> or to the difference

**Figure 2-8. Comparison of penetration curves for two  $PM_{10}$  beta gauge samplers using cyclone inlets. The Wedding  $PM_{10}$  sampler uses the U.S. EPA definition of  $PM_x$  as  $x = 50\%$  cut point. The Kimoto  $PM_{10}$  defines  $PM_x$  as  $x =$  the 100% cut point (or zero penetration).**

Source: Tsai and Cheng (1996).

1 between the particle concentration measured by a  $PM_{10}$  monitor and a  $PM_{2.5}$  monitor. In all  
 2 cases, the fraction of PM collected depends on the entire penetration curve (or curves); i.e., for  
 3  $PM_{2.5}$  some particles  $> 2.5 \mu m D_a$  are collected and not all particles  $< 2.5 \mu m D_a$  are collected.

4 In an analysis reported in 1979, EPA scientists endorsed the need to measure fine and  
 5 coarse particles separately (Miller et al., 1979). Based on the availability of a dichotomous  
 6 sampler with a separation size of  $2.5 \mu m D_a$ , they recommended  $2.5 \mu m D_a$  as the cut point  
 7 between fine and coarse particles. Because of the wide use of this cut point, the  $PM_{2.5}$  fraction is  
 8 frequently referred to as “fine” particles. However, although the  $PM_{2.5}$  sample will usually  
 9 contain all of the fine particles, it may collect a small fraction of the coarse particles, especially  
 10 in dry areas or during dry conditions. A  $PM_{10-2.5}$  size fraction may be obtained from a  
 11 dichotomous sampler or by subtracting the mass collected by a  $PM_{2.5}$  sampler from the mass  
 12 collected by a  $PM_{10}$  sampler. The resulting  $PM_{10-2.5}$  mass, or  $PM_{10-2.5}$ , is sometimes called  
 13 “coarse” particles. However, it would be more correct to call  $PM_{2.5}$  an indicator of fine particles

1 (because it contains some coarse particles) and  $PM_{10-2.5}$  an indicator of the thoracic component of  
2 coarse particles (because it excludes some coarse particles below  $2.5 \mu m D_a$  and above  $10 \mu m$   
3  $D_a$ ). It would be appropriate to call  $PM_{10}$  an indicator of thoracic particles.  $PM_{10}$  and thoracic  
4 PM, as shown in Figure 2-6, have the same 50% cut point. However, the thoracic cut is not as  
5 sharp as the  $PM_{10}$  cut; therefore, thoracic PM contains some particles between 10 and  $30 \mu m$   
6 diameter that are excluded from  $PM_{10}$ .

7 Over the years, the terms fine and coarse, as applied to particles, have lost the precise  
8 meaning given in Whitby's (1978) definition. In any given article, therefore, the meaning of fine  
9 and coarse, unless defined, must be inferred from the author's usage. In this document, fine  
10 particles means all particles in the nucleation, Aitken, and accumulation modes; and coarse  
11 particles means all particles in the coarse mode.  $PM_{2.5}$  and fine particles are not equivalent  
12 terms.

13  
14 ***Occupational Health or Dosimetric Size Cuts.*** The occupational health community has  
15 defined size fractions in terms of their entrance into various compartments of the respiratory  
16 system. This convention classifies particles into inhalable, thoracic, and respirable particles  
17 according to their upper size cuts. Inhalable particles enter the respiratory tract, including the  
18 head airways. Thoracic particles travel past the larynx and reach the lung airways and the  
19 gas-exchange regions of the lung. Respirable particles are a subset of thoracic particles that are  
20 more likely to reach the gas-exchange region of the lung. In the past, exact definitions of these  
21 terms have varied among organizations. As of 1993, a unified set of definitions was adopted by  
22 the American Conference of Governmental Industrial Hygienists (ACGIH, 1994), the  
23 International Standards Organization (ISO), and the European Standardization Committee  
24 (CEN). The curves which define inhalable (IPM), thoracic (TPM), and respirable (RPM)  
25 particulate matter are shown in Figure 2-6. These curves should not be taken to indicate that  
26 particles  $> 4 \mu m D_a$  do not reach the gas exchange regions or that particles  $< 4 \mu m D_a$  do not  
27 deposit in the bronchi. See Figure 6-13 for a graphical characterization of particle deposition in  
28 regions of the respiratory system as a function of particle size.

### 2.1.2.3 Ultrafine Particles

As discussed in Chapter 7 (Toxicology of Particulate Matter in Humans and Laboratory Animals) and in Chapter 8 (Epidemiology of Human Health Effects Associated with Ambient Particulate Matter), some scientists argue that ultrafine particles may pose potential health problems and that some health effects may be associated with particle number or particle surface area as well as or more closely than with particle mass. Some additional attention will be given to ultrafine particles because they contribute the major portion of particle number and a significant portion of particle surface area.

#### *Formation and Growth of Fine Particles*

Several processes influence the formation and growth of particles. New particles may be formed by nucleation from gas phase material. Particles may grow by condensation as gas phase material condenses on existing particles; and particles also may grow by coagulation as two particles combine to form one. Gas phase material condenses preferentially on smaller particles, and the rate constant for coagulation of two particles decreases as the particle size increases. Therefore, ultrafine particles grow into the accumulation mode; but accumulation-mode particles do not normally grow into the coarse mode (see Figure 2-4). More information and references on formation and growth of fine particles can be found in the 1996 AQCD PM (U.S. Environmental Protection Agency, 1996a).

#### *Equilibrium Vapor Pressures*

An important parameter in particle nucleation and in particle growth by condensation is the saturation ratio,  $S$ , defined as the ratio of the partial pressure of a species,  $p$ , to its equilibrium vapor pressure above a flat surface at a specified temperature,  $p_o$ :  $S = p/p_o$ . For either condensation or nucleation to occur, the species vapor pressure must exceed its equilibrium vapor pressure. For particles, the equilibrium vapor pressure is not the same as  $p_o$ . Two effects are important: (1) the Kelvin effect, which is an increase in the equilibrium vapor pressure above the surface due to its curvature (very small particles have higher vapor pressures and will not be stable to evaporation until they attain a critical size) and (2) the solute effect, which is a decrease in the equilibrium vapor pressure of the liquid due to the presence of other compounds in solution. Organic compounds may also be adsorbed on ultrafine carbonaceous particles.

1 For an aqueous solution of a nonvolatile salt, the presence of the salt decreases the  
2 equilibrium vapor pressure of the water over the droplet. This effect is in the opposite direction  
3 of the Kelvin effect, which increases the equilibrium vapor pressure above a droplet because of  
4 its curvature. The existence of an aqueous solution will also influence the vapor pressure of  
5 water-soluble species. The vapor pressure behavior of mixtures of several liquids or of liquids  
6 containing several solutes is complex.

### 7 8 ***New Particle Formation***

9 When the vapor concentration of a species exceeds its equilibrium concentration  
10 (expressed as its equilibrium vapor pressure), it is considered condensable. Condensable species  
11 can either condense on the surface of existing particles or can nucleate to form new particles.  
12 The relative importance of nucleation versus condensation depends on the rate of formation of  
13 the condensable species and on the surface or cross-sectional area of existing particles (McMurry  
14 and Friedlander, 1979). In ambient urban environments, the available particle surface area is  
15 usually sufficient to rapidly scavenge the newly formed condensable species. Formation of new,  
16 ultrafine particles is usually not observable in mass or volume distributions except near sources  
17 of condensable species. Wilson et al. (1977) report observations of the Aitkin nuclei mode in  
18 traffic. However, bursts of new particle formation can be observed in urban areas in the number  
19 distribution (Woo et al., 2001a; McMurray et al., 2000). New particle formation also can be  
20 observed in cleaner, remote regions. Bursts of new particle formation in the atmosphere under  
21 clean conditions usually occur when aerosol surface area concentrations are low (Covert et al.,  
22 1992). High concentrations of nuclei mode particles have been observed in regions with low  
23 particle mass concentrations indicating that new particle formation is inversely related to the  
24 available aerosol surface area (Clarke, 1992).

### 25 26 ***Sources of Ultrafine Particles***

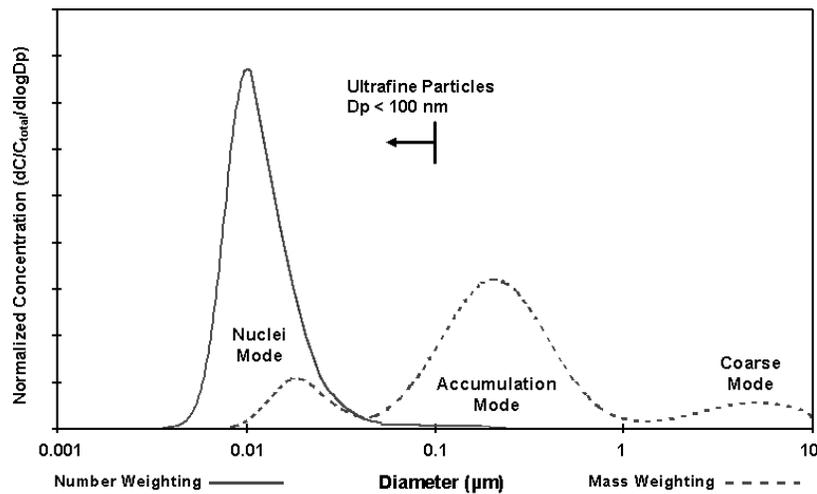

27 Ultrafine particles are the result of nucleation of gas phase species to form condensed  
28 phase species with very low equilibrium vapor pressure. In the atmosphere there are four major  
29 classes of substances that yield particulate matter with equilibrium vapor pressures low enough  
30 to form nuclei mode particles:

- 1 (1) *Particles containing heavy metals.* Nuclei mode particles of metal oxides or other metal  
compounds are generated when metallic impurities in coal or oil are vaporized during  
combustion and the vapor undergoes nucleation. Metallic ultrafine particles also may be  
formed from metals in lubricating oil or fuel additives that are vaporized during  
combustion of gasoline or diesel fuels. Ultrafine metallic particles were discussed in  
Section 6.9 of the 1996 PM AQCD (U.S. Environmental Protection Agency, 1996a).
- 2
- 3 (2) *Elemental carbon or soot (EC).* EC particles are formed primarily by condensation of C<sub>2</sub>  
molecules generated during the combustion process. Because EC has a very low  
equilibrium vapor pressure, ultrafine EC particles can nucleate even at high temperatures  
(Kittelson, 1998; Morawska et al., 1998).
- 4
- 5 (3) *Organic carbon (OC).* Recent smog chamber studies and indoor experiments show that  
atmospheric oxidation of certain organic compounds found in the atmosphere can  
produce highly oxidized organic compounds with an equilibrium vapor pressure  
sufficiently low to result in nucleation (Kamens et al., 1999; Weschler and Shields,  
1999).
- 6
- 7 (4) *Sulfates.* Sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) molecules are generated in the atmosphere by conversion  
of sulfur dioxide (SO<sub>2</sub>) to H<sub>2</sub>SO<sub>4</sub>. As H<sub>2</sub>SO<sub>4</sub> is formed, it can either nucleate to form new  
ultrafine particles, or it can condense on existing ultrafine or accumulation mode particles  
(Clark and Whitby, 1975; Whitby, 1978). Nucleation theory allows calculation of  
nucleation rates for both binary nucleation, involving water and sulfuric acid (Easter and  
Peters, 1994) or ternary nucleation, which requires sulfuric acid, ammonia (NH<sub>3</sub>), and  
water (Korhonen et al., 1999). Kulmala et al. (2000) compared nucleation rates of binary  
and ternary nucleation and concluded that the ternary rate is 1,000 times the binary rate.  
Results from an aerosol dynamics model with a ternary nucleation scheme indicate that  
nucleation in the troposphere should be ubiquitous and yield a reservoir of  
thermodynamically stable sulfate clusters 1-3 nm in diameter. The growth of these  
clusters to a detectable size (> 3 nm diameter) is limited by the availability of  
condensable vapor. Observations of atmospheric particle formation and growth from a  
continental and a coastal site suggest that a growth process including ternary nucleation is

responsible for the formation of cloud condensation nuclei. Nucleation processes in the atmosphere may also involve organic compounds as well as sulfuric acid, ammonia, and water. However, current formulations of nucleation theory only include the three inorganic components. (The possible formation of ultrafine  $\text{NH}_4\text{NO}_3$  by reaction of  $\text{NH}_3$  and nitric acid ( $\text{HNO}_3$ ) vapor has not been investigated.)

12  
13  
14  
15  
16

Vehicle engine exhaust may include all these substances. Ultrafine particles are observed in the emissions from spark, diesel, and jet engines (Kittelson, 1998). In these cases it seems likely that elemental carbon, organic compounds, ammonia and sulfuric acid from sulfur in the fuel, as well as metal additives in the fuel or fuel oil, may contribute to the formation of ultrafine particles (Tobias et al., 2001). An example of particles from a diesel engine showing number and volume distributions is given in Figure 2-9.

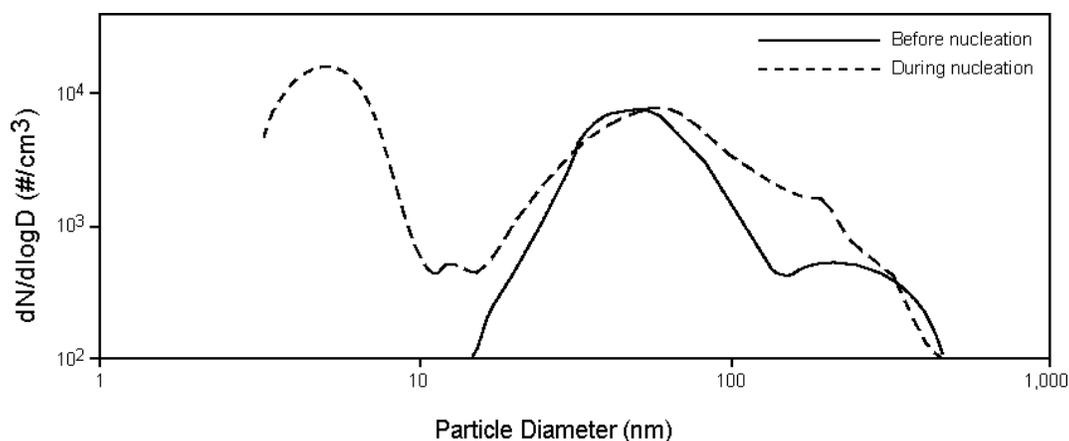

**Figure 2-9. Typical engine exhaust size distribution.**

## ***Recent Measurements of Ultrafine Particles***

Instruments, developed during the past decade, permit measurement of size distributions down to 3 nm diameter particles. Use of these techniques have led to new information on the formation of new particles by nucleation. Such measurements have been carried out during intensive field measurement campaigns, during continuous measurements in urban areas in several European cities, and in the U.S. as a part of the Supersite program (McMurry et al., 2000; Woo et al., 2001a). Nucleation has been observed in the free troposphere (Weber et al., 1999; Clarke, 1992; Schröder and Ström, 1997; Raes et al., 1997); in outflows of evaporating convective clouds (Clarke et al., 1998; Hegg et al., 1990, 1991; Radke and Hobbs, 1991; Perry and Hobbs, 1994); in the marine boundary layer (Covert et al., 1992; Hoppel et al., 1994; Van Dingenen et al., 1995; Weber et al., 1998; Clarke et al., 1998); downwind of coastal regions during low tide (McGovern et al., 1996; McGovern, 1999); on mountains (Weber et al., 1995, 1997; Raes et al., 1997; Wiedensohler et al., 1997); over forests (Mäkelä et al., 1997; Kulmala et al., 1998; O'Dowd et al., 2002); downwind of certain biogenic emissions (Weber et al., 1998); in urban areas (Birmili and Wiedensohler, 1998; McMurry et al., 2000; Woo et al., 2001a); near freeways (Zhu et al., 2002a,b); in engine exhaust (Kittelson, 1998; Tobias et al., 2001); and in homes (Wallace and Howard-Reed, 2002). Nucleation events in outdoor air almost always occur during daylight, indicating that photochemistry plays a role in producing the gas phase precursors of new particles.

The number size distributions observed over a boreal forest in Finland before and during the initial stages of a nucleation event are shown in Figure 2-10. The Aitken and accumulation modes can be seen clearly before the nucleation event. The nucleation mode, with a peak between 3 and 7 nm, appears during the event. Figure 2-11 shows the variety of size distributions that may be observed as nuclei are formed and grow, based on size distributions measured in the Arctic marine boundary layer (Covert et al., 1996). These distributions all show a trimodal distribution within the fine particle size range. The changes in size distribution due to coagulation (and dilution) immediately downwind of a freeway (Zhu et al., 2002b) are shown in Figure 2-12(a)-(g). At 30 m downwind the nucleation mode is larger than the Aitken mode, but by 60 m downwind coagulation has removed particles from the nucleation mode and added particles to the Aitken mode so that the Aitken mode is larger than the nucleation mode.

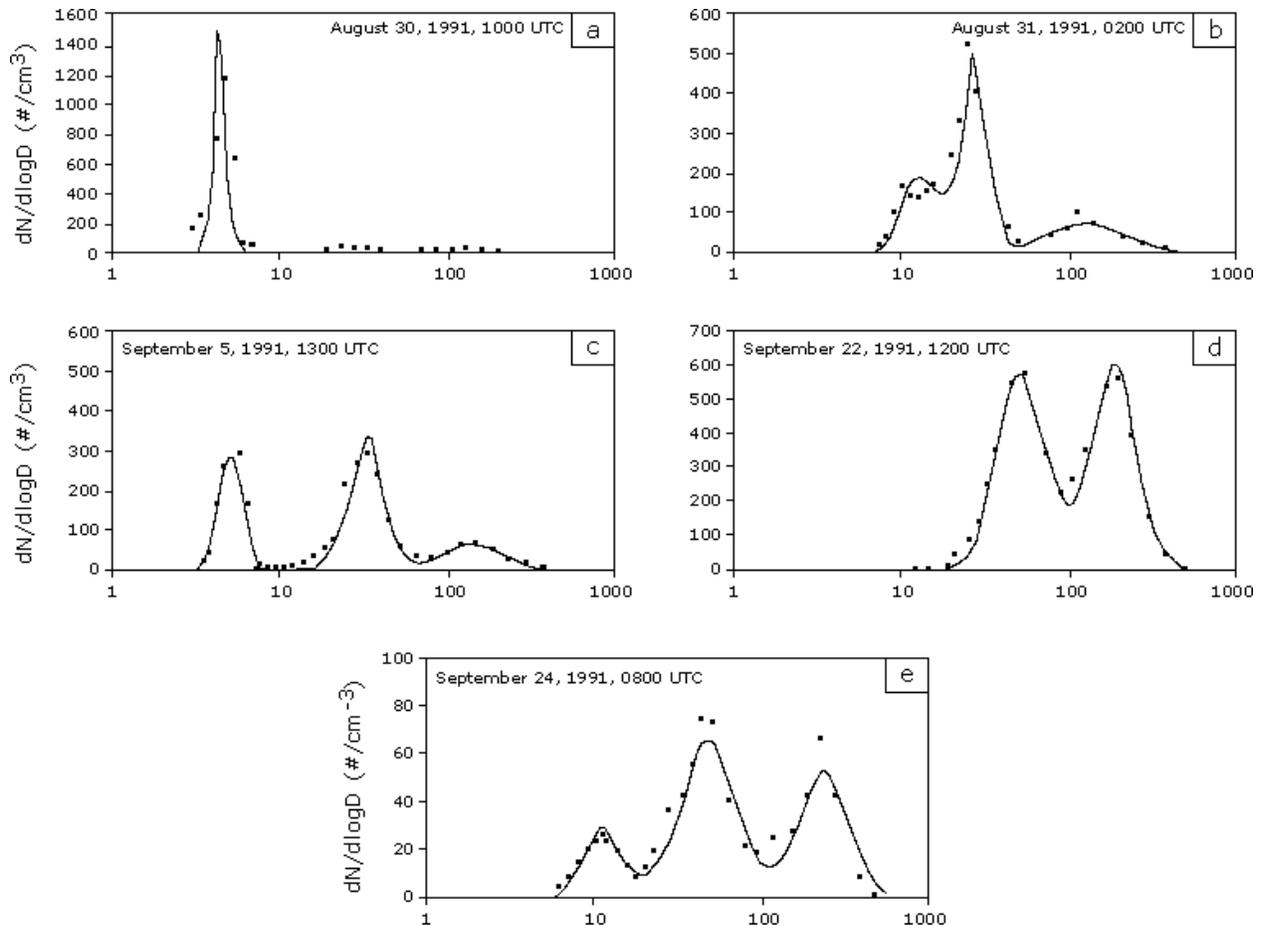

**Figure 2-10. Number size distributions showing measurement of a nucleation burst made in a boreal forest in Finland.**

Source: O'Dowd et al. (2002).

1           There is strong evidence that sulfuric acid vapor often participates in nucleation. However,  
 2           condensation of sulfuric acid and its associated water and ammonium ions typically can account  
 3           for only 10% to 20% of the observed growth rates for freshly nucleated particles. Therefore,  
 4           organic compounds may account for much of the formation and growth of freshly nucleated  
 5           particles. Evidence of nucleation of organic particles comes from smog chamber studies  
 6           (Kamens et al., 1999) and from field studies over forests (Mäkelä et al., 1997; Kulmala et al.,  
 7           1998; O'Dowd et al., 2002). Nucleation of organic particles may also occur indoors due to the  
 8           reaction of infiltrated ozone with indoor terpenes from air fresheners or cleaning solutions  
 9           (Weschler and Shields, 1999). The observation of bursts of nuclei-mode particles in Atlanta  
 10          (Woo et al., 2001a), perhaps due to unusually high rates of production of condensable species,  
 11          suggests that high concentrations of ultrafine particles may be a normal occurrence in polluted  
 12          urban areas.

13  
 14          ***Concentration of Ultrafine Particles: A Balance Between Formation and Removal***

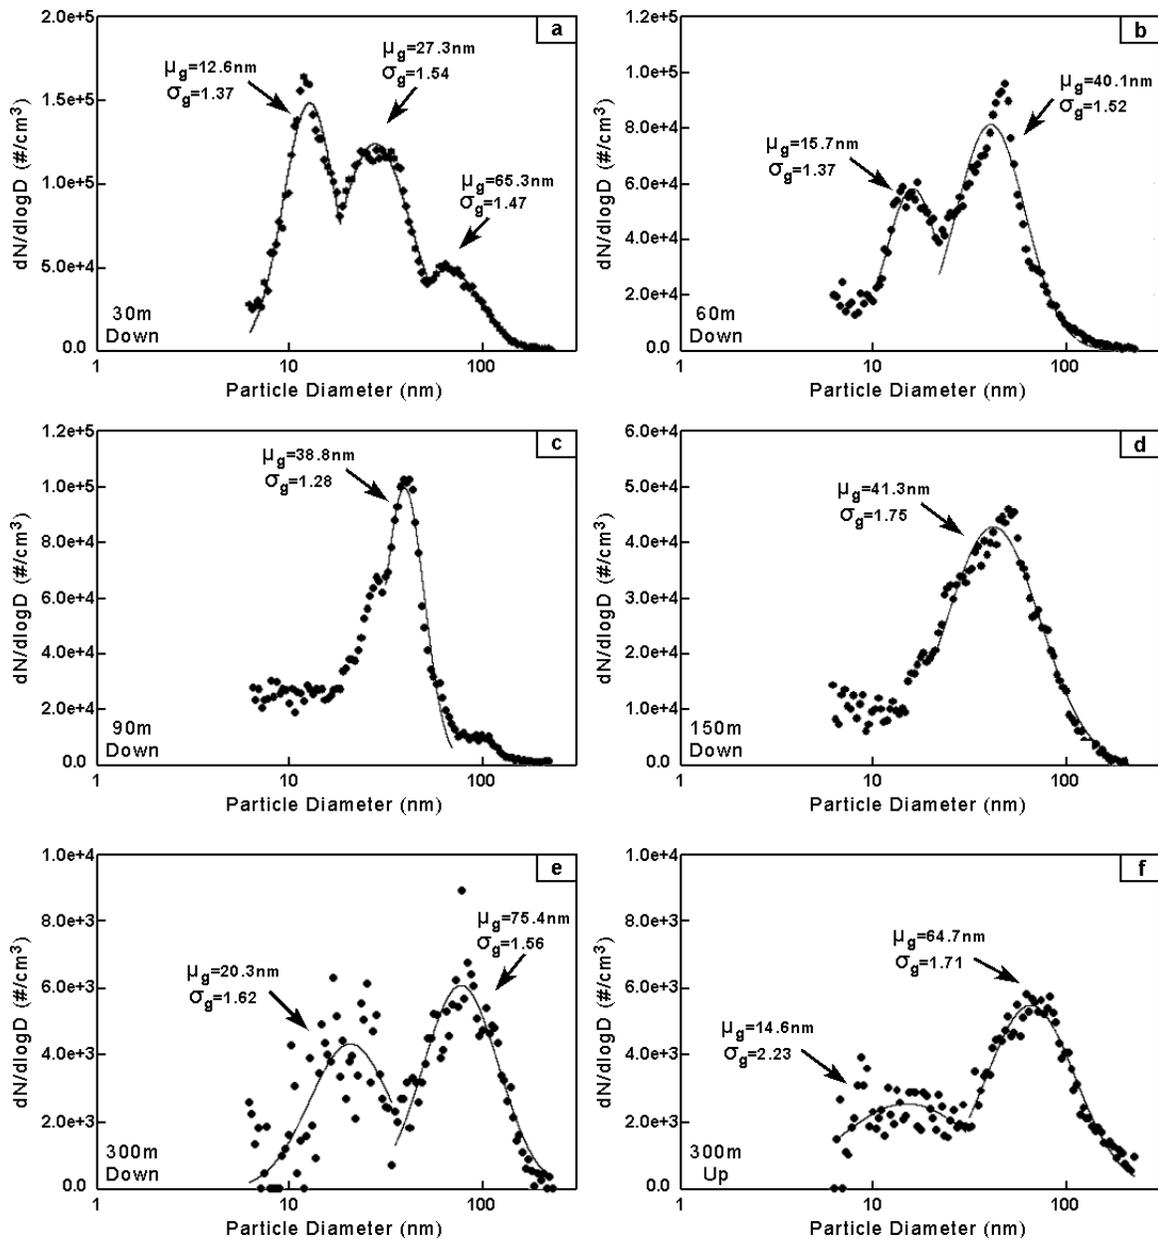

15          Nuclei-mode particles may be removed by dry deposition or by growth into the  
 16          accumulation mode. This growth takes place as other low vapor pressure material condenses on  
 17          the particles or as nuclei-mode particles coagulate with themselves or with accumulation mode

**Figure 2-11. Examples of the measured one hour average particle number size distributions and the log normal fits to the modes of the data. Squares are measured data, solid lines are the fitted log normal modes determined by DistFit™. These modes, nucleation between 3 and 20 nm, Aitken between 20 and 100 nm, and accumulation above 100 nm can be observed in most examples.**

1 particles. Because the rate of coagulation would vary with the concentration of accumulation-  
 2 mode particles, it might be expected that the concentration of nuclei-mode particles would  
 3 increase with a decrease in accumulation-mode mass. On the other hand, the concentration of  
 4 particles would be expected to decrease with a decrease in the rate of generation of particles by  
 5 reduction in emissions of metal and carbon particles or a decrease in the rate of generation of  
 6 H<sub>2</sub>SO<sub>4</sub> or condensable organic vapor. The rate of generation of H<sub>2</sub>SO<sub>4</sub> depends on the

1 concentration of  $\text{SO}_2$  and hydroxyl radical ( $\bullet\text{OH}$ ), which is generated primarily by reactions  
 2 involving ozone ( $\text{O}_3$ ). Thus, reductions in  $\text{SO}_2$  and  $\text{O}_3$  would lead to a decrease in the rate of  
 3 generation of  $\text{H}_2\text{SO}_4$  and condensable organic vapor and to a decrease in the concentration of  
 4 nuclei-mode particles. The balance between formation and removal is uncertain. However,  
 5 these processes can be modeled using a general dynamic equation for particle size distribution  
 6 (Friedlander, 2000) or by aerosol dynamics modules in newer air quality models (Binkowski and  
 7 Shanker, 1995; Binkowski and Ching, 1995).

### 9 **2.1.3 Chemistry of Atmospheric Particulate Matter**

10 The major constituents of atmospheric PM are sulfate, nitrate, ammonium, and hydrogen  
 11 ions; particle-bound water; elemental carbon; a great variety of organic compounds; and crustal  
 12 material. Atmospheric PM also contains a large number of elements in various compounds and  
 13 concentrations. More information and references on the composition of PM measured in a large  
 14 number of studies in the United States, may be found in 1996 PM AQCD (U.S. Environmental

1 Protection Agency, 1996a). In this document, the composition and concentrations of PM are  
2 discussed in Chapter 3, Section 3.1, Patterns and Trends in Ambient PM<sub>2.5</sub> Concentrations and  
3 ambient data for concentrations and composition of PM<sub>2.5</sub> are given in Appendices 3A, 3B,  
4 and 3C.  
5

#### 6 **2.1.3.1 Chemical Composition and Its Dependence on Particle Size**

7 Studies conducted in most parts of the United States indicate that sulfate, ammonium, and  
8 hydrogen ions; elemental carbon, secondary organic compounds and primary organic species  
9 from cooking and combustion; and certain transition metals are found predominantly in the fine  
10 particle mode. Crustal materials such as calcium, aluminum, silicon, magnesium, and iron are  
11 found predominately in the coarse particles. Some primary organic materials such as pollen,  
12 spores, and plant and animal debris are also found predominantly in the coarse mode. Some  
13 components such as potassium and nitrate may be found in both the fine and coarse particle  
14 modes but from different sources or mechanisms. Potassium in coarse particles comes from soil.  
15 Potassium also is found in fine particles in emissions from burning wood or cooking meat.  
16 Nitrate in fine particles comes primarily from the reaction of gas-phase nitric acid with gas-  
17 phase ammonia to form particulate ammonium nitrate. Nitrate in coarse particles comes  
18 primarily from the reaction of gas-phase nitric acid with preexisting coarse particles.  
19

#### 20 **2.1.3.2 Primary and Secondary Particulate Matter**

21 Particulate material can be primary or secondary. PM is called “primary” if it is in the  
22 same chemical form in which it was emitted into the atmosphere. PM is called “secondary” if it  
23 is formed by chemical reactions in the atmosphere. Primary coarse particles are usually formed  
24 by mechanical processes. This includes material emitted in particulate form such as wind-blown  
25 dust, sea salt, road dust, and combustion-generated particles such as fly ash and soot. Primary  
26 fine particles are emitted from sources either directly as particles or as vapors that rapidly  
27 condense to form ultrafine or nuclei-mode particles. This includes soot from diesel engines,  
28 a great variety of organic compounds condensed from incomplete combustion or cooking, and  
29 compounds of As, Se, Zn, etc., that condense from vapor formed during combustion or smelting.  
30 The concentration of primary particles depends on their emission rate, transport and dispersion,  
31 and removal rate from the atmosphere.

1 Secondary PM is formed by chemical reactions of free, adsorbed, or dissolved gases. Most  
2 secondary fine PM is formed from condensable vapors generated by chemical reactions of  
3 gas-phase precursors. Secondary formation processes can result in either the formation of new  
4 particles or the addition of particulate material to pre-existing particles. Most of the sulfate and  
5 nitrate and a portion of the organic compounds in atmospheric particles are formed by chemical  
6 reactions in the atmosphere. Secondary aerosol formation depends on numerous factors  
7 including the concentrations of precursors; the concentrations of other gaseous reactive species  
8 such as ozone, hydroxyl radical, peroxy radicals, or hydrogen peroxide; atmospheric conditions  
9 including solar radiation and relative humidity (RH); and the interactions of precursors and  
10 pre-existing particles within cloud or fog droplets or in the liquid film on solid particles. As a  
11 result, it is considerably more difficult to relate ambient concentrations of secondary species to  
12 sources of precursor emissions than it is to identify the sources of primary particles.

13 A significant effort is currently being directed toward the identification and modeling of organic  
14 products of photochemical smog including the conversion of gases to particulate matter. More  
15 information of the transformation of precursor gases into secondary PM is given in Chapter 3,  
16 Section 3.3.1, Chemistry of Secondary PM Formation.

17 Particle strong acidity is due almost entirely to  $\text{H}_2\text{SO}_4$  or  $\text{NH}_4\text{HSO}_4$ . Thus, the acidity of  
18 atmospheric particles depends on both the amount of  $\text{SO}_2$  that is oxidized to  $\text{SO}_3$  and  
19 subsequently forms  $\text{H}_2\text{SO}_4$  and the amount of ammonia available to react with the sulfuric acid.  
20 Nitric acid is more volatile than sulfuric acid. Thus, if gas phase  $\text{SO}_3$  or sulfuric acid or particles  
21 containing  $\text{H}_2\text{SO}_4$  or  $\text{NH}_4\text{HSO}_4$  contact particles containing  $\text{NH}_4\text{NO}_3$ , nitric acid gas will be  
22 released with the remaining ammonia contributing to further neutralization of the acid. Little  
23  $\text{NH}_4\text{NO}_3$  is found in atmospheres containing significant particle strong acidity. However, as  $\text{SO}_2$   
24 emissions are reduced to the point that there is more than enough ammonia to neutralize the  
25 sulfuric acid,  $\text{NH}_4\text{NO}_3$  particles will begin to form. Thus, ammonia emissions and  
26 concentrations relative to those of  $\text{SO}_2$  and  $\text{H}_2\text{SO}_4$  are important in determining the strong acidity  
27 in the atmosphere and the concentration of particulate  $\text{NH}_4\text{NO}_3$ . Therefore, once  $\text{SO}_2$  emissions  
28 have been reduced to the point that ammonia and sulfate are in balance to form  $(\text{NH}_4)_2\text{SO}_4$ ,  
29 further reductions in  $\text{SO}_2$  will not result in an equivalent reduction in airborne PM because one  
30  $(\text{NH}_4)_2\text{SO}_4$  unit will be replaced by two  $\text{NH}_4\text{NO}_3$  units.

31

### 2.1.3.3 Particle-Vapor Partitioning

Several atmospheric aerosol species, such as ammonium nitrate and certain organic compounds, are semivolatile and are found in both gas and particle phases. A variety of thermodynamic models have been developed to predict the temperature and relative humidity dependence of the ammonium nitrate equilibria with gaseous nitric acid and ammonia. However, under some atmospheric conditions, such as cool, cold, or very clean air, the relative concentrations of the gas and solid phases are not accurately predicted by equilibrium considerations alone, and transport kinetics can be important. The gas-particle distribution of semivolatile organic compounds depends on the equilibrium vapor pressure of the compound, total particle surface area, particle composition, atmospheric temperature, and relative humidity. Although it generally is assumed that the gas-particle partitioning of semivolatile organics is in equilibrium in the atmosphere, neither the equilibria nor the kinetics of redistribution are well understood. Diurnal temperature fluctuations cause gas-particle partitioning to be dynamic on a time scale of a few hours and can cause semivolatile compounds to evaporate during the sampling process. The pressure drop across the filter can also contribute to the loss of semivolatile compounds. The dynamic changes in gas-particle partitioning caused by changes in temperature, pressure, and gas-phase concentration, both in the atmosphere and after collection, cause serious sampling problems that are discussed in Section 2.2.3, Measurement of Semivolatile Particulate Matter.

#### *Equilibria with Water Vapor*

As a result of the equilibrium of water vapor with liquid water in hygroscopic particles, many ambient particles contain liquid water (particle-bound water). Unless removed, this particle-bound water will be measured as a component of the particle mass. Particle-bound water is important in that it influences the size of the particles, and in turn, their light scattering properties and their aerodynamic properties, which are important for deposition to surfaces, to airways following inhalation, and in sampling instrumentation. The aqueous solution provides a medium for reactions of dissolved gases including reactions that do not take place in the gas phase. The aqueous solutions also may act as a carrier to convey soluble toxic species to the gas-exchange regions of the respiratory system, including species that would be removed by deposition in the upper airways if the particles had remained in the gas phase (Friedlander and

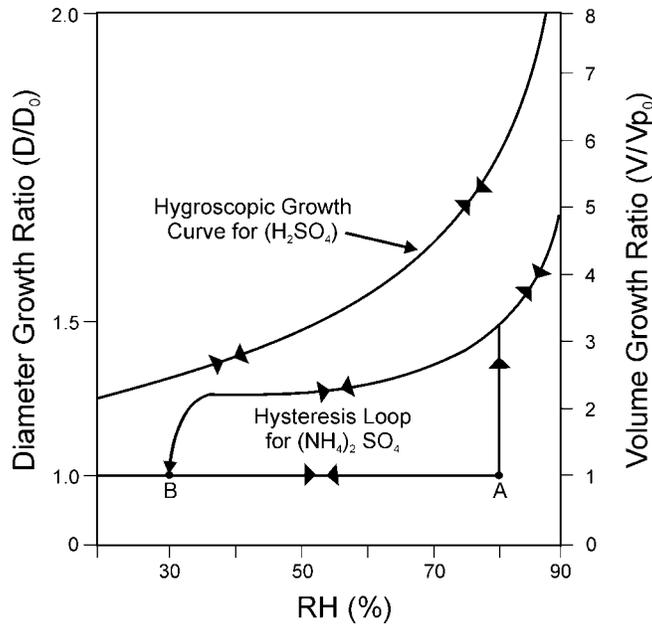

1 Yeh, 1998; Kao and Friedlander, 1995; Wilson, 1995). An extensive review of equilibrium with  
2 water vapor as it pertains to ambient aerosols was given in Chapter 3 of the 1996 PM AQCD  
3 (U.S. Environmental Protection, Agency, 1996a).

4 The interaction of particles with water vapor may be described briefly as follows.  
5 As relative humidity increases, particles of crystalline soluble salts, such as  $(\text{NH}_4)_2\text{SO}_4$ ,  
6  $\text{NH}_4\text{HSO}_4$ , or  $\text{NH}_4\text{NO}_3$ , undergo a phase transition to become aqueous solution particles.  
7 According to the phase rule, for particles consisting of a single component, this phase transition  
8 is abrupt, taking place at a relative humidity that corresponds to the vapor pressure of water  
9 above the saturated solution (the deliquescence point). With a further increase in relative  
10 humidity, the solution particle adds water (and the concentration of the solute decreases) so that  
11 the vapor pressure of the solution is maintained equal to that of the surrounding relative  
12 humidity; thus, the solution particle tends to follow the equilibrium growth curve. As relative  
13 humidity decreases, the solution particle follows the equilibrium curve to the deliquescence  
14 point. However, rather than crystallizing at the deliquescence relative humidity, the solute  
15 remains dissolved in a supersaturated solution to considerably lower relative humidities.  
16 Ultimately the solution particle abruptly loses its water vapor (efflorescence) and typically  
17 returns to the initial crystalline form.

18 For particles consisting of more than one component, the solid to liquid transition will take  
19 place over a range of relative humidities with an abrupt onset at the lowest deliquescence point  
20 of the several components and with subsequent growth as crystalline material in the particle  
21 dissolves according to the phase diagram for the particular multicomponent system. Under such  
22 circumstances, a single particle may undergo several more or less abrupt phase transitions until  
23 the soluble material is fully dissolved. At decreasing relative humidity, such particles tend to  
24 remain in solution to relative humidities well below the several deliquescence points. In the case  
25 of the sulfuric acid-ammonium sulfate-water system, the phase diagram is fairly well  
26 understood. For particles of composition intermediate between  $\text{NH}_4\text{HSO}_4$  and  $(\text{NH}_4)_2\text{SO}_4$ , this  
27 transition occurs in the range from 40% to below 10%, indicating that for certain compositions  
28 the solution cannot be dried in the atmosphere. At low relative humidities, particles of this  
29 composition would likely be present in the atmosphere as supersaturated solution droplets (liquid  
30 particles) rather than as solid particles. Thus, they would exhibit hygroscopic rather than  
31 deliquescent behavior during relative humidity cycles.

1 Other pure compounds, such as sulfuric acid, are hygroscopic (i.e., they form aqueous  
2 solutions at any relative humidity and maintain a solution vapor pressure over the entire range of  
3 relative humidity). Soluble organic compounds may also contribute to the hygroscopicity of the  
4 atmospheric aerosol (Saxena et al., 1995; Saxena and Hildeman, 1996), but the equilibria  
5 involving organic compounds and water vapor, and, especially for mixtures of salts, organic  
6 compounds, and water, are not so well understood. These equilibrium processes may cause an  
7 ambient particle to significantly increase its diameter at relative humidities above about 40%  
8 (Figure 2-13). A particle can grow to five times its dry diameter as the RH approaches 100%  
9 (Figure 2-14). The Federal Reference Methods, for filter measurements of PM<sub>2.5</sub> and PM<sub>10</sub> mass,  
10 require equilibration at a specified, low relative humidity after collection (for PM<sub>2.5</sub>, between  
11 30 and 40% RH with control of ±5% RH [Code of Federal Regulations, 2001a]). This  
12 equilibration removes much of the particle-bound water and provides a relatively stable PM  
13 mass for gravimetric measurements (see Section 2.2 for details and references). Otherwise,  
14 particle mass would be a function of relative humidity, and the particle mass would be largely  
15 particle-bound water at higher relative humidities. However, some particle-bound water may be  
16 retained even after equilibration. Recent studies have shown that significant amounts of particle-  
17 bound water are retained in particles collected on impaction surfaces even after equilibration and  
18 that the amount of retained particle-bound water increases with relative humidity during  
19 collection (Hitzenberger et al., 1997).

20 The retention of particle-bound water is a greater problem for continuous monitors that  
21 measure changes in mass collected on a filter over long sampling times. If particle-bound water  
22 is not removed, changes in relative humidity would cause changes in the mass of PM collected  
23 over previous hours or days. These changes could be much greater than amount of PM mass  
24 added in one hour. Therefore, continuous monitoring techniques generally attempt to remove  
25 particle-bound water before measurement either by heating or dehumidification. However, other  
26 semivolatile materials (e.g., ammonium nitrate and organic compounds) that may be partially  
27 lost during sampling or equilibration of an unheated filter are certainly lost when the collected  
28 sample is heated above ambient temperature. These changes in particle size with relative  
29 humidity also mean that particle measurements such as surface area or volume, or composition  
30 as a function of size, should be made at the same RH in order for the results are to be  
31

**Figure 2-13. Particle growth curves showing fully reversible hygroscopic growth of sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) particles, deliquescent growth of ammonium sulfate [(NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>] particles at the deliquescent point (A, about 80% relative humidity [RH]), reversible hygroscopic growth of ammonium sulfate solution droplets at RH greater than 80%, and hysteresis (the droplet remains supersaturated as the RH decreases below 80%) until the crystallization point (B, about 38% RH) is reached (adapted from National Research Council, 1993 and Tang, 1980).**

1 comparable. These problems are addressed in more detail in Section 2.2, Measurement of  
 2 Particulate Matter.

3

#### 4 **2.1.3.4 Atmospheric Lifetimes and Removal Processes**

5 The lifetimes of particles vary with size. Nuclei-mode particles rapidly grow into the  
 6 accumulation mode. However, the accumulation mode does not grow into the coarse mode.  
 7 Accumulation-mode fine particles are kept suspended by normal air motions and have very low  
 8 deposition rates to surfaces. They can be transported thousands of km and remain in the  
 9 atmosphere for a number of days. Coarse particles can settle rapidly from the atmosphere within

**Figure 2-14. Theoretical predictions and experimental measurements of growth of NH<sub>4</sub>HSO<sub>4</sub> particles at relative humidity between 95 and 100%.**

Source: Li et al. (1992).

1 hours and normally travel only short distances. However, when mixed high into the atmosphere,  
 2 as in dust storms, the smaller-sized coarse-mode particles have longer lives and travel greater  
 3 distances. Dry deposition rates are expressed in terms of a deposition velocity that varies with  
 4 particle size, reaching a minimum between 0.1 and 1.0  $\mu\text{m}$  aerodynamic diameter (e.g., Lin  
 5 et al., 1994). Accumulation-mode particles are removed from the atmosphere primarily by cloud  
 6 processes. Fine particles, especially particles with a hygroscopic component, grow as the  
 7 relative humidity increases, serve as cloud condensation nuclei, and grow into cloud droplets.  
 8 If the cloud droplets grow large enough to form rain, the particles are removed in the rain.  
 9 Falling rain drops impact coarse particles and remove them. Ultrafine or nuclei-mode particles  
 10 are small enough to diffuse to the falling drop, be captured, and be removed in rain. Falling rain  
 11 drops, however, are not nearly as effective in removing accumulation-mode particles as the  
 12 cloud processes mentioned above. A more detailed discussion of particle deposition, including  
 13 acid deposition, especially as it applies to deposition to vegetation, soil, and water surfaces is  
 14 given in Chapter 4 (Environmental Effects of Airborne Particulate Matter). Acid deposition and

1 PM are intimately related, first, because particles contribute to the acidification of rain and,  
2 secondly, because the gas-phase species that lead to dry deposition of acidity are also precursors  
3 of particles. Therefore, reductions in SO<sub>2</sub> and NO<sub>x</sub> emissions will decrease both acidic  
4 deposition and PM concentrations.

5 Sulfate, nitrate, and some partially oxidized organic compounds are hygroscopic and act as  
6 nuclei for the formation of cloud droplets. These droplets serve as chemical reactors in which  
7 (even slightly) soluble gases can dissolve and react. Thus, SO<sub>2</sub> can dissolve in cloud droplets  
8 and be oxidized to sulfuric acid by dissolved ozone or hydrogen peroxide. These reactions take  
9 place only in aqueous solution, not in the gas phase. Sulfur dioxide also may be oxidized by  
10 dissolved oxygen. This process will be faster if metal catalysts such as iron or manganese are  
11 present in solution. If the droplets evaporate, larger particles are left behind. If the droplets  
12 grow large enough, they will fall as rain; and the particles will be removed from the atmosphere  
13 with potential effects on the materials, plants, or soil on which the rain falls. (Similar  
14 considerations apply to dew.) Atmospheric particles that nucleate cloud droplets also may  
15 contain other soluble or nonsoluble materials such as metal salts and organic compounds that  
16 may add to the toxicity of the rain. Sulfuric acid, ammonium nitrate, ammonium sulfates, and  
17 organic particles also are deposited on surfaces by dry deposition. The utilization of ammonium  
18 by plants leads to the production of acidity. Therefore, dry deposition of particles can also  
19 contribute to the ecological impacts of acid deposition. These effects are discussed in Chapter 4  
20 (Environmental Effects of Airborne Particulate Matter).

#### 21 22 **2.1.4 Comparison of Fine and Coarse Particles**

23 The physical and chemical properties of fine particles (including ultrafine particles and  
24 accumulation-mode particles) and coarse particles are summarized for comparison purposes in  
25 Table 2-1. These include important differences in sources, formation mechanisms, composition,,  
26 atmospheric residence time, removal processes, and travel distances. Ensuing chapters in this  
27 document will also show that fine and coarse particles differ in aspects of concentrations,  
28 exposure, dosimetry, toxicology, and epidemiology. Collectively, these differences continue to  
29 warrant consideration of fine particles as a separate air pollutant class from coarse particles and  
30 the setting of separate standards for fine and coarse particles.

**TABLE 2-1. COMPARISON OF AMBIENT PARTICLES,  
FINE PARTICLES (Ultrafine Plus Accumulation-Mode) AND COARSE PARTICLES**

	Fine		
	Ultrafine	Accumulation	Coarse
Formation Processes:	Combustion, high-temperature processes, and atmospheric reactions		Break-up of large solids/droplets
Formed by:	Nucleation Condensation Coagulation	Condensation Coagulation Reactions of gases in or on particles Reactions of gases in or on particles Evaporation of fog and cloud droplets in which gases have dissolved and reacted	Mechanical disruption (crushing, grinding, abrasion of surfaces) Evaporation of sprays Suspension of dusts Reactions of gases in or on particles
Composed of:	Sulfate Elemental Carbon Metal compounds Organic compounds with very low saturation vapor pressure at ambient temperature	Sulfate, Nitrate, Ammonium, and Hydrogen ions Elemental carbon Large variety of organic compounds Metals: compounds of Pb, Cd, V, Ni, Cu, Zn, Mn, Fe, etc. Particle-bound water	Suspended soil or street dust Fly ash from uncontrolled combustion of coal, oil, and wood Nitrates/chlorides from HNO <sub>3</sub> /HCl Oxides of crustal elements (Si, Al, Ti, Fe) CaCO <sub>3</sub> , NaCl, sea salt Pollen, mold, fungal spores Plant and animal fragments Tire, brake pad, and road wear debris
Solubility:	Probably less soluble than accumulation mode	Largely soluble, hygroscopic, and deliquescent	Largely insoluble and nonhygroscopic
Sources:	Combustion Atmospheric transformation of SO <sub>2</sub> and some organic compounds High temperature processes	Combustion of coal, oil, gasoline, diesel fuel, wood Atmospheric transformation products of NO <sub>x</sub> , SO <sub>2</sub> , and organic compounds, including biogenic organic species (e.g., terpenes) High-temperature processes, smelters, steel mills, etc.	Resuspension of industrial dust and soil tracked onto roads and streets Suspension from disturbed soil (e.g., farming, mining, unpaved roads) Construction and demolition Uncontrolled coal and oil combustion Ocean spray Biological sources
Atmospheric half-life:	Minutes to hours	Days to weeks	Minutes to hours
Removal Processes:	Grows into accumulation mode Diffuses to raindrops	Forms cloud droplets and rains out Dry deposition	Dry deposition by fallout Scavenging by falling rain drops
Travel distance:	<1 to 10s of km	100s to 1000s of km	<1 to 10s of km (100s to 1000s in dust storms)

## 2.2 MEASUREMENT OF PARTICULATE MATTER

The 1996 PM AQCD (U.S. Environmental Protection Agency, 1996a) summarized sampling and analytical techniques for PM and acid deposition that had appeared in the literature since the earlier 1982 PM AQCD (U.S. Environmental Protection Agency, 1982). Excellent reviews have also been published by Chow (1995) and McMurry (2000). This section discusses problems in measuring PM; new techniques that attempt to alleviate these problems or measure problem species; Federal Reference Methods, speciation monitors, analytical methods for inorganic elements, organic and elemental carbon, and ionic species; and continuous and multiday monitors.

### 2.2.1 Particle Measurements of Interest

There are many PM components and parameters that are of interest across the various types of uses to which PM measurement data are applied. These uses include analyses of compliance with air quality standards and trends; source category apportionment studies related to the develop of pollution reduction strategies and the validation of air quality models; studies related to health, ecological, and radiative effects; and characterization of current air quality for presentation to the public in the context of EPA's Air Quality Index. PM measurement components and parameters of specific interest for these various purposes are noted below and summarized in Table 2-2.

Particle measurements are needed to determine if a location is in compliance with air quality standards, to determine long-term trends in air quality patterns, and for epidemiologic studies. For these purposes, precision of the measurements by a variety of measurement instruments in use is a critical consideration. Therefore, intercomparisons of various samplers under a variety of atmospheric and air quality conditions are important.

In order to reduce pollution to attain a standard, pollution control agencies and national research organizations need measurements to identify source categories and to develop and validate air quality models. For these purposes, PM parameters other than mass, such as chemical composition and size distribution, must also be measured. Moreover, measurements are needed with shorter time resolution in order to match changes in pollution with diurnal changes in the boundary layer.

**TABLE 2-2. PARTICULATE MATTER COMPONENTS/PARAMETERS OF INTEREST FOR HEALTH, ECOLOGICAL, OR RADIATIVE EFFECTS; FOR SOURCE CATEGORY APPORTIONMENT STUDIES; OR FOR AIR QUALITY MODELING EVALUATION STUDIES**

- 
- Particle number
  - Particle surface area
  - Particle size distribution
  - PM mass (fine PM mass [PM<sub>2.5</sub>] and coarse thoracic PM mass [PM<sub>10-2.5</sub>]) including both nonvolatile mass as measured by the current Federal Reference method and total mass (including semivolatile components such as ammonium nitrate and semivolatile organic compounds, but not particle-bound water)
  - Ions (sulfate, nitrate, and ammonium)
  - Strong acidity (H<sup>+</sup>)
  - Elemental carbon
  - Organic carbon (total, nonvolatile, and semivolatile; functional groups and individual species)
  - Transition metals (water soluble, bioavailable, oxidant generation)
  - Specific toxic elements and organic compounds
  - Crustal elements
  - Bioaerosols
  - Particle refractive index (real and imaginary)
  - Particle density
  - Particle size change with changes in relative humidity
- 

1           A number of PM measurements are needed for use in epidemiologic and exposure studies  
2 and to determine components of PM to guide planning and interpretation of toxicologic studies.  
3 For these purposes, size and chemical composition measurements are important, as is  
4 measurement across different time intervals. For epidemiologic studies of acute (i.e., short-term)  
5 PM exposures, 1-h or continuous measurements can provide important information beyond that  
6 provided by 24-h measurements. However, for epidemiologic studies of chronic PM exposures,  
7 measurements that permit integration over longer intervals (e.g., a week to a month) are more  
8 relevant. For dosimetric studies and modeling, information will be needed on the particle size

1 distribution and on the behavior of particles as the relative humidity and temperature changes  
2 found in the atmosphere are increased to those found in the respiratory system.

3 For studies of ecological effects and materials damage, measurements of particles and of  
4 the chemical components of particulate matter in rain, fog, and dew are needed to understand the  
5 contributions of PM to soiling of surfaces and damage to materials and to understand the wet and  
6 dry deposition of acidity and toxic substances to surface water, soil, and plants. Some  
7 differentiation into particle size is needed to determine dry deposition.

8 For studies of visibility impairment and radiative effects, information is needed that relates  
9 to how particles scatter and absorb light, including refractive index, ratio of scattering to  
10 absorption, size distribution, and change in particle size with change in relative humidity.

## 11 12 **2.2.2 Issues in Measurement of Particulate Matter**

13 The EPA decision to revise the PM standards by adding daily and yearly standards for  
14  $PM_{2.5}$  has led to a renewed interest in the measurement of atmospheric particles and also to a  
15 better understanding of the problems in developing precise and accurate measurements of  
16 particles. It is very difficult to measure and characterize particles suspended in the atmosphere;  
17 however, numerous improvements in PM monitoring are in use and others are in development.  
18 EPA's PM standards are based, in part, on epidemiologic relationships between health effects  
19 and PM concentrations as measured with existing monitoring methods. As understanding of  
20 suspended PM has advanced and new monitoring information has become available, EPA has  
21 changed the indicator for the PM NAAQS from TSP to  $PM_{10}$ , and added  $PM_{2.5}$ . During the  
22 current PM NAAQS review, consideration will be given to a standard for coarse thoracic PM.

23 The U.S. Federal Reference Methods (FRM) for  $PM_{2.5}$  and  $PM_{10}$  provide relatively precise  
24 ( $\pm 10\%$ ) methods for determining the mass of material remaining on a Teflon filter after  
25 equilibration. However, numerous uncertainties remain as to the relationship between the mass  
26 and composition of material remaining on the filter as determined by the FRM measurement  
27 procedure and the mass and composition of material that existed in the atmosphere as suspended  
28 PM. As a result, EPA defines accuracy for PM measurements in terms of agreement of a  
29 candidate sampler with a reference sampler. Therefore, intercomparison of samplers is very  
30 important in determining how well various samplers agree and how various design choices  
31 influence what is actually measured.

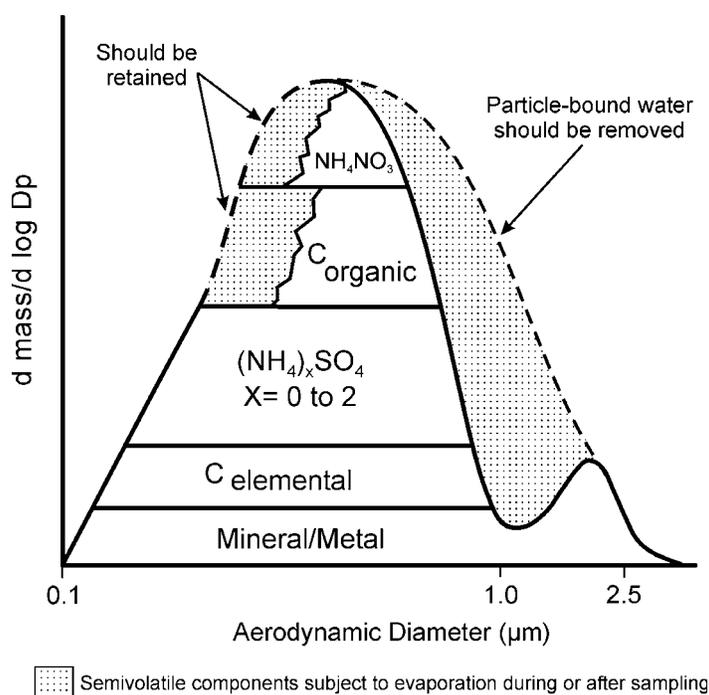

1           There are eight general areas where choices are made in the design and use of an aerosol  
2 sampler. These include (1) consideration of positive artifacts due to chemical reaction or  
3 adsorption; (2) treatment of semivolatile components; (3) selection of particle size cut  
4 characteristics for the upper cut point; (4) separation of fine and coarse PM; (5) treatment of  
5 pressure, temperature, and relative humidity; (6) time resolution; (7) assessment of the reliability  
6 of the measurement technique; and (8) operation and maintenance procedures needed to  
7 maintain consistent measurements over time. In many cases, choices have been made without  
8 adequate recognition of the consequences. As a result, measurement methods developed by  
9 different organizations may give different results when sampling the same atmosphere even  
10 though the techniques appear to be similar.

#### 11 12 **2.2.2.1 Artifacts Due to Chemical Reactions**

13           When TSP was collected on glass fiber filters, the reaction of SO<sub>2</sub> (and other acid gases)  
14 with basic sites on the glass fiber or with basic coarse particles on the filter led to the formation  
15 of sulfate (or other nonvolatile salts, e.g., nitrate, chloride). These positive artifacts led to  
16 overestimation of mass, sulfate (and probably also of nitrate). The metal impurities in the glass  
17 fiber caused a high background that led to low precision in the measurement of trace metals.  
18 These problems were largely overcome by changing to quartz fiber or Teflon filters and by  
19 separate collection of PM<sub>2.5</sub>. However, the possible reaction of acidic gases with basic coarse  
20 particles remains a possibility, especially with measurements of PM<sub>10</sub> and PM<sub>10-2.5</sub>. The reaction  
21 of NH<sub>3</sub> with acidic particles, either during sampling or during transportation, storage, and  
22 equilibration remains a problem in areas such as the eastern U.S. where PM is frequently acidic.  
23 Techniques have been developed that overcome this problem by use of a denuder to remove NH<sub>3</sub>  
24 during sampling and to protect the collected PM from NH<sub>3</sub> (Suh et al., 1992, 1994; Brauer et al.,  
25 1991; Koutrakis et al., 1988a,b). However, this technique has been applied primarily for  
26 measurement of particle strong acidity, not for the measurement of artifact-free ammonium or  
27 mass concentrations. In the measurement of particle strong acidity, basic coarse particles must  
28 be separated from acidic fine particles (Koutrakis et al., 1992).

### 2.2.2.2 Treatment of Semivolatile Components of Particulate Matter

Current filtration-based mass measurements can experience significant evaporative losses, during and possibly after collection, of a variety of semivolatile components (i.e., species that exist in the atmosphere in dynamic equilibrium between the condensed phase and gas phase). Important examples include ammonium nitrate, semivolatile organic compounds, and particle-bound water. This problem is illustrated in Figure 2-15.

**Figure 2-15. Schematic showing major nonvolatile and semivolatile components of PM<sub>2.5</sub>. Semivolatile components are subject to partial to complete loss during equilibration or heating. The optimal technique would be to remove all particle-bound water but no ammonium nitrate or semivolatile organic PM.**

Possible approaches that have been used to address the problem of potentially lost semivolatile components include those that follow, which will be discussed in more detail in subsequent sections.

- 1       1. Collect/measure all components present in the atmosphere in the condensed phase except  
particle-bound water. (Examples: Brigham Young absorptive sampler and Harvard  
pressure drop monitor. Both require preconcentration of the accumulation mode and  
reduction of ambient humidity.)
- 2
- 3       2. Stabilize PM at a specified temperature high enough to remove all, or almost all, particle-  
bound water. This results in loss of much of the semivolatile PM. (Examples: tapered  
element oscillating microbalance (TEOM) operated at 50 °C, beta gauge with heated  
inlet.)
- 4
- 5       3. Equilibrate collected material at fixed, near-room temperature and moderate relative  
humidity to reduce particle-bound water. Accept the loss of an unknown but possibly  
significant fraction of semivolatile PM. (Example: U.S. Federal Reference Method and  
most filter-weighing techniques.) Equilibration originally was designed to remove  
adsorbed water vapor from glass fiber filters in order to maintain a stable filter weight.  
The designated RH (35±5%) was a compromise. If the RH is too low, electrostatic  
charging becomes a problem. The equilibration process does help provide a stable and  
reproducible mass. It also reduces the particle-bound water. However, it may not  
remove all particle-bound water.

### 6 7   **2.2.2.3 Upper Cut Point**

8       The upper cut point of the high volume sampler varied with wind speed and direction.  
9       Newer PM samplers are usually designed to have an upper cut point and its standard deviation  
10      that are independent of wind direction and relatively independent of wind speed. Current PM  
11      samplers have upper cut points that are stable under normal operating conditions. However,  
12      problems may occur under unusual or adverse conditions. Ono et al. (2000) reported the results  
13      of a study in which several PM<sub>10</sub> samplers were collocated and operated at various sites at  
14      Owens Lake, CA, a location with high concentrations of coarse PM. Samplers included the  
15      Partisol sampler, the TEOM, a dichotomous sampler, the Wedding high-volume sampler, and the  
16      Graseby high-volume sampler. They found that the TEOM and Partisol samplers agreed to  
17      within 6% on average. The dichotomous sampler and the Graseby and Wedding high-volume

1 samplers, however, measured significantly lower PM<sub>10</sub> concentrations than the TEOM (on  
2 average 10, 25, and 35% lower, respectively). These lower concentrations were attributed to a  
3 decrease in the cut point at higher wind speeds and to a dirty inlet.

4 The choice of the cut point characteristics depends upon the application for the sampling  
5 device. A separation that simulates the removal of particles by the human upper respiratory  
6 system might appear to be a good choice for both health risk and regulatory monitoring (i.e.,  
7 measure what gets into the lungs). The ACGIH-ISO-CEN penetration curve for thoracic  
8 particles (particles able to pass the larynx and penetrate into the bronchial and alveolar regions of  
9 the lung) has a 50% cut point at 10 μm aerodynamic diameter (D<sub>a</sub>). The U.S. PM<sub>10</sub> separation  
10 curve is sharper than the thoracic penetration curve but has the advantage of reducing the  
11 problem of maintaining the finite collection efficiency specified by the thoracic penetration  
12 curve for particles larger than 10 μm D<sub>a</sub>. (See Section 2.1.2.2 and Figure 2-6).

#### 14 **2.2.2.4 Cut Point for Separation of Fine and Coarse Particulate Matter**

15 As shown in Table 2-1, fine and coarse particles differ not only in size but also in  
16 formation mechanisms; sources; and chemical, physical, and biological properties. They also  
17 differ in concentration-exposure relationships, dosimetry (deposition and retention in the  
18 respiratory system), toxicity, and health effects as observed by epidemiologic studies. Thus, it is  
19 desirable to measure fine and coarse PM separately in order to properly allocate health effects to  
20 either fine or coarse PM and to correctly determine sources by receptor modeling approaches.  
21 For example, sulfates in fine particles are associated with hydrogen or ammonium ions while  
22 sulfates in coarse particles are associated with basic metal ions. Transition metals in coarse  
23 particles are likely to be associated with soil and tend to be less soluble (and presumably less  
24 bioavailable) than transition metals in fresh combustion particles found in fine particles.

25 The 2.5 μm D<sub>a</sub> cut point was chosen in the early 1970s as the cut point for a new  
26 dichotomous sampler (Loo et al., 1976; Jaklevic et al., 1977) for use in the Regional Air  
27 Pollution Study in St. Louis, MO. At that time aerosol scientists were beginning to realize that  
28 there was a minimum between 1 and 3 μm in the distribution of particle size by volume (Whitby  
29 et al., 1974). The 2.5 μm cut point was subsequently used as an indicator of fine-mode PM in a  
30 number of studies including the Harvard Six-City Studies of the relationships between mortality  
31 and PM concentrations (Dockery et al., 1993; Schwartz et al., 1996). A 2.5 μm cut point was

1 also used in the Inhalable Particle Network (Suggs and Burton, 1983) which provided data for  
2 another major epidemiologic study of PM - mortality relationships using an American Cancer  
3 Society cohort (Pope et al., 1995). Therefore, at the time of the last review of the NAAQS for  
4 PM (U.S. Environmental Protection Agency, 1996a,b), there were a number of epidemiologic  
5 studies demonstrating a statistical relationship between PM<sub>2.5</sub> concentrations and mortality.

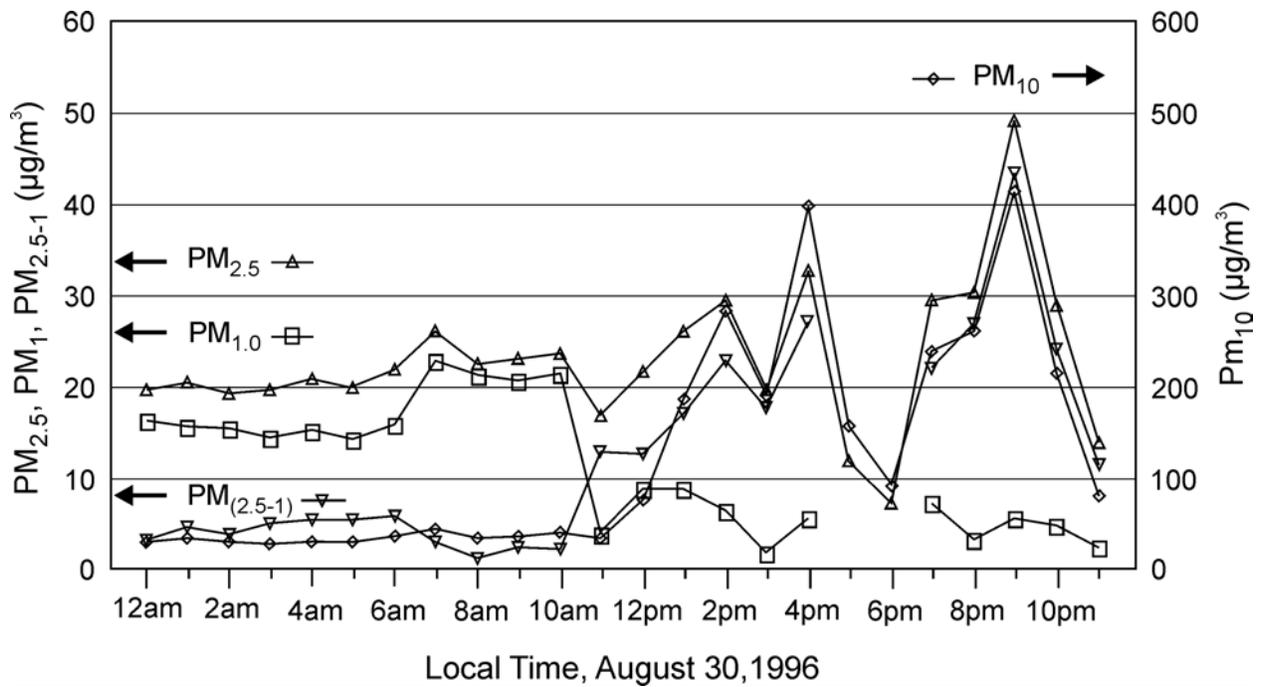

6 It is now understood that the size range between 1.0 and 2.5 μm, sometimes called the  
7 intermodal region may contain either accumulation-mode or coarse-mode material or both, i.e.,  
8 the two modes may overlap in this region (Kegler et al., 2001). The experimental information on  
9 the composition and source of the intermodal mass was discussed extensively in the 1996 PM  
10 AQCD (U.S. Environmental Protection Agency, 1996a). Depending on conditions, a significant  
11 amount of either accumulation- or coarse-mode material may be found in the intermodal region  
12 between 1.0 and 2.5 μm. The analysis demonstrated the important role of relative humidity in  
13 influencing the size of particles in both the accumulation and coarse modes.

14 As the relative humidity increases, hygroscopic accumulation-mode particles will increase  
15 in size due to accumulation of particle-bound water. At high relative humidities, some originally  
16 submicrometer accumulation-mode PM may be found with a D<sub>a</sub> above 1 μm. At a relative  
17 humidity of 100%, such as found in fog and clouds, accumulation-mode PM may extend above  
18 2.5 μm D<sub>a</sub>. What is not well understood is whether such particles will shrink to diameters below  
19 1 μm as the RH decreases or whether reactions occurring in the wet particles will result in an  
20 increase in non-aqueous mass so that even at low RH the diameters would exceed 1 μm. On the  
21 other hand, at very low relative humidity, coarse particles may be fragmented into smaller sizes,  
22 and small amounts of coarse PM may be found with an D<sub>a</sub> below 2.5 μm (Lundgren et al., 1984;  
23 Lundgren and Burton, 1995). Thus, a PM<sub>2.5</sub> sample will contain all of the accumulation-mode  
24 PM except during periods of RH near 100 %. However, under conditions of low RH, it may also  
25 contain a small fraction of the coarse PM. The selection of a cut point of 2.5 μm as a basis for  
26 EPA's 1997 NAAQS for fine particles (Federal Register, 1997) and its continued use in many  
27 health effects studies reflect the importance placed on more complete inclusion of accumulation-  
28 mode particles while recognizing that intrusion of coarse particles can occur under some  
29 conditions with this cut point.

30 In addition to the influence of relative humidity, in areas where winds cause high  
31 concentrations of windblown soil there is evidence that a significant amount of coarse-mode PM

1 may be found below 2.5  $\mu\text{m}$ . An example, taken from data collected during the August 1996  
 2 dust storm in Spokane, WA, is shown in Figure 2-16. Note that the  $\text{PM}_{10}$  scale is 10 times that  
 3 of the other size fractions.  $\text{PM}_1$ , although high in the morning, goes down as the wind increases  
 4 and  $\text{PM}_{10}$ ,  $\text{PM}_{2.5}$ , and  $\text{PM}_{2.5-1}$  go up. During the peak of the dust storm, around 9 pm,  $\text{PM}_{2.5-1}$  was  
 5 88% of  $\text{PM}_{2.5}$ . For the 24-h period,  $\text{PM}_{2.5-1}$  was 54% of  $\text{PM}_{2.5}$ . However,  $\text{PM}_1$  was not affected  
 6 by the intrusion of coarse particles. Similar considerations probably apply to short-term  
 7 intrusions of dust transported from distant sources such as the Sahara and Gobi deserts (Husar  
 8 et al., 2001).

9  
 10

**Figure 2-16. Particulate matter concentrations in Spokane, WA, during the August 30, 1996 dust storm.**

Source: Claiborn et al. (2000).

1 A cut point of 1.0  $\mu\text{m}$  could reduce the misclassification of coarse-mode material as fine,  
 2 especially in areas with high levels of wind blown soil, but under high RH conditions could  
 3 result in some accumulation-mode material being misclassified as coarse. A reduction in RH,

1 either intentionally or inadvertently, will reduce the mass mean diameter of the accumulation-  
2 mode particles. A sufficient reduction in RH should yield a dry accumulation mode with very  
3 little material above 1.0  $\mu\text{m}$ . Studies of the changes in particle size with changes in relative  
4 humidity suggest that only a small fraction of accumulation-mode particles will be above 1.0  $\mu\text{m}$   
5 in diameter at RH below 60%, but a substantial fraction will grow above 1.0  $\mu\text{m}$  for RH above  
6 80% (Hitzenberger et al., 1997; McMurry and Stolzenburg, 1989; U.S. Environmental Protection  
7 Agency, 1996a).

8 Under high relative humidity circumstances, a monitor using a 1.0  $\mu\text{m}$   $D_a$  cut point can  
9 achieve better modal separation if the air stream is dehumidified to some fixed humidity that  
10 would remove all or most particle-bound water without evaporating semivolatile components.  
11 New techniques which require reduction of RH prior to collection have been developed for  
12 measurement of fine particulate matter minus particle-bound water but including semivolatile  
13 nitrate and organic compounds. With such techniques,  $\text{PM}_1$  measurements in conjunction with  
14 concurrent  $\text{PM}_{2.5}$  measurements would be useful for exposure, epidemiologic, and source  
15 apportionment studies especially in areas where intrusion of coarse-mode particles into the  
16 intermodal range is likely.

#### 17 18 **2.2.2.5 Treatment of Pressure, Temperature, and Relative Humidity**

19 There are a variety of techniques for defining (or ignoring) the pressure, temperature, and  
20 relative humidity during and after sampling. For example, the sample volume may be based on  
21 the mass or volumetric flow corrected to standard temperature and pressure (273 °K and 1 atm.)  
22 (current FRM for  $\text{PM}_{10}$ ), or it may be based on the volumetric flow at ambient conditions of  
23 temperature and pressure (current FRM for  $\text{PM}_{2.5}$ ).

24 There are also a variety of options for the control of temperature during collection. The  
25 particles may be heated enough to remove much of the particle-bound water (i.e., TEOM at  
26 50 °C); the particles may be heated several degrees, just enough to prevent condensation of  
27 water in the sampling system; the particles and the sampler may be maintained near ambient  
28 temperature ( $\pm 5$  °C of ambient temperature is required for EPA FRM samplers); or the particles  
29 and sampler may be maintained at constant temperature inside a heated or air conditioned  
30 shelter. There are also options for control of temperature after collection: (a) no control (room

1 temperature) or (b) ship and store at cool temperature (4 °C is the current EPA FRM  
2 requirement).

3 Consideration must also be given to relative humidity. Changes in relative humidity cause  
4 changes in particle size of hygroscopic or deliquescent particles. Changing relative humidity by  
5 adding or removing water vapor affects measurements of particle number, particle surface area,  
6 and particle size distribution and the amount of overlap of accumulation-mode and coarse-mode  
7 particles. Changing relative humidity by intentional or inadvertent changes in temperature also  
8 affects the amount of loss of ammonium nitrate and semivolatile organic compounds.

9 Monitoring personnel should be aware of the various options for treatment of pressure,  
10 temperature, and relative humidity; make appropriate selections; and document which options  
11 are used.

12 Studies of relationships between personal/indoor/outdoor measurements present special  
13 problems. Indoor environments are typically dryer than outdoors and may be warmer or, if  
14 air-conditioned, cooler. These differences may change particle size and the amount of  
15 volatilization of semivolatile components. Such changes between indoors and outdoors will  
16 complicate the comparison of indoor to outdoor PM concentrations; the modeling of personal  
17 exposure to all particles; and apportionment of personal exposure into particles of ambient  
18 origin, particles of indoor origin, and particles originating from personal activity.

#### 20 **2.2.2.6 Time Resolution**

21 The classic 24-hour filter collection technique is being supplemented by a variety of  
22 continuous monitors for various PM constituents. This process is being accelerated by the lower  
23 operational cost of continuous monitors and the availability of new continuous monitors for  
24 mass, number, and certain chemical components, as well as refinements of older methods based  
25 on beta attenuation or light scattering. Most epidemiologic studies have used 24-hour  
26 concentrations as exposure indicators. However, one epidemiologic study of chronic effects  
27 uses a filter sampler with a two-week collection period (Gauderman et al., 2000). Another  
28 recent study used 1-2 h concentrations (see Peters et al., 2000). Continuous methods are  
29 discussed in Section 2.2.5.

### 2.2.2.7 Accuracy and Precision

Precision is typically determined by comparison of collocated samplers or through replicate analyses; whereas accuracy is determined through the use of traceable calibration standards. Unfortunately, no standard reference calibration material or procedure has been developed for suspended, atmospheric PM. It is possible to determine the accuracy of certain components of the PM measurement system (e.g., flow control, inlet aspiration, PM<sub>2.5</sub> cut, weighing, etc.). The absolute accuracy for collecting a test aerosol can also be determined by isokinetic sampling in a wind tunnel. However, it is not currently feasible to provide a simulated atmospheric aerosol with naturally occurring semivolatile components. It is particularly challenging to develop an atmospheric aerosol calibration standard suitable for testing samplers in the field. Therefore, it is not possible at the present time to establish the absolute accuracy of a PM monitoring technique. Intercomparison studies may be used to establish the precision of identical monitors and the extent of agreement between different types of monitors. Such studies are important for establishing the reliability of PM measurements. Intercomparison studies have contributed greatly to our understanding of the problems in PM measurement. Such studies will be discussed as they apply to specific measurement problems, monitoring instruments, or analytical techniques.

Some measurement errors of concern in PM<sub>10</sub> sampling, including those that arise due to uncertainty tolerances in cutpoint, particle bounce and reentrainment, impactor surface overloading, and losses to sampler internal surfaces, were discussed in detail in the 1996 PM AQCD (U.S. Environmental Protection Agency, 1996a). Other measurement errors of concern in PM<sub>2.5</sub> sampling arise because of our inability to assess accuracy in an absolute sense due to a lack of an atmospheric aerosol calibration standard, the inclusion in PM<sub>2.5</sub> of a small amount of coarse particles as discussed in Section 2.2.1.3, problems associated with the definition of PM<sub>2.5</sub> as what remains on a filter after collection and equilibration rather than as the mass of particles as they exist in the air. Still, it is possible to measure PM indicators with high precision. Detailed information on precision and quality assurance may be found on EPA's Technology Transfer Network website (U.S. Environmental Protection Agency, 2002a). See discussion in Section 2.2.4.

Because of the difficulties associated with determining the accuracy of PM measurements, EPA has sought to make FRM measurements equivalent by specifying operating conditions and,

1 in the case of PM<sub>2.5</sub> samplers, by specifying details of the sampler design. Thus, both the PM<sub>10</sub>  
2 as well as the PM<sub>2.5</sub> standards are defined with consistency of measurement technique rather than  
3 with the accuracy of the true mass concentration measurement in mind (McMurry, 2000). It is  
4 acknowledged in the Federal Register (1997) that, “because the size and volatility of the particles  
5 making up ambient particulate matter vary over a wide range and the mass concentration of  
6 particles varies with particle size, it is difficult to define the accuracy of PM<sub>2.5</sub> measurements in  
7 an absolute sense....” Thus, accuracy is defined as the degree of agreement between a field  
8 PM<sub>2.5</sub> sampler and a collocated PM<sub>2.5</sub> reference method audit sampler (McMurry, 2000). The  
9 Federal Reference Method for PM<sub>2.5</sub> is discussed in Section 2.2.3.3. As mentioned earlier,  
10 volatilization of organic compounds and ammonium nitrate during sampling or post-sampling  
11 handling can lead to significant underestimation of the fine particulate mass concentration in  
12 some locations. Sources of error in the measurement of mass of PM<sub>2.5</sub> suspended in the  
13 atmosphere also arise because of adsorption or desorption of semivolatile vapors onto or from  
14 collected PM, filter media, or other sampler surfaces; neutralization of acid or basic vapors on  
15 either filter media or collected PM; and artifacts associated with particle-bound water.

16 During the past 25 years, there have been advancements in the generation and  
17 classification of monodisperse aerosols as well as in the development of electron microscopy and  
18 imaging analysis that have contributed to the advancement in aerosol calibration (Chen, 1993).  
19 Still, one of the limitations in PM sampling and analysis remains the lack of primary calibration  
20 standards for evaluating analytical methods and for intercomparing laboratories. Klouda et al.  
21 (1996) examined the possibility of resuspending the National Institute of Science and  
22 Technology (NIST) Standard Reference Material 1649 (Urban Dust) in air for collection on up to  
23 320 filters simultaneously using Standard Research International’s dust generation and collection  
24 system. However, the fine component is not resuspended and the semivolatile component has  
25 evaporated. Consequently, this material is not a suitable standard for suspended PM. NIST is  
26 continuing work in this area with EPA support.

27 Methods validation was discussed in the 1996 PM AQCD (U.S. Environmental Protection  
28 Agency, 1996a), and the usefulness of intercomparisons and “internal redundancy” was  
29 emphasized. For example, a number of internal consistency checks are applied to the IMPROVE  
30 network (Malm et al., 1994). These include mass balances, sulfur measurements by both  
31 proton-induced X-ray emission (PIXE) and ion chromatography (IC), and comparison of organic

1 matter by combustion and by proton elastic scattering (PESA) of hydrogen. Mass balances  
2 compare the gravimetrically determined mass with the mass calculated from the sum of the  
3 major chemical components (i.e., crustal elements plus associated oxygen, organic carbon,  
4 elemental carbon, sulfate, nitrate, ammonium, and hydrogen ions). Mass balances are useful  
5 validation techniques; however, they do not check for, or account for, artifacts associated with  
6 the absorption of gases during sampling or the loss of semivolatile material during sampling.  
7 The mass balance check may appear reasonable even if such artifacts are present because only  
8 the material collected on the filter is included in the balance. Mass balance checks may also  
9 suffer from errors due to some particle-bound water remaining in the PM even after equilibration  
10 and from the use of an arbitrary factor to account for the amount of oxygen and hydrogen atoms  
11 per carbon atom in the organic carbon fractions (Andrews et al., 2000).

### 12 13 **2.2.3 Measurement of Semivolatile Particulate Matter**

14 PM suspended in the atmosphere is composed of many chemical species having a wide  
15 range of vapor pressures. Substances with vapor pressures below  $10^{-9}$  Torr (mmHg) will  
16 typically be nonvolatile; substances with vapor pressures above  $10^{-1}$  Torr will be primarily in the  
17 gas phase; substances with vapor pressures between  $10^{-1}$  and  $10^{-9}$  Torr may exist in an  
18 equilibrium state with some material in both the gas phase and the condensed (particulate) phase  
19 and are known semivolatile material (SVM) (Pankow, 1994a). SVM, originally in the  
20 atmosphere in the particulate phase and collected on a filter, may subsequently be lost from the  
21 filter. SVM may evaporate during sampling due to a reduction in its concentration in the  
22 atmosphere being sampled or due to the pressure drop across the filter. SVM may evaporate  
23 after sampling; during intentional equilibration at a low relative humidity; or during transport,  
24 handling, and storage if exposed to an atmosphere in which the vapor pressure of one or more  
25 semivolatile components is lower than in the atmosphere sampled. Since water is not a  
26 pollutant, it is necessary to remove most of the particle-bound water before weighing (Chow,  
27 1995). However, collection and measurement of ammonium nitrate and semivolatile organic  
28 compounds in suspended atmospheric PM represents a major analytical challenge (McMurry,  
29 2000).

### 2.2.3.1 Particle-Bound Water

It is generally desirable to collect and measure ammonium nitrate and semivolatile organic compounds. However, for many measurements of suspended particle mass, it is desirable to remove the particle-bound water before determining the mass. The mass of particle-bound water is strongly dependent on the relative humidity. However, the dependence is not linear since there is significant hysteresis in the water adsorption-desorption pathways (Seinfeld and Pandis, 1998). Water vapor is not a pollutant and cannot be controlled. Particle-bound water is not included in the mass of PM subject to regulation and control. Because the mass of particle-bound water could be equal or greater than that of the other components, a measurement of PM mass including particle-bound water would depend more on relative humidity than pollution. For all these reasons, it is usually desirable to remove most, if not all, particle-bound water before weighing collected PM. However, in some situations it may be important to know how much of the suspended particle's mass or volume results from particle-bound water.

Figures 2-13 and 2-14 show the change in diameter of sulfate particles as a function of relative humidity. Figure 2-13 also shows hysteresis resulting from the difference between deliquescence and crystallization points.

Pilinis et al. (1989) calculated the water content of atmospheric particulate matter above and below the deliquescent point. They predicted that aerosol water content is strongly dependent on composition and concluded from their calculations that liquid water could represent a significant mass fraction of aerosol concentration at relative humidities above 60%. Since then, a few researchers have attempted to measure the water content of atmospheric aerosol. Most techniques have focused on tracking the particle mass as the relative humidity is changed and are still in the development phase. There have been only a few demonstrations using actual ambient aerosol to date. Of interest, in particular, is the development of the Tandem Differential Mobility Analyzer (TDMA) and its applications in investigations of the effects of relative humidity on particle growth.

Lee et al. (1997) examined the influence of relative humidity on the size of atmospheric aerosol using a TDMA coupled with a scanning mobility particle sizer (SMPS). They reported that the use of the TDMA/SMPS system allowed for the abrupt size changes of aerosols at the deliquescence point to be observed precisely. They also reported that at relative humidities

1 between 81 and 89% the water content of ammonium sulfate aerosols (by mass) ranged from  
2 47 to 66%.

3 Andrews and Larson (1993) investigated the interactions of single aerosol particles coated  
4 with an organic film within a humid environment. Using an electrodynamic balance, they  
5 conducted laboratory experiments in which sodium chloride and carbon black particles were  
6 coated with individual organic surfactants (intended to simulate the surface-active, organic films  
7 that many atmospheric aerosol particles may exhibit) and their water sorption curves were  
8 examined. Their results showed that when ordinarily hydrophobic carbon black particles were  
9 coated with an organic surfactant, they sorbed significant amounts of water (20 to 40% of the dry  
10 mass of the particle).

11 Liang and Chan (1997) developed a fast technique using the electrodynamic balance to  
12 measure the water activity of atmospheric aerosols. In their technique, the mass of a levitated  
13 particle is determined as the particle either evaporates or grows in response to a step change in  
14 the relative humidity. Their technique was demonstrated using laboratory experiments with  
15 NaCl,  $(\text{NH}_4)_2\text{SO}_4$ ,  $\text{NaNO}_3$ , and  $(\text{NH}_4)_2\text{SO}_4/\text{NH}_4\text{NO}_3$  solutions. They concluded that one of the  
16 advantages of their fast method is the ability to measure the water activity of aerosols containing  
17 volatile solutes such as ammonium chloride and some organics.

18 McInnes et al. (1996) measured aerosol mass concentration, ionic composition, and  
19 associated water mass of marine aerosol over the remote Pacific Ocean. The mass of  
20 particle-bound water was determined by taking the difference between the mass obtained at 48%  
21 RH and at 19% RH, assuming the aerosol particles were dry at 19% RH. Based on a comparison  
22 of the remote Pacific aerosol to aerosol collected at a site at the marine/continental interface of  
23 the Washington coast, the amount of water associated with the aerosol was observed to be a  
24 function of the ammonium to sulfate ratio. They found that the amount of water associated with  
25 the submicrometer aerosol comprised 29% of the total aerosol mass collected at 47% RH and  
26 9% of the total mass at 35% RH.

27 Ohta et al. (1998) characterized the chemical composition of atmospheric fine particles  
28 (50% cut point of 2  $\mu\text{m}$ ) in Sapporo, Japan, and as part of their measurements, determined the  
29 water content using the Karl Fischer method (Meyer and Boyd, 1959). After exposing a Teflon  
30 filter, a portion of the filter was equilibrated at 30% RH for 24 h. Then the filter piece was  
31 placed in a water evaporator heated at 150 °C, vaporizing the particle-bound water. The vapor

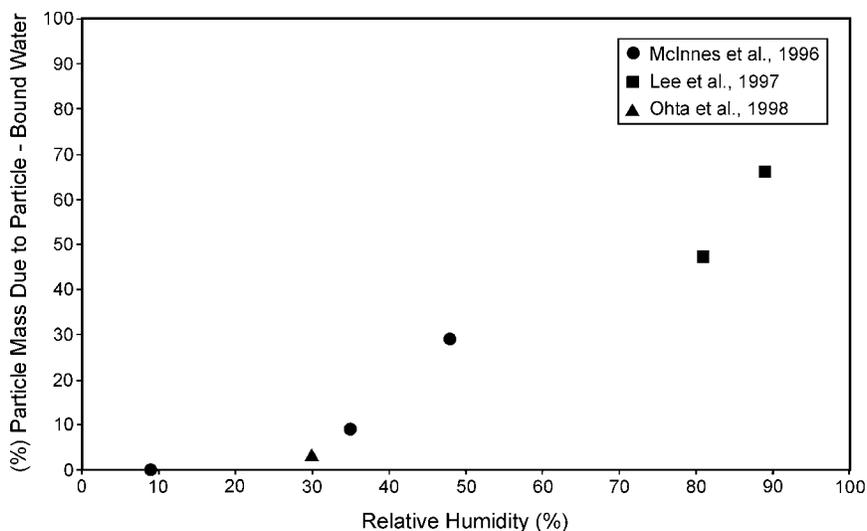

1 evolved was analyzed for water in an aqua-counter where it was titrated coulometrically in Karl  
2 Fischer reagent solution (containing iodine, sulfur, and methanol). The accuracy of the aqua-  
3 counter is  $\pm 1$  mg. Using this technique, they determined that the water content of the particles  
4 ranged from 0.4 to 3.2% of the total particulate mass (at RH < 30%). This represents a smaller  
5 portion of water compared to their previous reported values (Ohta and Okita, 1990) that were  
6 determined by calculation at RH of 50%.

7 Speer et al. (1997) developed an aerosol liquid water content analyzer (LWCA) in which  
8 aerosol samples are collected on PTFE filters and then placed in a closed chamber in which the  
9 relative humidity is closely controlled. The aerosol mass is monitored using a beta-gauge, first  
10 as the relative humidity is increased from low RH to high RH, and then as the RH is decreased  
11 again. They demonstrated the LWCA on laboratory-generated aerosol and on an ambient  $PM_{2.5}$   
12 sample collected in Research Triangle Park, NC. The ambient aerosol sample was also analyzed  
13 for chemical constituents. It is interesting to note that, although their laboratory-generated  
14  $(NH_4)_2SO_4$  aerosol demonstrated a sharp deliquescent point, their atmospheric aerosol, which  
15 was essentially  $(NH_4)_2SO_4$ , did not show a sharp deliquescent point.

16 Hygroscopic properties of aerosols have been studied from the viewpoint of their ability to  
17 act as condensation nuclei. The hygroscopic properties of fresh and aged carbon and diesel soot  
18 particles were examined by Weingartner et al. (1997) who found that fresh, submicron-size  
19 particles tended to shrink with increasing relative humidity because of a structural change.  
20 Lammel and Novakov (1995) found, in laboratory studies, that the hygroscopicity of soot  
21 particles could be increased by chemical modification and that the cloud condensation nucleation  
22 characteristics of diesel soot were similar to those of wood smoke aerosol.

23 The results of several of the above studies in which aerosol water content as a function of  
24 relative humidity was determined are summarized in Figure 2-17. In this figure, the results of  
25 Lee et al. (1997), McInnes et al. (1996), and Ohta et al. (1998) are included. Relative humidity  
26 ranged from 9%, at which the aerosol water content was assumed to be zero (McInnes et al.,  
27 1996), to 89%, at which the aerosol water content was determined to be 66% by mass (Lee et al.,  
28 1997). Koutrakis et al. (1989) and Koutrakis and Kelly (1993) also have reported field  
29 measurements of the equilibrium size of atmospheric sulfate particles as a function of relative  
30 humidity and acidity.

31

**Figure 2-17. Aerosol water content expressed as a mass percentage, as a function of relative humidity.**

1           The effects of relative humidity on particle growth were also examined in several studies.  
 2 Fang et al. (1991) investigated the effects of flow-induced relative humidity changes on particle  
 3 cut sizes for aqueous sulfuric acid particles in a multi-nozzle micro-orifice uniform deposit  
 4 impactor (MOUDI). Laboratory experiments were conducted in which polydisperse sulfuric  
 5 acid aerosols were generated and the RH was adjusted. The aerosols were analyzed by a  
 6 differential mobility analyzer. Fang et al. (1991) observed that for inlet RH less than 80%, the  
 7 cut sizes for the sulfuric acid aerosols were within 5% of that for nonhygroscopic particles  
 8 except at the stage for which the cut size was 0.047  $\mu\text{m}$  where the cut size was 10.7% larger than  
 9 the nonhygroscopic particle cut size. They concluded that flow-induced RH changes would have  
 10 only a modest effect on MOUDI cut sizes at  $\text{RH} < 80\%$ .

11           Hitzenberger et al. (1997) collected atmospheric aerosol in the size range of 0.06 to 15  $\mu\text{m}$   
 12 in Vienna, Austria, using a nine-stage cascade impactor and measured the humidity-dependent  
 13 water uptake when the individual impaction foils were exposed to high RH. They observed  
 14 particle growth with varying growth patterns. Calculated extinction coefficients and single  
 15 scattering albedo increased with humidity.

16           Hygroscopic properties, along with mixing characteristics, of submicrometer particles  
 17 sampled in Los Angeles, CA, during the summer of 1987 SCAQS study and at the Grand

1 Canyon, AZ, during the 1990 Navajo Generating Station Visibility Study were reported by  
2 Zhang et al. (1993). They used a tandem differential mobility analyzer (TDMA; McMurry and  
3 Stolzenburg, 1989) to measure the hygroscopic properties for particles in the 0.05- to 0.5- $\mu\text{m}$   
4 range. In their experimental technique, monodisperse particles of a known size are selected from  
5 the atmospheric aerosol with the first DMA. Then, the relative humidity of the monodisperse  
6 aerosol is adjusted, and the new particle size distribution is measured with the second DMA.  
7 At both sites, they observed that monodisperse particles could be classified according to “more”  
8 hygroscopic and “less” hygroscopic. Aerosol behavior observed at the two sites differed  
9 markedly. Within the experimental uncertainty ( $\pm 2\%$ ) the “less” hygroscopic particles sampled  
10 in Los Angeles did not grow when the RH was increased to 90%; whereas at the Grand Canyon,  
11 the growth of the “less” hygroscopic particles varied from day to day, but ranged from near 0 to  
12 40% when the RH was increased to 90%. The growth of the “more” hygroscopic particles in  
13 Los Angeles was dependent on particle size (15% at 0.05  $\mu\text{m}$  to 60% at 0.5  $\mu\text{m}$ ); whereas at the  
14 Grand Canyon, the “more” hygroscopic particles grew by about 50% with the growth not  
15 varying significantly with particle size. By comparison of the TDMA data to impactor data,  
16 Zhang et al. (1993) surmised that the more hygroscopic particles contained more sulfates and  
17 nitrates while the less hygroscopic particles contained more carbon and crustal components.

18 Although most of the work to date on the hygroscopic properties of atmospheric aerosols  
19 has focused on the inorganic fraction, the determination of the contribution of particle-bound  
20 water to atmospheric particulate mass is greatly complicated by the presence of organics. The  
21 effect of RH on adsorption of semivolatile organic compounds is discussed elsewhere in this  
22 chapter. Saxena et al. (1995) observed that particulate organic compounds also can affect the  
23 hygroscopic behavior of atmospheric particles. They idealized the organic component of aerosol  
24 as containing a hydrophobic fraction (high-molecular weight alkanes, alkanolic acids, alkenolic  
25 acids, aldehydes, and ketones) and a hydrophilic fraction (e.g., lower molecular weight  
26 carboxylic acids, dicarboxylic acids, alcohols, aldehydes, etc.) that would be likely to absorb  
27 water. They then analyzed data from a tandem differential mobility analyzer in conjunction with  
28 particle composition observations from an urban site (Claremont, CA) and from a nonurban site  
29 (Grand Canyon) to test the hypothesis that, by adding particulate organics to an inorganic  
30 aerosol, the amount of water absorbed would be affected, and the effect could be positive or  
31 negative, depending on the nature of the organics added. They further presumed that the

1 particulate organic matter in nonurban areas would be predominantly secondary and thus  
2 hydrophilic, compared to the urban aerosol that was presumed to be derived from primary  
3 emissions and thus hydrophobic in nature. Their observations were consistent with their  
4 hypothesis, in that at the Grand Canyon, the presence of organics tended to increase the water  
5 uptake by aerosols; whereas at the Los Angeles site, the presence of organics tended to decrease  
6 water uptake.

7 Peng and Chan (2001) also recently studied the hygroscopic properties of nine water  
8 soluble organic salts of atmospheric interest using an electrodynamic balance operated at 25°C.  
9 Salts studied included sodium formate, sodium acetate, sodium succinate, sodium pyruvate,  
10 sodium methanesulfonate, sodium oxalate, ammonium oxalate, sodium malonate, and sodium  
11 maleate. They observed that hygroscopic organic salts have a growth factor of 1.76-2.18 from  
12 RH=10-90%, comparable to that of typical hygroscopic inorganic salts such as NaCl and  
13  $(\text{NH}_4)_2\text{SO}_4$ .

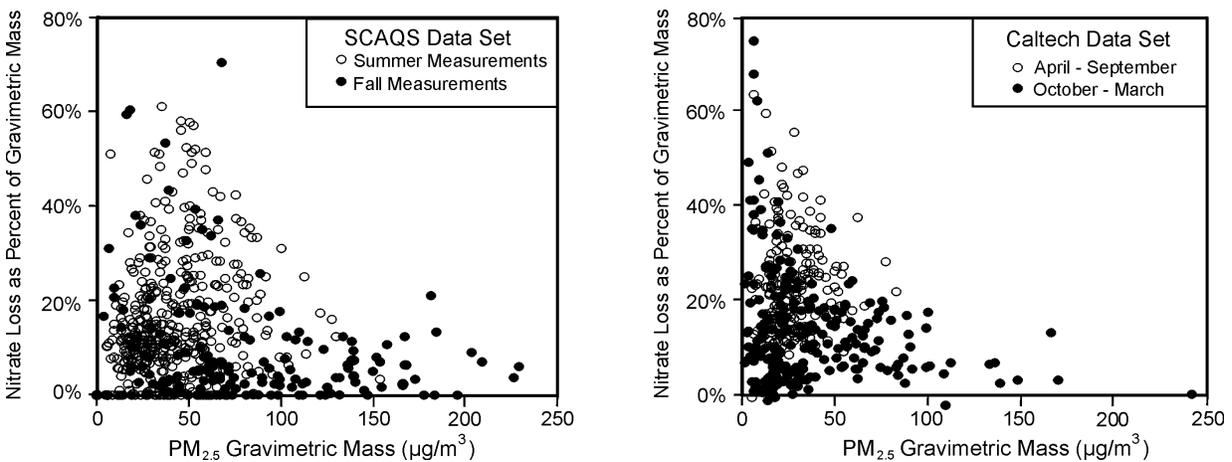

14 Nonequilibrium issues may be important for the TDMA, as well as for other methods of  
15 measuring water content. Although approach to equilibrium when the RH is increased is  
16 expected to be rapid for pure salts, it may be much slower for aerosols containing a complex mix  
17 of components (Saxena et al., 1995). For example, if an aerosol contains an organic film or  
18 coating, that film may impede the transport of water across the particle surface, thus increasing  
19 the time required for equilibrium (Saxena et al., 1995). Insufficient time to achieve equilibrium  
20 in the TDMA could result in underestimation of the water content.

### 22 **2.2.3.2 Nitrate and Organic Species**

#### 23 *Particulate Nitrates*

24 It is now well known that volatilization losses of particulate nitrates occur during sampling  
25 on Teflon filters (e.g., Zhang and McMurry [1992]; see also Hering and Cass [1999] and Babich  
26 et al., [2000]). The effect on the accuracy of atmospheric particulate measurements from these  
27 volatilization losses is more significant for  $\text{PM}_{2.5}$  than for  $\text{PM}_{10}$ . The FRM for  $\text{PM}_{2.5}$  will likely  
28 suffer loss of nitrates similar to that experienced with other simple filter collection systems.  
29 Sampling artifacts resulting from the loss of particulate nitrates represents a significant problem  
30 in areas such as southern California that experience high amounts of nitrates. Hering and Cass  
31 (1999) reported on errors in  $\text{PM}_{2.5}$  mass measurements due to volatilization of particulate nitrate

1 (Figure 2-18). They examined data from two field measurement campaigns conducted in  
2 southern California: (1) the Southern California Air Quality Study (SCAQS) (Lawson, 1990)  
3 and (2) the 1986 CalTech study (Solomon et al., 1992). In both these studies, side-by-side  
4 sampling of  $PM_{2.5}$  was conducted. One sampler collected particles directly onto a Teflon filter.  
5 The second sampler consisted of a denuder to remove gaseous nitric acid followed by a nylon  
6 filter that absorbs the  $HNO_3$  which evaporates from ammonium nitrate. In both studies, the  
7 denuder consisted of MgO-coated glass tubes (Appel et al., 1981). Fine particulate nitrate  
8 collected on the Teflon filter was compared to fine particulate nitrate collected on the denuded  
9 nylon filter. In both studies, the  $PM_{2.5}$  mass lost because of volatilization of ammonium nitrate  
10 represented a significant fraction of the total  $PM_{2.5}$  mass. The fraction of mass lost was higher  
11 during summer than during fall (17% versus 9% during the SCAQS study and 21% versus 13%  
12 during the CalTech study; Figure 2-18). In regard to percentage loss of nitrate, as opposed to  
13 percentage loss of mass discussed above, Hering and Cass (1999) found that nitrate remaining on  
14 the Teflon filter samples was on average 28% lower than that on the denuded nylon filters.  
15

**Figure 2-18. Amount of ammonium nitrate volatilized from Teflon filters, expressed as a percentage of the measured  $PM_{2.5}$  mass, for the SCAQS and CalTech studies, for spring and fall sampling periods.**

Source: Hering and Cass (1999).

1 Hering and Cass (1999) also analyzed these data by extending the evaporative model  
2 developed by Zhang and McMurry (1987). The extended model utilized by Hering and Cass  
3 (1999) takes into account dissociation of collected particulate ammonium nitrate on Teflon  
4 filters into nitric acid and ammonia via three mechanisms: (1) scrubbing of nitric acid and  
5 ammonia in the sampler inlet (John et al., 1988 showed that clean  $PM_{10}$  inlet surfaces serve as an  
6 effective denuder for nitric acid), (2) heating of the filter substrate above ambient temperature by  
7 sampling, and (3) pressure drop across the Teflon filter. For the sampling systems modeled, the  
8 flow-induced pressure drop was measured to be less than 0.02 atm, and the corresponding  
9 change in vapor pressure was 2%, so losses driven by pressure drop were not considered to be  
10 significant in this work. Losses from Teflon filters were found to be higher during the summer  
11 compared to the winter, higher during the day compared to night, and reasonably consistent with  
12 modeled predictions.

13 Finally, during the SCAQS study, particulate samples also were collected using a Berner  
14 impactor and greased Tedlar substrates in size ranges from 0.05 to 10  $\mu m$  in aerodynamic  
15 diameter. The Berner impactor  $PM_{2.5}$  nitrate values were much closer to those from the denuded  
16 nylon filter than those from the Teflon filter with the impactor nitrate being approximately  
17 2% lower than the nylon filter nitrate for the fall measurements and approximately 7% lower  
18 during the summer measurements. When the impactor collection was compared to the Teflon  
19 filter collection for a nonvolatile species (sulfate), the results were in agreement.

20 It should be noted that filters or collection surfaces were removed immediately after  
21 sampling and placed into vials containing a basic extraction solution during these  
22 intercomparison studies. Therefore, losses that might occur during handling, storage, and  
23 equilibration of filters or impaction surfaces were avoided. The loss of nitrate observed from  
24 Teflon filters and impaction surfaces in this study, therefore, is a lower limit compared to losses  
25 that might occur during the normal processes involved in equilibration and weighing of filters  
26 and impaction surfaces. Brook and Dann (1999) observed much higher nitrate losses during a  
27 study in which they measured particulate nitrate in Windsor and Hamilton, Ontario, Canada, by  
28 three techniques: (1) a single Teflon filter in a dichotomous sampler, (2) the Teflon filter in an  
29 annular denuder system (ADS), and (3) total nitrate including both the Teflon filter and the  
30 nylon back-up filter from the ADS. The Teflon filter from the dichotomous sampler averaged  
31 only 13% of the total nitrate. The Teflon filter from the ADS averaged 46% of the total nitrate.

1 The authors concluded that considerable nitrate was lost from the dichotomous sampler filters  
2 during handling, which included weighing and x-ray fluorescence (XRF) measurement in a  
3 vacuum.

4 Kim et al. (1999) also examined nitrate sampling artifacts by comparing denuded and  
5 undenuded quartz and nylon filters, during the PM<sub>10</sub> Technical Enhancement Program (PTEP) in  
6 the South Coast Air Basin of California. They observed negative nitrate artifacts (losses) for  
7 most measurements; however, for a significant number of measurements they observed positive  
8 nitrate artifacts. Kim et al. (1999) pointed out that random measurement errors make it difficult  
9 to measure true amounts of nitrate loss.

10 Diffusion denuder samplers, developed primarily to measure particle strong acidity  
11 (Koutrakis et al., 1988a,b, 1992), also can be used to study nitrate volatilization. Such  
12 techniques were used to measure loss of particulate nitrate from Teflon filters in seven U.S.  
13 cities (Babich et al., 2000). Measurements were made with two versions of the Harvard-EPA  
14 Annular Denuder System (HEADS). Nitric acid vapor was removed by a Na<sub>2</sub>CO<sub>3</sub>-coated  
15 denuder. Particulate nitrate was the sum of nonvolatile nitrate collected on a Teflon filter and  
16 volatilized nitrate collected on a Na<sub>2</sub>CO<sub>3</sub>-coated denuder downstream of the Teflon filter (full  
17 HEADS) or on a Nylon filter downstream of the Teflon filter (Nylon HEADS). It was found that  
18 full HEADS (using a Na<sub>2</sub>CO<sub>3</sub> denuder) consistently underestimated the total particulate nitrate  
19 by approximately 20% compared to the nylon HEADS. Nonvolatilized nitrate was also  
20 measured on a Teflon filter from collocated Harvard Impactors (HI). The PM<sub>2.5</sub> HI sampler, like  
21 the PM<sub>2.5</sub> FRM, use impactors with a 50% cut at 2.5 μm. The HI uses a 37 mm filter and a flow  
22 rate of 10 L/min (0.465 L/min/cm<sup>2</sup>) which the FRM uses a 47 mm filter and a flow rate of 16.7  
23 L/min (0.481 L/min/cm<sup>2</sup>). Therefore, the flow rate and pressure drop across the filters are  
24 similar and the loss of nitrate should be similar in both types of samples. Babich et al. (2000)  
25 found significant nitrate losses in Riverside, CA; Philadelphia, PA; and Boston, MA but not in  
26 Bakersfield, CA; Chicago, IL; Dallas, TX; or Phoenix, AZ where measurements were made only  
27 during winter.

28 Eatough et al. (1999a) developed a high-volume diffusion denuder system in which  
29 diffusion denuder and particle concentrator techniques were combined (see Section 2.2.3.2). The  
30 particle concentrator reduces the flow through the denuder so that the denuder can be operated  
31 for weeks without a loss of collection efficiency, making the sampler suitable for routine field

1 sampling. The system was evaluated for the collection of fine particulate sulfate and nitrate in  
2 Riverside, CA (Eatough et al., 1999b). Concentrations of PM<sub>2.5</sub> nitrate obtained from the PC-  
3 BOSS agreed with those obtained using the Harvard-EPA Annular Denuder Sampler, HEADS  
4 (Koutrakis et al., 1988b).

### 6 *Particulate Organic Compounds*

7 Many semivolatile organic compounds (SVOC) are of interest because of their possible  
8 health effects. SVOC include products of incomplete combustion such as polycyclic aromatic  
9 hydrocarbons (PAHs) and polycyclic organic matter, which has been identified as a hazardous  
10 air pollutant. PAHs also have been suggested as alternative particulate tracers for automobile  
11 emissions because the phase-out of organo-lead additives to gasoline means that lead is no  
12 longer a good tracer for automobiles (Venkataraman et al., 1994). PAHs also are emitted during  
13 biomass burning, including burning of cereal crop residues and wood fuels (Jenkins et al., 1996;  
14 Roberts and Corkill, 1998).

15 A number of studies have used absorbing material following quartz filters to determine  
16 phase equilibria of specific organic compounds (Liang et al., 1997; Gundel et al., 1995; Kamens  
17 et al., 1995). Much work has also gone into the development of a theory to help understand the  
18 phase relationships (Yamasaki et al., 1982; Rounds and Pankow, 1990; Pankow, 1987, 1994a,b;  
19 Pankow et al., 1993; Rounds et al., 1993; Odum et al., 1994). The theory describing phase  
20 equilibria of semivolatile organic compounds (SVOC) and the gas/particle partitioning of SVOC  
21 on inorganic, organic, and ambient smog aerosols continues to be developed (Liang et al., 1997;  
22 Jang et al., 1997, 1999; Strommen and Kamens, 1997; Jang and Kamens, 1998, 1999, 2001;  
23 Leach et al., 1999; Kamens et al., 1999, 2001).

24 The mass of organic and elemental carbon is usually determined by analysis of PM  
25 collected on a quartz filter. However, quartz fiber filters have a large specific surface area on  
26 which adsorption of gases can occur. Possible artifacts associated with adsorption of organic  
27 gases onto quartz filters have been examined in experiments in which two quartz fiber filters  
28 were deployed in series. The second quartz filter may indicate gaseous volatile organic  
29 compounds (VOC) adsorbed on both filters (positive artifact), SVOC evaporated from particles  
30 on the first filter and subsequently adsorbed on the second filter (negative artifact), or a  
31 combination of both effects. Unless the individual compounds are identified, the investigator

1 does not know what to do with the loading value on the second filter (i.e., to add or subtract from  
2 the first filter loading value). Moreover, even if the individual compounds were identified on the  
3 back-up filter, the decision concerning adding or subtracting the back-up filter loading would not  
4 be straightforward.

5 The positive quartz filter artifact has been discussed by Gundel et al. (1995) and Turpin  
6 et al. (2000). It is also possible that some SVOC may desorb from the filter resulting in a  
7 negative artifact (Eatough et al., 1993; Tang et al., 1994; Eatough et al., 1995; Gundel et al.,  
8 1995; Cui et al., 1998; Pang et al., 2001; Finn et al., 2001). Semivolatile organic compounds can  
9 similarly be lost from Teflon filters because of volatilization, causing the PM<sub>2.5</sub> mass to be  
10 significantly underestimated (negative artifact). Like particulate nitrates, the FRM for PM<sub>2.5</sub> will  
11 suffer loss of SVOC, similar to the losses experienced with other simple filter collection  
12 systems. Most studies that have focused on the positive and negative sampling artifacts  
13 associated with SVOC compounds have utilized either diffusion denuder technology (Eatough  
14 et al., 1995; Mader et al., 2001) or placed an adsorbent media, such as a back-up quartz filter or a  
15 polyurethane foam adsorbent behind the main filter (Wallace and Hites, 1995). Further  
16 information on denuder techniques are given in Appendix 2A.

17 Using their multichannel diffusion denuder sampling system (BOSS), Eatough et al. (1995)  
18 reported that, for samples collected at the South Coast Air Quality Management District  
19 sampling site at Azusa, CA, changes in the phase distribution of SVOC could result in a loss on  
20 average of 35% of the particulate organic material. Cui et al. (1998) found that losses of SVOC  
21 from particles in the Los Angeles Basin during the summer were greater during the night  
22 (average = 62%) than during the day (average = 42%).

23 The percent SVOC lost from the front filter in a filter-denuder system may be greater than  
24 that lost in a filter-only system such as the FRM. In a filter-denuder system, the gas-phase  
25 component of the SVOC is removed. The absence of the gas-phase causes the gas-particle  
26 equilibrium to shift so the SVOC collected on the filter may evaporate more rapidly in a filter-  
27 denuder system than in a filter-only collection system. To determine the fraction of SVOC lost  
28 from a Teflon filter in a filter-only system, it is necessary to compare the amount measured by a  
29 nondenuder system with that measured by a denuder system. At present, little information is  
30 available on the volatilization losses of SVOC. However, in one study (Pang et al., 2001), the  
31 total mass on denuded and undenuded filters were compared and found to be identical within

1 error limits ( $R^2 = 0.816$ , slope =  $0.961 \pm 0.027$  for total mass compared to  $R^2 = 0.940$ , slope =  
2  $0.986 \pm 0.020$  for sulfate). Pang et al. interpreted this result as suggesting that the major cause of  
3 loss of SVOC is the pressure drop across the filter.

4 Positive artifacts may occur during sample collection because of the adsorption of gases  
5 onto the filter materials (e.g., Gundel et al., 1995). Using a quartz filter behind a Teflon filter,  
6 Kim et al. (2001a) estimated that on an annual average basis 30% of the  $PM_{2.5}$  organic carbon  
7 concentration resulted from positive artifacts. There is a larger positive artifact because of  
8 greater adsorption of organic vapor onto quartz fiber filters than onto Teflon filters (Turpin et al.,  
9 1994; Chow et al., 1994a,b, 1996; Eatough et al., 1996; Finn et al., 2001; Kirchstetter et al.,  
10 2001).

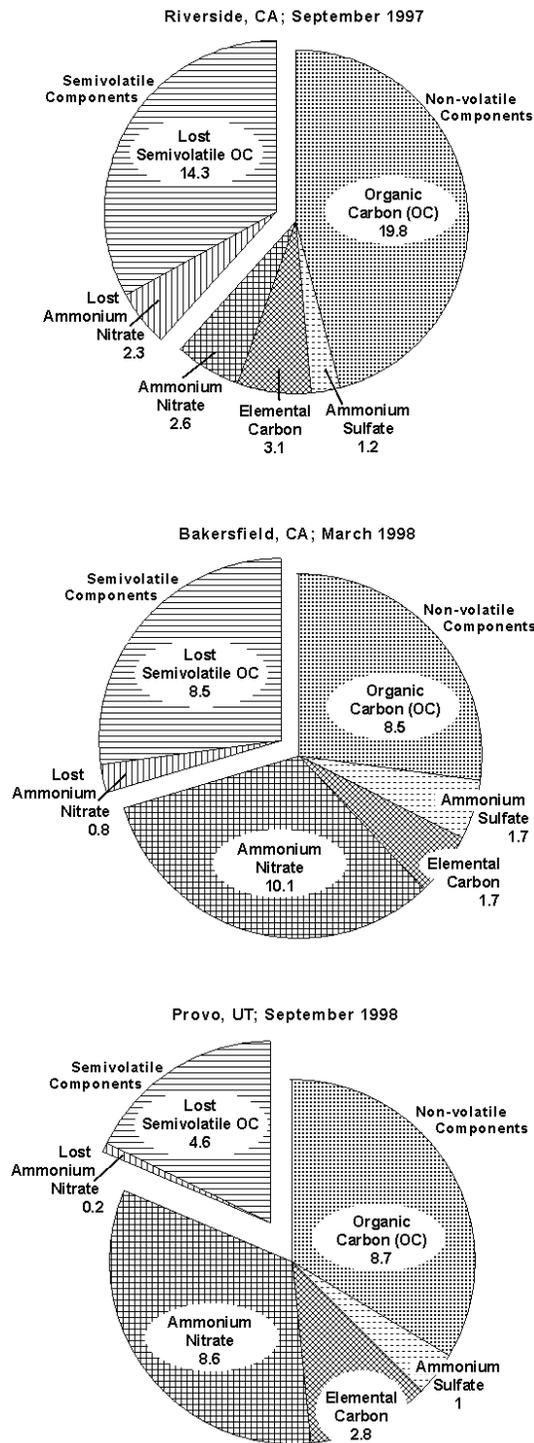

11 Kirchstetter et al. (2001) report that adsorptive properties of quartz fiber filters vary with  
12 lot number; therefore, front and back-up filters should be taken from the same lot. The literature  
13 suggests that a Teflon filter followed by a quartz back-up filter appears to provide a better  
14 estimate of the adsorption of gases on a quartz fiber front filter than does a quartz filter followed  
15 by a quartz backup and that the difference between these two adsorption estimates can be  
16 substantial for short durations (Novakov et al., 1997; Kirchstetter et al., 2001; Turpin et al.,  
17 2000). The typically lower organic carbon loadings on concurrently collected quartz followed  
18 by quartz filters relative to Teflon followed by quartz filters are believed to occur because  
19 adsorption on the quartz front filter acts to reduce the gas-phase concentration downstream until  
20 adsorption equilibrium has been achieved in the vicinity of the front quartz filter surface.  
21 Because Teflon filters have little affinity for organic vapors, this equilibrium occurs almost  
22 instantaneously for Teflon filters, and the Teflon-quartz back-up filter is exposed to the ambient  
23 concentration of organic vapors from the beginning of the sampling period. It might be expected  
24 that the quantity of organic vapor adsorbed on quartz filters would depend on the organic  
25 composition and would vary by season and location. However, it is also possible that the quartz  
26 possesses a limited number of adsorption sites which are rapidly occupied so that the quantity of  
27 OC on the back up filter would be relatively constant and depend on the pretreatment of the  
28 quartz.

1 *Combined Measurement of Semivolatile Nitrate and OC and Nonvolatile Species (OC, EC,*  
2 *Nitrate, and Sulfate)*

3 Fine particles in urban atmospheres contain substantial quantities of semivolatile material  
4 (e.g.,  $\text{NH}_4\text{NO}_3$  and semivolatile organic compounds [SVOC]) that are lost from particles during  
5 collection on a filter. Several diffusion denuder samplers have been developed for the  
6 determination of both  $\text{NO}_3^-$  and organic semivolatile fine particulate components as well as  
7 nonvolatile nitrate and organic compounds and nonvolatile sulfate (Pang et al., 2001; Eatough  
8 et al., 1993). The combination of technology used in the BOSS diffusion denuder sampler and  
9 the Harvard particle concentrator has resulted in the Particle Concentrator-Brigham Young  
10 University Organic Sampling System (PC-BOSS) for the 24-hr integrated collection of  $\text{PM}_{2.5}$ ,  
11 including  $\text{NH}_4\text{NO}_3$  and semivolatile organic material. Modifications of the BOSS sampler allow  
12 for the determination of these same species on a time scale from a few hours to weekly (Ding et  
13 al., 2002; Eatough et al., 1999a,b; 2001). Episodic studies have been conducted in Riverside,  
14 CA and Bakersfield, CA (Obeidi et al., 2002) and Provo, UT (Obeidi and Eatough, 2002). The  
15 average concentration of semivolatile and nonvolatile components in the three cities, during the  
16 study periods, are shown in Figure 2-19.

17  
18 **2.2.3.3 Continuous Measurement of Semivolatile and Nonvolatile Mass**

19 Techniques for the continuous measurement of PM mass is needed both to provide  
20 real-time information on pollution levels (Long et al., 2002) and to reduce the costs involved in  
21 visiting sites to change filters and in the equilibration and weighing of filters. Two techniques  
22 are currently in use for the continuous measurement of PM mass. The TEOM is normally  
23 operated at 50° C in order to remove particle-bound water. However, at 50° C most semivolatile  
24 material is also evaporated. Therefore, the TEOM, operated at 50° C, may be considered to  
25 measure the mass of nonvolatile PM. The beta gauge mass monitor changes the filter more  
26 frequently than the TEOM and is less sensitive to changes in mass caused by changes in relative  
27 humidity. It does not control the temperature at the filter. However, most beta gauge monitors  
28 heat the inlet. This heating causes evaporation of a substantial fraction of the particle-bound  
29 water and an unknown fraction of the semivolatile PM. Thus, the beta gauge may be considered  
30 to measure the nonvolatile PM plus a small fraction of the particle-bound water and an unknown  
31 fraction of the semivolatile PM. Three new techniques have been developed to address the issue  
32 of lost semivolatile PM mass.

**Figure 2-19. Average concentration of nonvolatile and semivolatile PM components in three cities ( $\mu\text{g}/\text{m}^3$ ).**

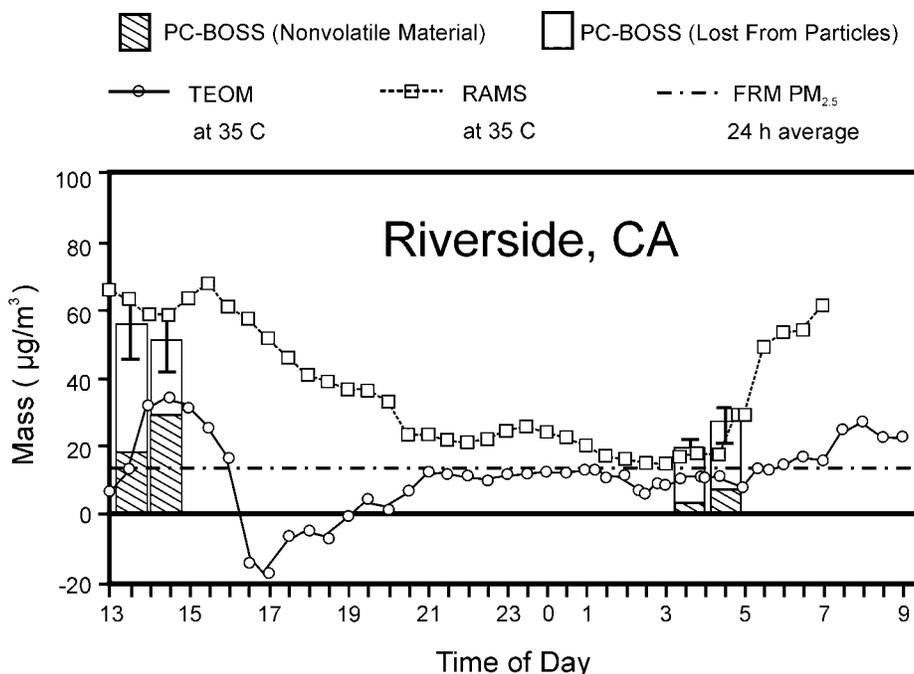

Source: Obeidi and Eatough (2002); Obeidi et al. (2002).

### ***Real-Time Total Ambient Mass Sampler (RAMS)***

The RAMS, a monitor based on diffusion denuder and TEOM monitor technology, has been developed, validated, and field tested for the real-time determination of total fine PM mass, including semivolatile PM (Eatough et al., 1999a; Obeidi and Eatough, 2002; Obedi et al., 2002; Pang et al., 2001). The RAMS measures the total mass of collected particles including semivolatile species with a TEOM monitor using a “sandwich filter.” The sandwich contains a Teflon coated particle collection filter followed by a charcoal-impregnated filter (CIF) to collect any semivolatile species lost from the particles during sampling. Because the instrument measures total mass collected by the sandwich filter, all gas phase compounds that can be adsorbed by a CIF must be removed from the sampling stream prior to the TEOM monitor. Laboratory and field validation data indicate that the precision of fine PM mass determination is better than 10%. The RAMS uses a Nafion dryer to remove particle-bound water from the suspended particles and a particle concentrator to reduce the amount of gas phase organics that must be removed by the denuder. An example of data from the RAMS, the TEOM, and the PC-BOSS is shown in Figure 2-20. This figure also shows the PM<sub>2.5</sub> mass from the TEOM as being negative for the hours of 16 to 19. This likely results from the loss of volatile materials from the heated filter.

### ***Differential TEOM***

Patashnick et al. (2001) developed a differential TEOM system that is based on a pair of TEOM sensors, each of which is preceded by its own electrostatic precipitator (ESP) and downstream from a common size selective inlet. By alternately switching the ESPs on and off and out of phase with each other, the two sensors measure “effective mass” that includes both the nonvolatile component and the volatile component sampled by the TEOM, less the volatile component that vaporized during the sampling interval. On the sensor side with the ESP turned on, there is no particle collection on that filter so that only volatilization of previously collected particles continues. This allows a correction for the effective mass as measured by the first sensor by subtracting out the volatilization artifact and leaving the nonvolatile and volatile components of the particulate matter. This system has yet to be well characterized for other biases or interferences such as reactions on the filters, particle collection efficiency of the ESPs, and particle and semivolatile material losses.

**Figure 2-20. Comparison of mass measurements with collocated RAMS (real-time data), PC-BOSS (1-h data), FRM PM<sub>2.5</sub> sampler (average of 24-h data), and a conventional TEOM monitor (real-time data). The semivolatile fine particulate matter is sampled with the RAMS and PC-BOSS, but not with the TEOM monitor or the FRM PM<sub>2.5</sub> single filter sampler. The PC-BOSS provides information on both the nonvolatile component (NV) and the semivolatile organic component (SVOC).**

Source: Eatough et al. (1999a).

1 ***Continuous Ambient Mass Monitor (CAMM)***

2 Koutrakis and colleagues (Koutrakis et al., 1996; Wang, 1997) have developed CAMM, a  
 3 technique for the continuous measurement of ambient particulate matter mass concentration  
 4 based on the measurement of pressure drop increase with particle loading across a membrane  
 5 filter. Recently, Sioutas et al. (1999) examined the increase in pressure drop with increasing  
 6 particle loading on Nuclepore filters. They tested filters with two pore diameters (2 and 5 µm)  
 7 and filter face velocities ranging from 4 to 52 cm s<sup>-1</sup> and examined the effects of relative  
 8 humidity in the range of 10 to 50%. They found that, for hygroscopic ammonium sulfate  
 9 particles, the change in pressure drop per unit time and concentration was a strong function of

1 relative humidity, decreasing with increasing relative humidity. These results suggest that  
2 particulate concentration measurements, similar to the method of Koutrakis et al. (1996) that  
3 uses the pressure drop method, may be subject to additional uncertainties if used in an  
4 environment where the ambient relative humidity is quite variable and the relative humidity  
5 where the particles are measured cannot be controlled accurately. The current version of the  
6 CAMM (Wang, 1997) uses a particle concentrator, a Nafion dryer, and frequently moves the  
7 filter tape to avoid artifacts due to evaporation of semivolatile components from the active  
8 portion of the filter tape which would occur if the atmospheric concentration of the semivolatile  
9 components decreased.

10 The CAMM was recently operated alongside a gravimetric PM method (the Harvard  
11 Impactor, or HI) in seven U.S. cities selected for their distinctly different ambient particulate  
12 compositions and densities. The correlation between the two methods was high, with an overall  
13  $r^2$  of 0.90 and average CAMM/HI ratio of 1.07 (Babich et al., 2000).

## 14 15 **2.2.4 U. S. Environmental Protection Agency Monitoring Methods**

### 16 **2.2.4.1 The Federal Reference Methods for Measurement of Equilibrated Mass for $PM_{10}$ , 17 $PM_{2.5}$ , and $PM_{10-2.5}$**

18 In 1997, EPA promulgated new standards for  $PM_{2.5}$  to address fine-fraction thoracic  
19 particles and retained with minor revisions the 1987  $PM_{10}$  standards to continue to address  
20 coarse-fraction thoracic particles (Federal Register, 1997). In partial response to numerous  
21 challenges to these standards, the U.S. Court of Appeals for the District of Columbia Circuit in  
22 *American Trucking Association v. EPA*, 175 F. 3d 1027 (U.S. Court of Appeals, D.C. Cir. 1999)  
23 found “ample support” for regulating coarse-fraction particles but revoked the revised  $PM_{10}$   
24 standards (leaving in effect the 1987  $PM_{10}$  standards) on the basis of  $PM_{10}$  being a “poorly  
25 matched indicator for coarse particulate pollution” because  $PM_{10}$  includes fine particles.  
26 Consistent with this specific aspect of the Court’s ruling, which EPA did not appeal, EPA is now  
27 considering use of  $PM_{10-2.5}$  as the indicator for coarse-fraction thoracic particles, in conjunction  
28 with  $PM_{2.5}$  standards that address fine-fraction thoracic particles. Thus, EPA is now developing  
29 a Federal Reference Method for the measurement of  $PM_{10-2.5}$ .

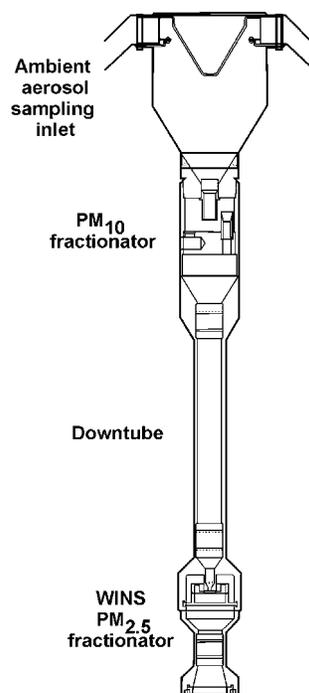

#### 1 **2.2.4.1.1 PM<sub>10</sub>**

2 The FRM specified for measuring PM<sub>10</sub> (Code of Federal Regulations, 2001a,b) has been  
3 discussed in previous PM AQCD's and will only be mentioned briefly. The PM<sub>10</sub> FRM defines  
4 performance specifications for samplers in which particles are inertially separated with a  
5 penetration efficiency of 50% at an aerodynamic diameter (D<sub>a</sub>) of 10 ± 0.5 μm. The collection  
6 efficiency increases to ≈100% for smaller particles and drops to ≈ 0% for larger particles.  
7 Particles are collected on filters and mass concentrations are determined gravimetrically.  
8 Instrument manufacturers are required to demonstrate through field tests a measurement  
9 precision for 24-h samples of ± 5 μg/m<sup>3</sup> for PM<sub>10</sub> concentrations below 80 μg/m<sup>3</sup> and 7% above  
10 this value. A number of samplers have been designated as PM<sub>10</sub> reference samplers. The TEOM  
11 and several beta gauge samplers with 1-h time resolution have been designated as automated  
12 equivalent methods (U.S. Environmental Protection Agency, 2001).

#### 14 **2.2.4.1.2 PM<sub>2.5</sub>**

15 In contrast to the performance-based FRM standard for PM<sub>10</sub>, the FRM for PM<sub>2.5</sub> (Code of  
16 Federal Regulations, 2001a) specifies certain details of the sampler design, as well as of sample  
17 handling and analysis, whereas other aspects have performance specifications (Noble et al.,  
18 2001). The PM<sub>2.5</sub> FRM sampler consists of a PM<sub>10</sub> inlet/impactor, a PM<sub>2.5</sub> impactor with an oil-  
19 soaked impaction substrate to remove particles larger than 2.5 μm D<sub>a</sub>, and a 47-mm PTFE filter  
20 with a particle collection efficiency greater than 99.7%. The sample duration is 24 h, during  
21 which time the sample temperature is not to exceed ambient temperatures by more than 5 °C.  
22 A schematic diagram of the PM<sub>2.5</sub> FRM sample collection system is shown in Figure 2-21. After  
23 collection, samples are equilibrated for 24 h at temperatures in the range of 20 to 23 °C (± 2 °C)  
24 and at relative humidities in the range of 30 to 40% (± 5%). The equilibration tends to reduce  
25 particle-bound water and stabilizes the filter plus sample weight. Filters are weighed before and  
26 after sampling under the same temperature and relative humidity conditions. For sampling  
27 conducted at ambient relative humidity less than 30%, mass measurements at relative humidities  
28 down to 20% are permissible (Code of Federal Regulations, 2001a).

29 The PM<sub>10</sub> inlet specified for the PM<sub>2.5</sub> FRM is modified from a previous low flow-rate  
30 PM<sub>10</sub> inlet that was acceptable in both EPA-designated reference and equivalent PM<sub>10</sub> methods.  
31 The modification corrects a flaw that was reported for the previous sampler, in that under some

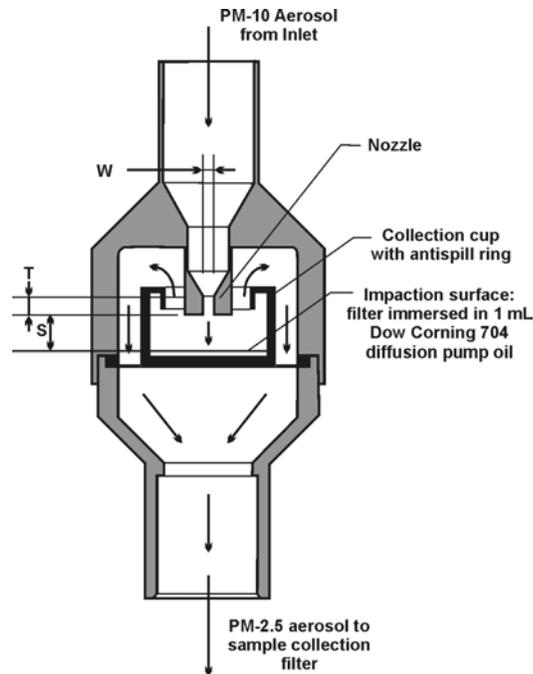

**Figure 2-21. Schematic diagram of the sample collection portion of the PM<sub>2.5</sub> FRM sampler.**

Source: Noble et al. (2001).

1 meteorological conditions, the inlet may allow precipitation to penetrate the inlet. The  
 2 modification includes a larger drain hole, a one-piece top plate, and louvers. Tolocka et al.  
 3 (2001a) evaluated the performance of this modified inlet in a series of wind tunnel experiments.  
 4 The modified inlet was found to provide a size cut comparable to the original inlet, for both  
 5 PM<sub>2.5</sub> and PM<sub>10</sub> sampling. Since the modification did not change the characteristics of the size  
 6 cut, the modified inlet may be substituted for the original inlet as part of a reference or  
 7 equivalent method for PM<sub>10</sub> and PM<sub>2.5</sub> (Tolocka et al., 2001a).

8

9 **WINS Impactor.** Design and calibration of the EPA PM<sub>2.5</sub> Well Impactor Ninety-Six  
 10 (WINS) is given by Peters et al. (2001a). The WINS impactor was designed to be deployed  
 11 downstream of the Graseby-Andersen 246B PM<sub>10</sub> inlet as part of a sampler operating at a flow  
 12 rate of 16.7 L/m. The WINS is pictured in Figure 2-22. The PM<sub>2.5</sub> inlet consists of a single jet,  
 13 directed toward a round hole, with a jet exit impaction surface comprised of a 37 mm diameter

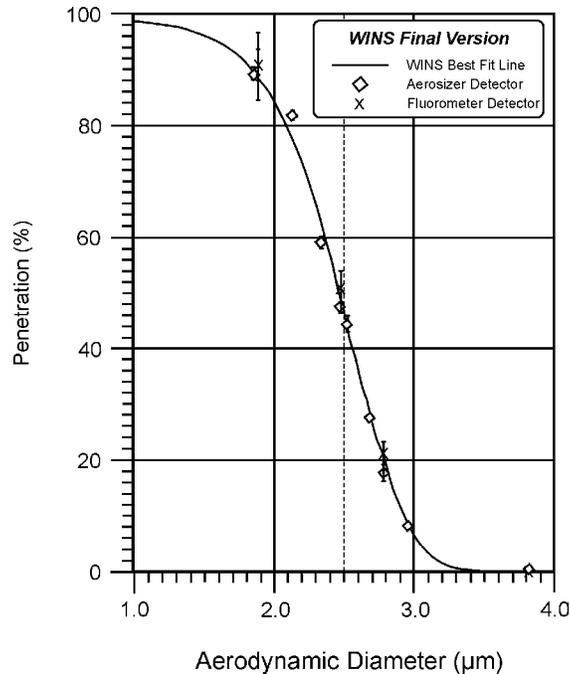

**Figure 2-22. Schematic view of the final design of the WINS.**

Source: Peters et al. (2001a).

1 glass fiber filter immersed in 1 ml of low volatility diffusion pump oil (i.e., the well). Particles  
 2 not having enough inertia to be removed by the impactor are captured downstream on the sample  
 3 collection filter. This design was selected to minimize impactor overloading that would  
 4 otherwise result in particle bounce. The oil wicks through the particulate deposit on the  
 5 impactor to provide a continuously wetted surface for impaction. The penetration curve  
 6 indicated a 50% cutpoint of  $2.48 \mu\text{m } D_a$  with a geometric standard deviation of 1.18  
 7 (Figure 2-23).

8 The WINS separator was evaluated for its loading characteristics (Vanderpool et al., 2001)  
 9 by monitoring the performance after repeated operation in an artificially generated, high  
 10 concentration, coarse-mode aerosol composed of Arizona Test Dust, as well as in the field in  
 11 Rubidoux, Phoenix, Philadelphia, Research Triangle Park, and Atlanta. In the wind tunnel  
 12 experiments, the WINS performance was found to be a monotonic function of loading. A minus  
 13 5% bias in the  $\text{PM}_{2.5}$  measurement resulted from a coarse particulate loading of approximately  
 14 16 mg. This negative bias was due to a slight reduction in the separator cutpoint. It was also

**Figure 2-23. Evaluation of the final version of the WINS.**

Source: Peters et al. (2001a).

1 found that the predictable results from the controlled laboratory experiments could not be  
 2 extrapolated to field settings and that the WINS performance was more sensitive to the impactor  
 3 loading in the field than it was in experiments with the single component aerosol. Significant  
 4 particle bounce was not observed in either the laboratory or the field experiments. Vanderpool  
 5 et al. (2001) concluded that their study supports the recommendation that the FRM WINS wells  
 6 should be replaced after every 5 days of 24-h operation (U.S. Environmental Protection Agency,  
 7 1998).

8 A detailed sensitivity study of the WINS impactor was conducted (Vanderpool et al., 2001)  
 9 in which the effects on the impactor performance of a number of parameters were examined.  
 10 The results of this study are summarized in Table 2-3.

11 The regulations also allow for Class I, II, and III equivalent methods for PM<sub>2.5</sub> (Code of  
 12 Federal Regulations, 2001c). Class I equivalent methods use samplers with relatively small  
 13 deviations from the sampler described in the FRM. Class II equivalent methods include “all  
 14 other PM<sub>2.5</sub> methods that are based upon 24-h integrated filter samplers that are subjected to

**TABLE 2-3. SUMMARY OF SENSITIVITY STUDIES OF WINS IMPACTOR PERFORMANCE**

<b>Parameter</b>	<b>Amount of variance</b>	<b>Cutpoint variation</b>	<b>PM<sub>2.5</sub> mass concentration bias</b>
Manufacturing tolerances on WINS components	Specified tolerances	0.05 micrometers	<1%
Flow control biases	4%	0.05 micrometers	Cutpoint shift partially offset volume bias
T and P measurement	Allowable ambient	± 0.02 micrometers	± 0.4%
Diffusion oil volume	0.75 ml to 3 ml	No effect	
Impactor loading	After 5 24 h events	-0.07 micrometers	<1.5%
Ambient P variations		Negligible	Negligible
Air Properties	0 C	2.40 micrometers	NA
Impactor oil crystallization		No effect	No effect
Impactor oil viscosity	-20 C	No effect	No effect
	-35 C	Need to change WINS more frequently than every 5 days

subsequent moisture equilibration and gravimetric mass analysis.” Class III equivalent methods include non-filter-based methods such as beta attenuation, harmonic oscillating elements, or nephelometry (McMurry, 2000). As of July 2001, 11 PM<sub>2.5</sub> samplers (listed in Table 2-4) had been tested and led to the conclusion that the PM<sub>10</sub> sampling systems can be designed such that concentration measurements are precise to ± 10%. For PM<sub>2.5</sub>, cutpoint tolerances are not expected to affect the mass concentration as much as for PM<sub>10</sub>, because the 2.5 μm D<sub>a</sub> cutpoint generally occurs near a minimum in the mass distribution (e.g., Figure 2-5).

The PM<sub>2.5</sub> mass concentration will be affected, on the other hand, by other sampling issues mentioned but not discussed extensively in the previous 1996 PM AQCD (U.S. Environmental Protection Agency, 1996a). These issues have been discussed earlier in this chapter and include gas/particle, particle/particle, and particle/substrate interactions for sulfates and nitrates (e.g., Appel et al., 1984), volatilization losses of nitrates (Zhang and McMurry, 1992), semivolatile organic compound artifacts (e.g., Eatough et al., 1993), and relative humidity effects (e.g., Keeler et al., 1988).

1           Several studies now have been reported in which the FRM was collocated with other PM<sub>2.5</sub>  
2 samplers in intercomparison studies. During the Aerosol Research and Inhalation Epidemiology  
3 Study (ARIES), several PM<sub>2.5</sub> samplers were collocated at a mixed industrial-residential site near  
4 Atlanta, GA (Van Loy et al., 2000). These samplers included a standard PM<sub>2.5</sub> FRM, a TEOM  
5 with Nafion drier, a particulate composition monitor (PCM; Atmospheric Research and  
6 Analysis, Cary, NC), a medium-volume (113 L/min flow rate) fine particle (PM<sub>2.5</sub>) and  
7 semivolatile organic compound (i.e., a filter followed by a solid adsorbent) sampler, operated by  
8 the Desert Research Institute, a HEADS sampler, and a dichotomous sampler for coarse PM.  
9 The PCM sampler has three channels, all of which have PM<sub>10</sub> cyclone inlets. The first two  
10 channels both have two denuders preceding a 2.5- $\mu$ m WINS impactor and filter packs. The first  
11 denuder is coated with sodium carbonate to remove acid gases, and the second is coated with  
12 citric acid to remove ammonia. The third channel has a carbon coated parallel-plate denuder  
13 preceding the WINS impactor. Measurements of 24-h mass from the FRM, PCM, and TEOM  
14 samplers, as well as reconstructed PM<sub>2.5</sub> mass (RPM), were compared for a 12-mo period. The  
15 slopes for the TEOM-FRM, PCM-FRM, and RPM-FRM correlations were 1.01, 0.94, and 0.91,

1 respectively; whereas the y-intercepts for each were 0.68, 0.04, and 0.98. Particulate sulfate  
2 measurements on the FRM Teflon filter, the PCM Teflon filter, and PCM Nylon filter were  
3 nearly identical. Nitrate results from the three filters were much less consistent, with the FRM  
4 collecting substantially less nitrate than that collected on either the denuded nylon filter or a  
5 denuder followed by a Teflon-nylon filter sandwich. Particulate ammonia measurements were  
6 also compared and showed more scatter than the sulfate measurements but less than the nitrate  
7 measurements.

8 An intercomparison of both  $PM_{10}$  and  $PM_{2.5}$  mass measurements was conducted during the  
9 1998 Baltimore PM Study (Williams et al., 2000). PM monitors were collocated at a residential  
10 indoor, residential outdoor, and ambient monitoring site within Baltimore County, MD. PM  
11 samplers included TEOMs,  $PM_{2.5}$  FRMs, cyclone-based inlets manufactured by University  
12 Research Glassware (URG), and Versatile Air Pollution Samplers (VAPS). The VAPS sampler  
13 is a dichotomous sampler operating at 33 L/min (one coarse particle channel at 3 L/min, and two  
14 fine particle channels at 15 L/min, each). In the configuration employed during this study, one  
15 fine particle channel was operated with a Teflon filter backed by a nylon filter and preceded by a  
16 sodium carbonate coated annular denuder; the second fine particle channel had a quartz filter  
17 preceded by a citric acid-coated annular denuder; and the coarse particle channel had a  
18 polycarbonate filter followed by a Zefluor filter for flow distribution. Differences in  $PM_{2.5}$  mass  
19 concentrations between the samplers, although not large, were attributed to potential particle  
20 nitrate losses, denuder losses, and losses of SVOC for some samplers. Differences between  
21 coarse particulate mass concentrations, on the other hand, varied widely between the  
22 instruments.

23 In another intercomparison study, Tolocka et al. (2001b) examined the magnitude of  
24 potential sampling artifacts associated with the use of the FRM by collocating FRMs alongside  
25 other chemical speciation samplers at four U.S. cities. The locations included a high nitrate and  
26 carbon, low sulfate site (Rubidoux, CA); high crustal, moderate carbon and nitrate site  
27 (Phoenix); high sulfate, moderate carbon, and low nitrate (Philadelphia); and low  $PM_{2.5}$  mass  
28 (Research Triangle Park, NC). The use of Teflon and heat-treated quartz filters was also  
29 examined in this study. The Teflon filters collected less nitrate than the heat-treated quartz  
30 filters. Filters in samplers using denuders to remove organic gases collected less organic PM  
31 than filters in samplers without denuders.

1 Peters et al. (2001b) compiled the results of several field studies in which a number of  
2 FRM and other PM<sub>2.5</sub> samplers were intercompared. In addition to the FRM samplers listed in  
3 Table 2-3, other PM<sub>2.5</sub> samplers included the Sierra Instruments dichotomous sampler, the  
4 Harvard impactor, the IMPROVE sampler, and the Air Metrics saturation monitor. Results were  
5 compiled from PM<sub>2.5</sub> field studies conducted in Birmingham, Denver, Bakersfield, Phoenix,  
6 Research Triangle Park, Atlanta, and Rubidoux. Limited studies on precision for the non-FRM  
7 samplers suggest that the Harvard Impactor and dichotomous samplers had the lowest coefficient  
8 of variations (CV), with both under 10%. The CV for this study was calculated by dividing the  
9 sample standard deviation by the average concentration. The IMPROVE samplers had CVs  
10 between 10 and 12%, and the Air Metrics samplers had the highest observed CVs, over 15%.  
11 In intercomparisons with FRM samplers, the non-FRM samplers showed strong linear  
12 relationships in comparison to the FRM sampler; however, none of the comparisons passed the  
13 current EPA Subpart C equivalent method criteria, which EPA is in the process of revising.

14 Detailed information on precision of PM samplers used in monitoring networks may be  
15 found in EPA's Technology Transfer Network website (U.S. Environmental Protection Agency,  
16 2002a).

#### 17 18 **2.2.4.1.3 PM<sub>10-2.5</sub>**

19 Measurement techniques for PM<sub>10-2.5</sub> are somewhat more complex than those for PM<sub>2.5</sub> or  
20 PM<sub>10</sub> because, for PM<sub>10-2.5</sub>, it is necessary to isolate a size fraction between an upper 50% cut  
21 point of 10 μm D<sub>a</sub> and a lower 50% cut point of 2.5 μm D<sub>a</sub>. EPA is currently developing an  
22 FRM for PM<sub>10-2.5</sub>. Several candidate techniques are discussed below.

23  
24 ***The Difference Method.*** One approach to measurement of PM<sub>10-2.5</sub> is to make separate  
25 measurements of PM<sub>10</sub> and PM<sub>2.5</sub> and take the difference of the resulting equilibrated masses.  
26 One problem is that, if either the PM<sub>2.5</sub> or the PM<sub>10</sub> sampler fails, no PM<sub>10-2.5</sub> measurement can be  
27 obtained. In addition, errors in cut-point, flow rate, and filter weights (both before use and after  
28 collection and equilibration of particles) and uncertainties due to loss of semivolatile  
29 components of PM may occur for each size cut. Careful control of flow rate and equivalent  
30 treatment of PM<sub>10</sub> and PM<sub>2.5</sub> filters in terms of pressure drop across the filter and temperature of  
31 the filter during and after collection can improve precision and accuracy. Allen et al. (1999a)

1 summarized several sampling issues to consider in measuring coarse particulate mass by  
2 difference, including the use of identical instrumentation (except cutpoints), filter media, filter  
3 face velocity, and ambient-filter temperature differences; common flow measurement devices;  
4 use of higher sampler flow rates (10 L/min minimum for 24-h sample is recommended); and  
5 avoiding excessive filter loading. The concern, expressed by Allen et al. (1999a), that the “pie-  
6 plate” inlet required by the final version of the PM<sub>2.5</sub> FRM might have a different cut point than  
7 the “flat-top” inlet of the PM<sub>10</sub> FRM, has been addressed by a wind tunnel study which found  
8 both to have an appropriate PM<sub>10</sub> cut point (Tolocka et al., 2001a).

9 Since the difference method requires weighing two filters, the key to obtaining high  
10 precision in the coarse mass measurement is precise measurements of filter weights. Allen et al.  
11 (1999a) discuss techniques for increasing the precision of the difference method by reducing  
12 errors in filter weights. These include proper temperature and humidity controls, use of a high  
13 quality microbalance, 100% replicate weighings, control of static charge, aging of new filters,  
14 weighing of a sufficient number of laboratory blank filters, and accounting for buoyancy errors  
15 caused by variability in barometric pressure. Allen et al. (1999a) emphasize the necessity of  
16 replicate weighing of filters and a third weighing if the difference between the first two weights  
17 exceeds a specified minimum. Lawless et al. (2001) investigated the magnitude of uncertainties  
18 attributed to fluctuations in some of these parameters (humidity, temperature, drafts, vibration,  
19 and electrostatic charges) and recommended methods for improving their control. Koistinen  
20 et al. (1999) and Hänninen et al. (2002) give an excellent discussion of the procedures developed  
21 to overcome problems associated with gravimetric measurements of PM<sub>2.5</sub> mass in the EXPOLIS  
22 (The Air Pollution Exposure Distributions Within Adult Urban Populations in Europe) Study.  
23 They discuss factors such as corrections for buoyancy, elimination of static charge, and increases  
24 in the mass of blank filters with time. The establishment of a temperature and humidity  
25 controlled room required for the equilibration and weighing of filters for the FRM is expensive.  
26 Allen et al. (2001) describe a more cost-effective technique that uses a chamber with relative  
27 humidity controlled at 34% relative humidity by a saturated aqueous solution of MgCl<sub>2</sub>.

28 Allen et al. (1999a) recommend that, in reporting precision from collocated samplers both  
29 the (CV) and the square of the correlation coefficient ( $r^2$ ) be reported. For a study in Boston with  
30 27 pairs of mass data from collocated PM<sub>10</sub> and PM<sub>2.5</sub> using standard weighing methods, they  
31 obtained a CV of 4.7% and an  $r^2$  of 0.991 for PM<sub>2.5</sub>, a CV of 4.4% and an  $r^2$  of 0.994 for PM<sub>10</sub>,

1 and a CV of 15% and an  $r^2$  of 0.88 for  $PM_{10-2.5}$ . By using duplicate weighings and other  
2 techniques suggested for improving precision, they obtained a CV of 1.3% and an  $r^2$  of 0.998 for  
3  $PM_{2.5}$  in a study in Chicago with 38 collocated measurements. On the basis of the improvement  
4 in the CV for  $PM_{2.5}$ , they estimate that use of the recommended techniques for  $PM_{10-2.5}$  by  
5 difference would have yielded a CV of 3.8% and an  $r^2$  of 0.98 if they had been applied in the  
6 Chicago study.

7  
8 ***Multistage Impaction.*** A second technique involves the use of impaction to isolate the  
9 size fraction between 2.5 and 10  $\mu m D_a$ . In the impaction process, the air stream is first  
10 accelerated through a small hole (nozzle) or slit. The air stream is directed so that it “impacts”  
11 on a surface. Depending on the velocity and pressure of the air stream, particles smaller than a  
12 certain size will follow the air stream around the impactor surface. Larger particles will impact  
13 on the surface. In practice, impactors have 50% cut points similar to those for the rejection of  
14 larger particles in  $PM_{2.5}$  and  $PM_{10}$  samples (see Figure 2-6).

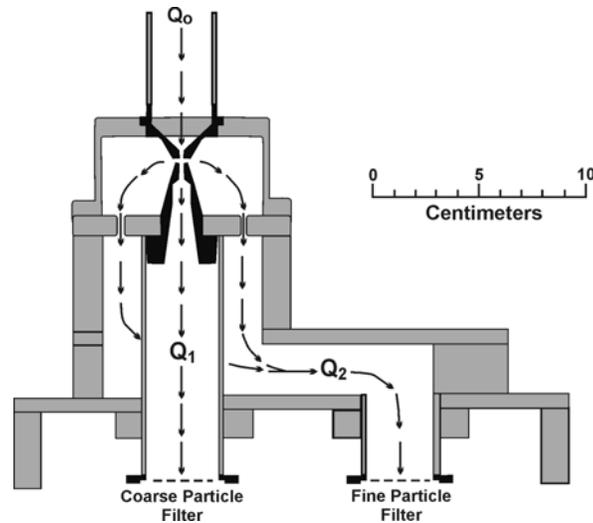

15 Multistage impactors are used to separate particles into several size fractions for the  
16 determination of mass and chemical composition as a function of size (Wang and John, 1988;  
17 Marple et al., 1991). The major problem with the use of impactors to separate the 10-2.5  $\mu m D_a$   
18 fraction of coarse particles (thoracic coarse PM) is bounce. Coarse particles tend to be dry, solid  
19 particles. When they hit a hard surface, they can bounce and be carried away with the air stream  
20 (e.g., Dzubay et al., 1976; Wesolowski et al., 1977; Rao and Whitby, 1978; Cheng and Yeh,  
21 1979; Wang and John, 1987; John and Sethi, 1993). Various techniques have been used to  
22 reduce bounce. One technique is to use a porous substance such as a glass or quartz fiber filter  
23 (Chang et al., 1999) material or a polyurethane foam (Breum, 2000; Kavouras and Koutrakis,  
24 2001). These techniques may result in less precise separation and yield a sample that must be  
25 extracted before chemical analyses can be performed. Another technique is to coat the impactor  
26 with a soft wax or grease (Rao and Whitby, 1977; Turner and Hering, 1987; Pak et al., 1992).  
27 This can cause problems with weighing and chemical analyses. In addition, as the deposit of  
28 particles builds up, incoming particles may not hit the soft surface, but instead hit a previously  
29 collected hard particle and bounce off of it. The WINS impactor discussed earlier uses a filter in  
30 a well of low volatility oil to ensure a wetted surface at all times. However, such a technique,

1 while appropriate for removing unwanted particles, would not yield a particle sample suitable for  
2 weighing or for chemical analyses.

3  
4 ***Virtual Impaction.*** The problems of bounce and blow off of particles from impactors,  
5 especially for the collection of large quantities of particles, was addressed by aerosol scientists in  
6 the mid-1960s by the development of what is now known as “virtual” impaction (Hounam and  
7 Sherwood, 1965; Conner, 1966).

8 In a virtual impactor, a hole is placed in the impaction plate just below the accelerating jet.  
9 Two controlled flows allow a fraction, e.g., 10% (or another predetermined fraction, typically 5 -  
10 20%), of the air containing the coarse particles to go through the hole and through a filter (minor  
11 flow). A 10% minor flow gives a coarse channel enrichment factor of 10. The remaining  
12 fraction (e.g., 90% of the airflow) containing the fine particles follows a different path and goes  
13 through a second filter (major flow). The upper cutpoint is usually set by the inlet (e.g.,  
14 10  $\mu\text{m}$   $D_a$ ). The flow rates, pressures, and distance from the nozzle to the virtual impactor  
15 surface can be varied to direct particles with an  $D_a$  greater than the lower cutpoint (i.e.,  
16  $> 2.5 \mu\text{m}$ ) to go through the hole and be collected on the first filter and to direct smaller particles  
17 (i.e.,  $< 2.5 \mu\text{m}$ ) to flow around the impactor be collected on the second filter. Large particles  
18 “impact” into the hole with a small amount of the air flow. The smaller particles follow the  
19 major air flow around the impactor plate. This technique overcomes the problem of bounce.  
20 An example of the separation into fine and coarse particles is shown in Figure 2-24.

21 The usefulness of this technique for collecting samples of fine and coarse particles for  
22 chemical analysis was recognized by EPA in the mid-1970s. A development program was  
23 undertaken leading to the development of the now well known “dichotomous sampler” (a virtual  
24 impactor that separates particles into two size fractions) and an associated XRF analyzer  
25 (Dzubay and Stevens, 1975; Loo et al., 1976; Jaklevic et al., 1977; Dzubay et al., 1977). The  
26 dichotomous sampler was originally developed for use in the Regional Air Monitoring Study  
27 (RAMS), part of the Regional Air Pollution Study (RAPS), conducted in St. Louis, Missouri in  
28 the mid-1970s. Dichotomous samplers were operated at 10 RAMS sites from March 1975 to  
29 March 1977; and 33,695 filters were collected and analyzed by XRF with an overall sampling  
30 efficiency of 97.25% (Strothmann and Schiermeier, 1979; Loo et al., 1976; Loo et al., 1978;  
31 Dzubay, 1980; Lewis and Macias, 1980). Dichotomous samplers were a novel concept at that

**Figure 2-24. Schematic diagram showing the principle of virtual impaction. The initial flow,  $Q_0$ , is split into a minor flow,  $Q_1$ , which carries the larger particles, which impact into the hole, to the coarse particle filter and a major flow,  $Q_2$ , which carries the smaller particles, which can follow the airflow, to the fine particle filter.**

Source: Loo et al. (1976).

1 time. Concern over particle losses and other problems at cut point sizes smaller than  $2.5 \mu\text{m } D_a$   
 2 influenced the decision to choose 2.5 instead of 1.0 as the cut point diameter.

3 Subsequent to the use of the dichotomous sampler in RAPS, considerable progress has  
 4 been made in the theory and practice of designing virtual impactors, especially in how to reduce  
 5 losses and provide a sharp cut (Masuda et al., 1979; Marple and Chien, 1980; Chen et al., 1985,  
 6 1986; Loo and Cork, 1988). Now virtual impactors, with rectangular slits or round holes, are  
 7 used (a) to provide cut point sizes as low as  $0.15 \mu\text{m } D_a$  and (b) to concentrate coarse,  
 8 accumulation, and ultrafine mode particles for use in health studies (Solomon et al., 1983;  
 9 Marple et al., 1990; Sioutas et al., 1994a,b,c). Dichotomous samplers were also used in a  
 10 national network to measure  $\text{PM}_{2.5}$  and  $\text{PM}_{10-2.5}$  in the Harvard Six City Study (Spengler and  
 11 Thurston, 1983; Dockery et al., 1993) and the Inhalable Particulate Network (Suggs and Burton,  
 12 1983). A trichotomous high volume sampler has also been developed that provides samples of  
 13 particles less than  $1.0 \mu\text{m}$ ,  $1.0 \mu\text{m} - 2.5 \mu\text{m}$ , and  $2.5 \mu\text{m}$  (Marple and Olsen, 1995). This

1 sampler was intended for study of the composition of the intermodal mass between 1.0 and  
2 2.5  $\mu\text{m D}_a$ .

3 More recently, two dichotomous sequential PM air samplers were collocated with a manual  
4 Federal Reference Method (FRM) air sampler and operated for over one year at a waterfront site  
5 on Tampa Bay (Poor et al., 2002). The FRM sampler was alternately configured as a  $\text{PM}_{2.5}$ , then  
6 as a  $\text{PM}_{10}$  sampler. For the dichotomous sampler measurements, daily 24-h integrated  $\text{PM}_{2.5}$  and  
7  $\text{PM}_{10-2.5}$  ambient air samples were collected at a total flow rate of  $16.71 \text{ min}^{-1}$ . As was the case in  
8 earlier versions of the dichotomous sampler, a virtual impactor split the air into flow rates of  
9  $1.67$  and  $15.01 \text{ min}^{-1}$  and collected  $\text{PM}_{10-2.5}$  and  $\text{PM}_{2.5}$  on 47-mm diameter PTFE<sup>®</sup> filters.  
10 Between the two dichotomous air samplers, the average concentration, relative bias and relative  
11 precision for  $\text{PM}_{2.5}$  were  $13.3 \mu\text{g m}^{-3}$ , 0.02% and 5.2% concentrations ( $n = 282$ ), and for  $\text{PM}_{10-2.5}$   
12 were  $12.3 \mu\text{g m}^{-3}$ , 3.9% and 7.7% ( $n = 282$ ). FRM measurements were alternate day 24-h  
13 integrated  $\text{PM}_{2.5}$  or  $\text{PM}_{10}$  ambient air samples collected onto 47-mm diameter PTFE<sup>®</sup> filters at a  
14 flow rate of  $16.71 \text{ min}^{-1}$ . Between a dichotomous and a  $\text{PM}_{2.5}$  FRM air sampler, the average  
15 concentration, relative bias and relative precision were  $12.4 \mu\text{g m}^{-3}$ , -5.6% and 8.2% ( $n = 43$ );  
16 and between a dichotomous and a  $\text{PM}_{10}$  FRM air sampler, the average concentration, relative  
17 bias and relative precision were  $25.7 \mu\text{g m}^{-3}$ , -4.0% and 5.8% ( $n = 102$ ). The  $\text{PM}_{2.5}$  concentration  
18 measurement standard errors for two dichotomous and one FRM samplers were 0.95, 0.79 and  
19  $1.02 \mu\text{g m}^{-3}$ ; and for  $\text{PM}_{10}$ , the standard errors were 1.06, 1.59, and  $1.70 \mu\text{g m}^{-3}$ . The authors  
20 (Poor et al., 2002) concluded that their results indicate that “the dichotomous samplers have  
21 superior technical merit” and demonstrate “the potential for the dichotomous sequential air  
22 sampler to replace the combination of the  $\text{PM}_{2.5}$  and  $\text{PM}_{10}$  FRM air samplers, offering the  
23 capability of making simultaneous, self-consistent determinations of these particulate matter  
24 fractions in a routine ambient monitoring mode.”

25 The dichotomous sampler provides two separate samples. However, a fraction of the  
26 smaller particles, equal to the minor flow, will go through the virtual impaction opening with the  
27 air stream and be collected on the coarse particle filter. In the dichotomous sampler used in the  
28 RAPS program, 10% of the fine particles were collected with the coarse particles. Thus, in order  
29 to determine the mass or composition of the coarse particles, it is necessary to determine the  
30 mass and composition of the fine particles and subtract the appropriate fraction from the mass or  
31 composition of the particles collected on the coarse particle filter. Allen et al. (1999b) discuss

1 potential errors in the dichotomous sampler caused by uncertainties in the coarse mass channel  
2 enrichment factor. Virtual impactors have also been designed with a clean air jet in the center of  
3 the round nozzle. This makes possible lower contamination of coarse particles by fine particles  
4 but maintains low losses and sharp cuts (Chen and Yeh, 1986; Chien and Lundgren, 1993). The  
5 fine particle intrusion into the coarse particle sample can also be reduced by operating two  
6 virtual impactors in series (Dzubay and Stevens, 1975).

7       Aerosol physicists have also conducted theoretical and experimental investigations of  
8 virtual impaction using slits instead of round holes (Forney et al., 1978, 1982; Ravenhall et al.,  
9 1978; Masuda and Nakasita, 1988; Sioutas et al., 1994b, c, d; Ding and Koutrakis, 2000). The  
10 slit virtual impactor permits much higher flow rate than round hole virtual impactors and  
11 resolves problems that occur with multihole virtual impactors (Marple et al., 1990; Fang et al.,  
12 1991). The slit technique has been used to develop virtual impaction systems for concentrating  
13 particles in the size range 0.1 to 2.5  $\mu\text{m}$   $D_a$  for exposure studies using animals and people  
14 (Sioutas et al., 1995a, b). The slit impactor can also be used to concentrate coarse particles for  
15 measurement (Misra et al., 2001) or exposure studies (Chang et al., 2002). It has also been  
16 possible to concentrate ultrafine particles ( $> 0.1 \mu\text{m}$ ) by first separating ultrafine particles from  
17 larger particles, adding water vapor to saturate the air containing the ultrafine particles, cooling  
18 the air to cause supersaturation and growth of the ultrafine particles into the 1.0 – 4.0  $\mu\text{m}$  size  
19 range, concentrating these particles with a slit virtual impactor, and heating the air to return the  
20 particles to their original size (Sioutas and Koutrakis, 1996; Sioutas et al., 1999; Sioutas et al.,  
21 2000; Kim et al., 2001b,c; Geller et al., 2002).

## 22 23 **2.2.5 Speciation Monitoring**

### 24 ***Speciation Network and Monitoring***

25       In addition to FRM sampling to determine compliance with PM standards, EPA requires  
26 states to conduct chemical speciation sampling primarily to determine source categories and  
27 trends (Code of Federal Regulations, 2001b). Source category apportionment calculations are  
28 discussed in Chapter 3. A  $\text{PM}_{2.5}$  chemical Speciation Trends Network (STN) has been deployed  
29 that consists of 54 core National Ambient Monitoring Stations (NAMS) and approximately  
30 250 State and Local Air Monitoring Stations (SLAMS). In addition, over 100 IMPROVE  
31 (Interagency Monitoring of Protected Visual Environments) samplers located at regional

1 background and transport sites can be used to fulfill SLAMS requirements. The overall goal of  
2 the speciation program is “to provide ambient data that support the Nation’s air quality program  
3 objectives” (U.S. Environmental Protection Agency, 1999). Information and reports on EPA’s  
4 speciation monitoring program may be found on EPA’s Technology Transfer Network at  
5 <http://www.epa.gov/ttn/amtic/pmspec.html>. The NAMS speciation sites will provide routine  
6 chemical speciation data that will be used to develop annual and seasonal aerosol  
7 characterization, air quality trends analysis, and emission control strategies. The SLAMS  
8 speciation sites will further support the NAMS network and provide information for  
9 development of State Implementation Plans (SIPs).

10 At both NAMS and SLAMS sites, aerosol samples will be collected for analysis of trace  
11 elements, ions (sulfate, nitrate, ammonium, sodium, and potassium), and total carbon. The  
12 NAMS speciation sites will operate on a 1 in 3 day schedule, with 10 of these sites augmented  
13 with continuous speciation analyses for everyday operation. The SLAMS speciation sites will  
14 generally operate on a 1 in 6 day basis; however, many sites may be operated on a 1 in 3 day  
15 basis in locations where increased data collection is needed. There are several samplers that are  
16 suitable for use in the NAMS/SLAMS network. These samplers include an inlet cutpoint with  
17 size cut characteristics comparable to the WINS FRM; proven denuder technology for nitrate;  
18 and sampler face velocity and sample volume similar to that of the FRM. The current samplers  
19 include three filters: (1) Teflon for equilibrated mass and elemental analysis by energy  
20 dispersive x-ray fluorescence (EDXRF), (2) a nitric acid denuded Nylon filter for ion analysis  
21 (ion chromatography), (3) a quartz fiber filter for elemental and organic carbon. EC and OC are  
22 determined by thermal optical analysis via a modification of the NIOSH (National Institute for  
23 Occupational Safety and Health) method 5040 (Thermal Optical Transmission) [TOT]).  
24 However, no corrections are made for positive artifacts caused by adsorption on organic gases or  
25 the quartz filters or negative artifacts due to evaporation of semivolatile organic compounds  
26 from the collected particles.

27 Since 1987, the IMPROVE network has provided measurements of ambient PM and  
28 associated light extinction in order to quantify PM chemical components that affect visibility at  
29 Federal Class 1 areas that include designated national parks, national monuments, and  
30 wilderness areas. Management of this network is a cooperative effort between U.S. EPA, federal  
31 land management agencies, and state governments. The IMPROVE program has established

1 protocols for analysis of aerosol measurements that provide ambient concentrations for PM<sub>10</sub>,  
2 PM<sub>2.5</sub>, sulfates, nitrates, organic and elemental carbon, crustal material, and a number of other  
3 elements. Information on the IMPROVE program may be found at  
4 <http://vista.cira.colostate.edu/improve>.

5 IMPROVE aerosol monitoring consists of a combination of particle sampling and sample  
6 analysis. The IMPROVE sampler, which collects two 24-hour duration samples per week,  
7 simultaneously collects one sample of PM<sub>10</sub> on a Teflon filter, and three samples of PM<sub>2.5</sub> on  
8 Teflon, nylon, and quartz filters. PM<sub>10</sub> mass concentrations are determined gravimetrically from  
9 the PM<sub>10</sub> filter sample, while PM<sub>2.5</sub> mass concentrations are determined gravimetrically from the  
10 PM<sub>2.5</sub> Teflon filter sample. The PM<sub>2.5</sub> Teflon filter sample is also used to determine  
11 concentrations of selected elements using particle-induced x-ray emission (PIXE), x-ray  
12 fluorescence (XRF), and Proton Elastic Scattering Analysis (PESA). The PM<sub>2.5</sub> nylon filter  
13 sample, which is preceded by a denuder to remove acidic gases, is analyzed to determine nitrate  
14 and sulfate aerosol concentrations using Ion Chromatography (IC). Finally, the PM<sub>2.5</sub> quartz  
15 filter sample is analyzed for organic and elemental carbon using the Thermal Optical Reflectance  
16 (TOR) method. Corrections are made for positive artifacts but not for negative artifacts.

17 The STN and the IMPROVE networks represent a major advance in the measurement of  
18 nitrate since the combination of a denuder to remove nitric acid vapor and a Nylon filter to  
19 adsorb nitric acid vapor that volatilizes from the collected ammonium nitrate particles  
20 overcomes the loss of nitrate from Teflon filters. However, the different techniques used for the  
21 measurement of OC and EC lead to significant differences between OC and EC measurements  
22 when the two techniques are intercompared (Chow et al., 2001). IMPROVE yields higher EC  
23 and lower OC although there is good agreement for TC. Another difference arises from the  
24 treatment of the positive artifact due to the absorption of organic gases by the quartz filters used  
25 in IMPROVE and STN samplers. More information on these differences is given in Section  
26 2.2.7 and details are discussed in Appendix 2B.

27 Several of the PM<sub>2.5</sub> size selectors developed for use in the EPA National PM<sub>2.5</sub> STN were  
28 recently evaluated by comparing their penetration curves under clean room experiments with  
29 that of the WINS impactor (Peters et al., 2001c). The corresponding speciation monitors were  
30 then compared to the FRM in four cities. The PM<sub>2.5</sub> inlets tested were the SCC 2.141 cyclone  
31 (6.7 L/min) that is in the Met One Instruments SASS sampler; the SCC 1.829 cyclone

1 (5.0 L/min) that is proposed for use in the Rupprecht and Patashnik real-time sulfate/nitrate  
2 monitor; the AN 3.68 cyclone (24.0 L/min) that is in the Andersen RAAS; and the spiral  
3 separator (7.0 L/min) that was previously in the Met One SASS. The cutpoints of the SCC  
4 cyclones compared reasonably well with the WINS (2.52 and 2.44 micrometers for the SCC  
5 2.141 and SCC 1.829, respectively, at their design flowrates), but both demonstrated a tail  
6 extending into the coarse particle mode. The AN inlet had the sharpest cutpoint curve, but the  
7 50% cutpoint diameter was 2.7  $\mu\text{m D}_a$  at its design flowrate. The spiral inlet had the shallowest  
8 cutpoint curve, and the 50% cut point was 2.69 and 2.67  $\mu\text{m D}_a$  for an ungreased and greased  
9 inlet, respectively. The speciation samplers were also compared to the FRM sampler with WINS  
10 inlet under ambient conditions in four cities. The Andersen RAAS equipped with the AN 3.68  
11 cyclone compared well to the FRM in all four cities, when compared on the basis of  $\text{PM}_{2.5}$  mass,  
12 sulfate, and crustal concentrations. Greasing the spiral inlet in the Met One sampler improved  
13 the performance of that sampler, which tended to give much higher  $\text{PM}_{2.5}$  concentrations than the  
14 FRM in cities with high crustal particulate matter.

## 16 **2.2.6 Inorganic Elemental Analyses**

17 In addition to the lighter elements, hydrogen, carbon, oxygen and nitrogen, the following  
18 40 heavier elements are commonly found in ambient air samples: sodium, magnesium,  
19 aluminum, silicon, phosphorus, sulfur, chlorine, potassium, calcium, titanium, vanadium,  
20 chromium, manganese, iron, cobalt, nickel, copper, zinc, gallium, arsenic, selenium, bromine,  
21 rubidium, strontium, yttrium, zirconium, molybdenum, palladium, silver, cadmium, indium, tin,  
22 antimony, barium, lanthanum, gold, mercury, thallium, lead, and uranium. These often indicate  
23 air pollution sources and several of them are considered to be toxic (transition metals,  
24 water-soluble metals, and metals in certain valence states [e.g., Fe(II), Fe(III), Cr(III), Cr(VI),  
25 As(III), As(V)]). Measurement methods for inorganic elements are listed in Table 2-5. These  
26 methods differ with respect to detection limits, sample preparation, and cost (Chow, 1995).  
27 EDXRF and PIXE are the most commonly applied methods because they quantify more than  
28 40 detectable elements, they are non-destructive, and they are relatively inexpensive. Both were  
29 discussed in the previous 1996 PM AQCD. TRXRF and S-XRF are newer techniques with  
30 lower detection limits. AAS, ICP-AES, and ICP-MS are also appropriate for ionic  
31 measurements of elements that can be dissolved. PESA provides a means for measuring

**TABLE 2-5. MEASUREMENT METHODS FOR INORGANIC ELEMENTS**

#	Acronym	Full Name	Comments
1.	EDXRF	energy dispersive x-ray fluorescence	heavier elements
2.	S-XRF	synchrotron induced X-ray emission	heavier elements; lower detection limits than EDXRF
3.	PIXE	proton induced x-ray emission	heavier elements; lower detection limits than EDXRF
4.	PESA	proton (or particle) elastic scattering analysis	lighter elements
5.	TRXRF	total reflection X-ray fluorescence	heavier elements; lower detection limits than EDXRF
6.	INAA	instrumental neutron activation analysis	many elements; sensitivity different than EDXRF
7.	AAS	atomic absorption spectrophotometry	many elements that can be dissolved
8.	ICP-AES	inductively coupled plasma with atomic emission spectroscopy	many elements that can be dissolved
9.	ICP-MS	inductively coupled plasma with mass spectroscopy	many elements that can be dissolved
10.	SEM	scanning electron microscopy	heavier elements

1 elements with lower atomic numbers from hydrogen to carbon. More detailed information on  
2 each technique is given in Appendix 2B.1.

### 4 **2.2.7 Elemental and Organic Carbon in Particulate Matter**

5 Ambient particles from combustion sources contain carbon in several chemically and  
6 optically distinct forms. Health- and visibility-related studies of these particles require  
7 information about the relative contributions to total particle mass by these different forms of  
8 carbon. With the exception of carbonate-based carbon, however, a clear classification scheme  
9 has not yet been established to distinguish organic carbon, light-absorbing carbon, black carbon,  
10 soot and elemental carbon. The absence of clear, physically-based definitions results in  
11 confusion in the interpretation of speciation data. For example, depending on the radiation  
12 wavelength specified, “light absorbing” carbon can include compounds that volatilize without  
13 oxidation. “Black” carbon includes various mixtures containing “elemental” (graphitic) carbon;

1 partially degraded, oxidized graphitic fragments; and partially-oxidized amorphous aromatic  
2 carbon. For studying visibility reduction, a measurement of light-absorbing carbon may be more  
3 useful than one of elemental carbon. For source apportionment by receptor models, several  
4 consistent but distinct fractions of carbon in both source and receptor samples are desired,  
5 regardless of their light-absorbing or chemical properties. Differences in ratios of the carbon  
6 concentrations in these fractions form part of the source profiles that distinguish the contribution  
7 of one source from the contributions of other sources (Watson et al., 1994a,b).

8 Three method-dependent operational classes of carbon are commonly measured in ambient  
9 aerosol samples collected on quartz-fiber filters: (1) semi-volatile organic or non-visible light-  
10 absorbing carbon, termed “organic carbon (OC)”; (2) elemental carbon, soot, black carbon, or  
11 light-absorbing carbon, termed “elemental carbon (EC)”; and (3) carbon present as  $K_2CO_3$ ,  
12  $Na_2CO_3$ ,  $MgCO_3$ ,  $CaCO_3$ , termed “carbonate carbon (CC).” The sum of OC, EC, and CC in PM  
13 gives the total carbon (TC).

14 The thermal/optical reflectance (TOR), thermal/optical transmission (TOT), and thermal  
15 manganese oxidation (TMO) methods are most commonly used for the analysis of organic and  
16 elemental carbon in atmospheric PM. In thermal separation methods, OC is vaporized and the  
17 EC remaining on the filter is then oxidized to  $CO_2$  and quantified by nondispersive infrared  
18 detection, by electrochemical techniques or by reducing the  $CO_2$  to  $CH_4$  and quantifying  $CH_4$  via  
19 flame ionization detection (FID). OC that does not vaporize below 550 C can pyrolyze at higher  
20 temperatures to form additional black carbon. Thermal/optical methods must correct for this  
21 effect in order to correctly distinguish OC from EC. The various methods give similar results for  
22 TC, but not for EC or OC, due to differing assumptions regarding the thermal behavior of  
23 ambient aerosol carbon. These methods are discussed in detail in Appendix 2B.2.

24 Carbonate carbon (i.e.,  $K_2CO_3$ ,  $Na_2CO_3$ ,  $MgCO_3$ ,  $CaCO_3$ ) can be determined thermally, or  
25 on a separate filter section by measurement of the carbon dioxide ( $CO_2$ ) evolved upon  
26 acidification (Johnson et al., 1980). It is usually on the order of 5% or less of TC for ambient  
27 particulate samples collected in urban areas (Appel, 1993).

28 The forms of carbon present in natural materials that may be burnt to generate atmospheric  
29 aerosol tend to be poorly defined. Thus, the pyrolysis products of these materials during  
30 thermal/optical analysis cannot be predicted. The Geochemical Society convened an  
31 international steering committee in 1999 to define a set of representative black carbon and black

1 carbon-containing benchmark materials to be used to support ambient aerosol sample analysis.  
2 These standard materials may be used to provide thermal/optical “fingerprints” for deducing  
3 primary aerosol sources, and to establish characteristic analytic interferences or artifacts  
4 associated with such sources. The materials recommended to date include n-hexane soot,  
5 lignocellulosic chars, soils, marine sediments, and the NIST urban dust standard reference  
6 material (SRM 1649a). The committee has also recommended a set of standard materials that  
7 may potentially interfere with black carbon analyses: shale, natural organic matter, melanoidin  
8 (an amino acid-based material) and coals. These recommendations are discussed on the steering  
9 committee website: <http://www.du.edu/~dwismith/bcsteer.html>.

### 11 **2.2.8 Ionic Species**

12 Ion chromatography (IC) is widely used for analyzing ionic species in the water-soluble  
13 portion of suspended PM. IC is the method of choice for the measurement of sulfate, nitrate,  
14 ammonium, sodium, and potassium ions for the NAMS program. Aerosol strong acidity,  $H^+$ , is  
15 determined by titration of a water solution of PM collected following a series of annular  
16 denuders to remove acid and basic gases with back-up filters to collect  $NH_3$  and  $HNO_3$  that  
17 volatilize from the PM during collection. The 1996 PM AQCD (U.S. Environmental Protection  
18 Agency, 1996a) discussed measurement of ions by IC (Section 4.3.3.1) and of strong acidity  
19 (Sections 3.3.1.1 and 4.3.3.1); so, no further details will be discussed here.

### 21 **2.2.9 Continuous Monitoring**

22 The EPA expects that many local environmental agencies will operate continuous PM  
23 monitors. All currently available continuous measurements of suspended particle mass share the  
24 problem of dealing with semivolatile PM components. So as not to include particle-bound water  
25 as part of the mass, the particle-bound water must be removed by heating or dehumidification.  
26 However, heating also causes loss of ammonium nitrate and semivolatile organic components.  
27 A variety of potential candidates for continuous measurement of particle mass and related  
28 properties are listed in Table 2-6. These techniques are discussed in more detail in Appendix  
29 2B.3.

**TABLE 2-6. METHODS FOR CONTINUOUS MEASUREMENT OF PM MASS, COMPONENTS, ETC.**

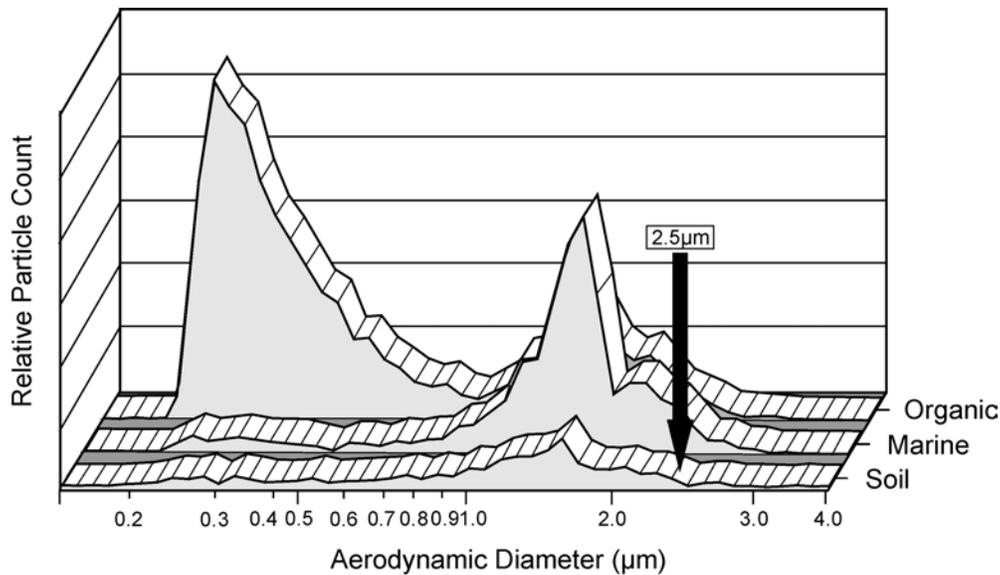

#	Acronym	Name	Comments
1.	TEOM	Tapered Element Oscillating Microbalance	Measures only nonvolatile components of PM.
2.	TEOM with SES	TEOM with Sample Equilibration System	By using dehumidification instead of heat for drying and a lower temperature for stabilization, includes some of the semivolatile components of PM.
3.	—	Differential TEOM	Research instrument designed to measure both the nonvolatile and semivolatile components of PM.
4.	FDMS	Filter Dynamics Measurement System	Commercial version of the differential TEOM.
5.	RAMS	Real-Time Total Ambient Mass Sampler	Research instrument designed to measure total PM using denuders and an adsorptive filter.
6.	CAMM	Continuous Ambient Mass Monitor	Measures total PM by pressure drop across a frequently changed filter.
7.	—	Beta gauge	Measures PM mass by beta attenuation. Unless dried by heat or dehumidification will also measure particle-bound water.
8.	—	Piezoelectric microbalance	Measures mass by change in resonance frequency when particles are deposited on a crystal.
9.	CCPM	Continuous Coarse Particle Monitor	Virtual impaction is used to concentrate PM <sub>10-2.5</sub> which is then measured by a TEOM.
10.	—	Semi-continuous EC/OC	Several commercially available instruments automate the thermal technique for EC/OC and provide hourly measurements.
11.	—	Semi-continuous nitrate	Collection of PM followed by flash vaporization and determination of NO <sub>x</sub> provides 10 minute measurements of particulate nitrate.
12.	—	Semi-continuous sulfate	Several techniques are available in which particulate sulfate is measured using flame ionization detection.
13.	—	Continuous ion chromatography of water-soluble ions	Particles are grown by mixing with water vapor, collected in water, and injected into an automatic ion chromatography.
14.	—	Mass spectroscopy of individual particles	Single particles are evaporated, ionized and the components analyzed by mass spectroscopy. Several different systems are in use in research studies.
15.	EAD	Electrical Aerosol Detector	This instrument measures charge collected by particles and gives a continuous signal that is proportional to the integral of the particle diameter.
16.	—	Integrating nephelometer	Light scattering by suspended particles, collected over a large solid angle, provides an indicator for particle mass including particle-bound water unless the air sample is dried by heating or dehumidification.

## 2.2.10 Measurements of Individual Particles

Recently, several researchers have developed instruments for real-time *in situ* analysis of single particles (e.g., Noble and Prather, 1996; Gard et al., 1997; Johnson and Wexler, 1995; Silva and Prather, 1997; Thomson and Murphy, 1994). Although the technique varies from one laboratory to another, the underlying principle is to fragment each particle into ions, using either a high-power laser or a heated surface and, then, a time-of-flight mass spectrometer (TOFMS) to measure the ion fragments in a vacuum. Each particle is analyzed in a suspended state in the air stream (i.e., without collection), avoiding sampling artifacts associated with impactors and filters. The technique is called aerosol time-of-flight mass spectrometry (ATOFMS).

By measuring both positive and negative ions from the same particle, information can be obtained about the composition, of individual particles of known aerodynamic diameter. This information is especially useful in determining sources of particles. Noble and Prather (1996) used ATOFMS to provide compositionally resolved particle-size distributions. Their instrument is capable of analyzing size and chemical composition of 50 to 100 particles/min at typical ambient concentrations and up to 600/min at high particle concentrations. Four systems for measurement of single particles using mass spectroscopy are reviewed by Middlebrook (2002). An example of the type of information that can be determined is shown in Figure 2-25.

Because particles are analyzed individually, biases in particle sampling (the efficiency of particle transmission into the sensor chamber as a function of size; particle size measurement, and detection of particles prior to fragmentation) represent a major challenge for these instruments. Moreover, the mass spectrometer has a relatively large variability in ion yields (i.e., identical samples would yield relatively large differences in mass spectrometer signals [Thomson and Murphy, 1994]); therefore, quantitation is inherently difficult (Murphy and Thomson, 1997). Quantitation will be even more challenging for complex organic mixtures because of the following two reasons: (1) a large number of fragments are generated from each molecule, and (2) ion peaks for organics can be influenced or obscured by inorganic ions (Middlebrook et al., 1998). Nonetheless, scientists have been successful in using these techniques to identify the presence of organics in atmospheric particles and laboratory-generated particles (i.e., as contaminants in laboratory-generated sulfuric acid droplets) as well as the identification of specific compound classes such as PAHs in combustion emissions (Castaldi and Senkan, 1998; Hinz et al., 1994; Middlebrook et al., 1998; Murphy and Thomson, 1997;

**Figure 2-25. Size distribution of particles divided by chemical classification into organic, marine, and crustal.**

Source: Noble and Prather (1998).

1 Neubauer et al., 1998; Noble and Prather, 1998; Reilly et al., 1998; Silva and Prather, 1997).  
 2 A new multivariate technique for calibration of ATOFMS using microorifice impactors shows  
 3 promise for simplifying the calibration process (Ferguson et al., 2001). This calibration  
 4 technique has been applied to gasoline and diesel particles to demonstrate the feasibility of using  
 5 this technique for the source apportionment of gasoline and diesel particles in an atmospheric  
 6 mixture (Song et al., 2001).

7 Until recently, ATOFMS systems have only been able to characterize particles that are  
 8 larger than approximately 0.2 to 0.3 µm in diameter. Wexler and colleagues (Carson et al.,  
 9 1997; Ge et al., 1998) have developed an ATOFMS instrument that is able to size, count, and  
 10 provide chemical composition on individual particles ranging in size from 10 nm to 2 µm.

### 2.2.11 Low Flow Filter Samples for Multiday Collection of Particulate Matter

For some purposes, such as demonstrating attainment of an annual standard or as an exposure indicator for epidemiologic studies of chronic health effects, 24-h measurements are not essential. Annual or seasonal averages may be adequate. Multiday sampling techniques can result in lower costs for weighing, chemical analysis, and travel time to change filters. The multiday sampler serves a second purpose. Most commercially available samplers are optimized for collecting 24-h samples of the PM concentrations found in the U.S., Europe, or Japan. Many cities in other parts of the world have significantly higher PM concentrations. Under these conditions, the 16.7 L/min flow through 37 or 47 mm diameter filters may overload the filter and prevent the sampler from maintaining the prescribed flow rate for 24 h. A low flow sampler with a 0.4 L/min flow rate and a 47 mm diameter filter has been designed by Aerosol Dynamics, Inc. With this sampler, the sample collection time can be chosen to suit the ambient concentration level. This sampler, with a one-week collection period, has been used to characterize PM<sub>2.5</sub> in Beijing, PRC (He et al., 2001). With a two-week collection period, it is being used in a chronic epidemiologic study in southern California, USA (Gauderman, et al., 2000).

The sampler, as described by He et al. (2001), has three PM<sub>2.5</sub> channels. One channel collects PM on a Teflon filter for gravimetric mass measurement and elemental analysis by XRF. A second channel collects PM on a quartz filter for organic and elemental carbon analysis. A denuder to remove organic gases and a backup filter to collect semivolatile organic compounds may be added. The third channel uses a carbonate denuder to remove acid gases (HNO<sub>3</sub> and SO<sub>2</sub>), a Teflon filter to collect PM for analysis of ions by ion chromatography, and a nylon filter to collect volatilized nitrate. The Teflon filter can also be weighed prior to extraction. Thus, the multiday sampler can provide the information needed for source apportionment by Chemical Element Balance techniques (Watson et al., 1990a,b; U.S. Environmental Protection Agency, 2002b).

For monitoring sites with high day-to-day variability in PM concentrations, a sample integrated over a week may provide a more accurate measurement of the annual average than can be obtained by 1-in-3 or 1-in-6 day sampling schedules. Daily PM data from Spokane, WA were resampled to simulate common sampling schedules and the error due to less-than-everyday sampling was computed (Rumburg et al., 2001). The error in the annual mean concentration for

1 PM<sub>2.5</sub>, expressed as a percentage difference from the everyday sampling mean, was 1.7, 3.4, and  
2 7.7% for 1-in-2 day, 1-in-3 day, and 1-in-6 day sampling, respectively.

## 3 4 5 **2.3 SUMMARY AND KEY POINTS**

### 6 **2.3.1 Atmospheric Physics and Chemistry of Particles**

7 Atmospheric particles originate from a variety of sources and possess a range of  
8 morphological, chemical, physical, and thermodynamic properties. The composition and  
9 behavior of aerosols are linked with those of the surrounding gas. Aerosol may be defined as a  
10 suspension of solid or liquid particles in air and includes both the particles and all vapor or gas  
11 phase components of air. However, the term aerosol often is used to refer to the suspended  
12 particles only.

13 A complete description of the atmospheric aerosol would include an accounting of the  
14 chemical composition, morphology, and size of each particle, and the relative abundance of each  
15 particle type as a function of particle size. Recent developments in single particle analysis  
16 techniques are bringing such a description closer to reality.

17 The diameter of a spherical particle may be determined geometrically, from optical or  
18 electron microscopy, by light scattering and Mie theory, or by a particle's behavior (e.g.,  
19 electrical mobility or its aerodynamic behavior). However, the various types of diameters may  
20 be different, and atmospheric particles often are not spherical. Therefore, particle diameters are  
21 described by an "equivalent" diameter. Aerodynamic diameter,  $D_a$  (the diameter of a unit  
22 density sphere that would have the same terminal settling velocity as the real particle), and the  
23 Stokes diameter,  $D_p$  (the diameter of a sphere of the same density as the particle that would have  
24 the same aerodynamic resistance or drag), are the most widely used equivalent diameters.

25 Atmospheric size distributions show that most atmospheric particles are quite small, below  
26 0.1  $\mu\text{m}$ ; whereas most of the particle volume (and therefore most of the mass) is found in  
27 particles greater than 0.1  $\mu\text{m}$ . An important feature of the mass or volume size distributions of  
28 atmospheric particles is their multimodal nature. Volume distributions, measured in ambient air  
29 in the United States, are almost always found to have a minimum between 1.0 and 3.0  $\mu\text{m}$ . That  
30 portion of the size distribution that contains particles that are mostly larger than the minimum is  
31 called "coarse" particles or the "coarse" mode. That portion of the size distribution that contains

1 particles that are mostly smaller than the minimum is called “fine” particles and includes several  
2 modes. “Accumulation-mode” refers to that portion of fine particles with diameters above about  
3 0.1  $\mu\text{m}$ . That portion of fine particles with diameters below 0.1  $\mu\text{m}$  are usually called “ultrafine”  
4 by toxicologists and epidemiologists and “nanoparticles” by aerosol physicists and material  
5 scientists. In the number distribution of ultrafine particles, particles in the size range below 0.01  
6 are called the nucleation mode and particles between 0.01 and 0.1 are called the Aitken mode.  
7 The Aitken mode can be observed as a separate mode in mass or volume distributions only in  
8 clean or remote areas or near sources of new particle formation by nucleation.

9 The aerosol community uses three different approaches or conventions in the classification  
10 of particles by size: (1) modes, based on the observed size distributions and formation  
11 mechanisms; (2) cut point, usually based on the 50% cut point of the specific sampling device,  
12 including legally specified, regulatory sizes for air quality standards; and (3) dosimetry or  
13 occupational sizes, based on the entrance into various compartments of the respiratory system.  
14 Over the years, the terms fine and coarse as applied to particle sizes have lost the original precise  
15 meaning of fine and coarse. In any given article, therefore, the meaning of fine and coarse,  
16 unless defined, must be inferred from the author’s usage. In particular,  $\text{PM}_{2.5}$  and fine particles  
17 are not equivalent.  $\text{PM}_{2.5}$  refers to the aggregate sample of PM that is collected following a size-  
18 selective inlet with a specified penetration as a function of size and a 50% cutpoint of 2.5  $\mu\text{m}$   $D_a$ .  
19 It may also be used to refer to number (or other measure of particles suspended in the  
20 atmosphere that would be collected by such a sampler).  $\text{PM}_{10}$  is defined similarly.  $\text{PM}_{10-2.5}$   
21 refers to the sample that would be collected if the  $\text{PM}_{2.5}$  component could be removed from a  
22  $\text{PM}_{10}$  sample.

23 Several processes influence the formation and growth of particles. New particles may be  
24 formed by nucleation from gas phase material. Particles may grow by condensation as gas phase  
25 material condenses onto existing particles. Particles may also grow by coagulation as two  
26 particles combine to form one. Gas phase material condenses preferentially on smaller particles,  
27 and the rate constant for coagulation of two particles decreases as the particle size increases.  
28 Therefore, nuclei mode particles grow into the accumulation mode, but growth of accumulation  
29 mode particles into the coarse mode is rare.

30 The major constituents of atmospheric PM are sulfate, nitrate, ammonium, and hydrogen  
31 ions; particle-bound water; elemental carbon; a great variety of organic compounds; and crustal

1 material. Atmospheric PM contains a large number of elements in various compounds and  
2 concentrations and hundreds of specific organic compounds. Particulate material can be primary  
3 or secondary. PM is called primary if it is in the same chemical form in which it was emitted  
4 into the atmosphere. PM is called secondary if it is formed by chemical reactions in the  
5 atmosphere. Primary coarse particles are usually formed by mechanical processes; whereas  
6 primary fine particles are emitted from sources either directly as particles or as vapors that  
7 rapidly condense to form particles.

8 Most of the sulfate and nitrate and a portion of the organic compounds in atmospheric  
9 particles are secondary. Secondary aerosol formation depends on numerous factors including the  
10 concentrations of precursors; the concentrations of other gaseous reactive species such as ozone,  
11 hydroxyl radical, peroxy radicals, and hydrogen peroxide; atmospheric conditions, including  
12 solar radiation and relative humidity; and the interactions of precursors and preexisting particles  
13 within cloud or fog droplets or on or in the liquid film on solid particles. As a result, it is  
14 considerably more difficult to relate ambient concentrations of secondary species to sources of  
15 precursor emissions than it is to identify the sources of primary particles.

16 The lifetimes of particles vary with particle size. Coarse particles can settle rapidly from  
17 the atmosphere within minutes or hours and normally travel only short distances. However,  
18 when mixed high into the atmosphere, as in dust storms, the smaller-sized, coarse-mode particles  
19 may have longer lives and travel greater distances. Accumulation-mode particles are kept  
20 suspended by normal air motions and have a lower deposition velocity than coarse-mode  
21 particles. They can be transported thousands of kilometers and remain in the atmosphere for a  
22 number of days. Accumulation-mode particles are removed from the atmosphere primarily by  
23 cloud processes. Dry deposition rates are expressed in terms of a deposition velocity that varies  
24 with the particle size, reaching a minimum between 0.1 and 1.0  $\mu\text{m}$  aerodynamic diameter.

25 PM is a factor in acid deposition. Particles serve as cloud condensation nuclei and  
26 contribute directly to the acidification of rain. In addition, the gas-phase species that lead to dry  
27 deposition of acidity are also precursors of particles. Therefore, reductions in  $\text{SO}_2$  and  $\text{NO}_x$   
28 emissions will decrease both acid deposition and PM concentrations. Sulfuric acid, ammonium  
29 nitrate, and organic particles also are deposited on surfaces by dry deposition and can contribute  
30 to ecological effects.

31

### 2.3.2 Measurement of Atmospheric Particles

The decision by the EPA to revise the PM standards by adding daily and yearly standards for PM<sub>2.5</sub> has led to a renewed interest in the measurement of atmospheric particles and to a better understanding of the problems in developing precise and accurate measurements of particles. Unfortunately, it is very difficult to measure and characterize particles suspended in the atmosphere.

PM monitoring is used to develop information to guide implementation of standards (i.e., to identify sources of particles; to determine whether or not a standard has been attained; and to determine health, ecological, and radiative effects). Federal Reference Methods (FRM) specify techniques for measuring PM<sub>10</sub> and PM<sub>2.5</sub>. Particles are collected on filters and mass concentrations are determined gravimetrically. The PM<sub>10</sub> FRM sampler consists of a PM<sub>10</sub> inlet/impactor and a 47-mm Teflon filter with a particle collection efficiency greater than 99.7%. The PM<sub>2.5</sub> FRM is similar except that it includes a PM<sub>2.5</sub> impactor with an oil-covered impaction substrate to remove particles larger than 2.5 μm. Both techniques provide relatively precise (±10%) methods for determining the mass of material remaining on a Teflon filter after equilibration. Despite considerable progress in measuring the atmospheric PM mass concentration, numerous uncertainties continue to exist as to the relationship between the mass and composition of material remaining on the filter as measured by the FRMs and the mass and composition of material that exists in the atmosphere as suspended PM. There is no reference standard for particles suspended in the atmosphere, nor is there an accepted way to remove particle-bound water without losing some of the semivolatile components of PM such as ammonium nitrate and semivolatile organic compounds. It also is difficult to cleanly separate fine and coarse PM. As a result, EPA defines accuracy for PM measurements in terms of agreement of a candidate sampler with a reference sampler. Therefore, intercomparisons of samplers become very important in determining how well various samplers agree and how various design choices influence what is actually measured.

Current filtration-based mass measurements lead to significant evaporative losses of a variety of semivolatile components (i.e., species that exist in the atmosphere in dynamic equilibrium between the condensed phase and gas phase) during and possibly after collection. Important examples include ammonium nitrate, semivolatile organic compounds, and particle-bound water. Loss of these components may significantly affect the quality of the measurement

1 and can lead to both positive and negative sampling artifacts. Negative artifacts resulting from  
2 loss of ammonium nitrate and semivolatile organic compounds may occur during sampling  
3 because of changes in temperature, relative humidity, or composition of the aerosol or because  
4 of the pressure drop across the filter. Negative artifacts also may occur during handling and  
5 storage because of evaporation. Positive artifacts occur when gas-phase compounds ( $H_2O$ ,  
6  $HNO_3$ ,  $SO_2$ , and organic compounds) absorb onto or react with filter media or collected PM or  
7 when some particle-bound water is not removed.

8         Sampling systems for semivolatile PM components make use of denuders to remove the  
9 gas-phase fraction and absorptive filters to remove the condensed phase and retain any material  
10 that subsequently evaporates from the collected PM. The loss of particulate nitrate may be  
11 determined by comparing nitrate collected on a Teflon filter to that collected on a nylon filter  
12 (which absorbs nitric acid which evaporates from ammonium nitrate particles) preceded by a  
13 denuder to remove gas-phase nitric acid. In two studies in southern California, the  $PM_{2.5}$  mass  
14 lost because of volatilization of ammonium nitrate was found to represent 10 to 20% of the total  
15  $PM_{2.5}$  mass and almost a third of the nitrate. Denuder/absorptive filter sampling systems also  
16 have been developed for measuring particulate phase organic compounds. This technique is an  
17 improvement over the filter/adsorbent collection method. However, the denuder systems  
18 currently discussed in the literature are not straightforward in their use, and the user must have a  
19 thorough understanding of the technology. The FRM for  $PM_{2.5}$  will likely suffer loss of  
20 particulate nitrates and semivolatile organic compounds, similar to the losses experienced with  
21 other single filter collection systems.

22         It is generally desirable to collect and measure ammonium nitrate and semivolatile organic  
23 compounds as part of particulate matter mass. However, it is usually desirable to remove the  
24 particle-bound water before determining the mass. In some situations, it may be important to  
25 know how much of the suspended particle's mass or volume results from particle-bound water.  
26 Calculations and measurements indicate that aerosol water content is strongly dependent on  
27 relative humidity and composition. Particle-bound water can represent a significant mass  
28 fraction of the PM concentration at relative humidities above 60%. A substantial fraction of  
29 accumulation-mode PM is hygroscopic or deliquescent. The more hygroscopic particles tend to  
30 contain more sulfates, nitrates, and secondary organic compounds, while the less hygroscopic  
31 particles tend to contain more elemental carbon, primary organic compounds, and crustal

1 components. Fresh, submicron-size soot particles may tend to shrink with increasing relative  
2 humidity because of a structural change. The effects of relative humidity on the sorption of  
3 semivolatile organic compounds on particles are not well understood. The amount of water  
4 sorbed to an atmospheric aerosol may be affected by the presence of an organic film on the  
5 particle, which may impede the transport of water across the surface.

6 Fine and coarse particles differ not only in formation mechanisms and size, but also in  
7 sources; composition; and chemical, physical, and biological properties. Fine and coarse  
8 particles overlap in the intermodal size range (1-2.5  $\mu\text{m D}_a$ ). As relative humidity increases, fine  
9 particles grow into this size range; as relative humidity decreases, more coarse particles may be  
10 suspended in this size range. It is desirable to measure fine PM and coarse PM separately in  
11 order to properly allocate health effects to either fine PM or coarse PM and to correctly  
12 determine sources by factor analysis or chemical mass balance. The selection of a cut point of  
13 2.5  $\mu\text{m}$  as a basis for EPA's 1997 NAAQS for fine particles (Federal Register, 1997) and its  
14 continued use in many health effects studies reflects the importance placed on more complete  
15 inclusion of accumulation-mode particles, while recognizing that intrusion of coarse-mode  
16 particles can occur under some conditions with this cut point.

17 In addition to FRM sampling of equilibrated mass to determine compliance with PM  
18 standards, EPA requires states to conduct speciation sampling primarily to determine source  
19 categories and trends. The current speciation samplers collect  $\text{PM}_{2.5}$  on three filters:  
20 (1) a Teflon filter for gravimetric determination of mass and for analysis of heavy elements by  
21 X-ray fluorescence; (2) a Nylon filter preceded by a nitric acid denuder for artifact-free  
22 determination of nitrate and measurement of other ionic species by ion chromatography; and  
23 (3) a quartz filter for measurement of elemental carbon (EC) and organic carbon (OC). In  
24 addition, IMPROVE (Interagency Monitoring of Protected Visual Environments) samplers  
25 provide information on regional PM background and transport. IMPROVE samplers, in addition  
26 to the three types of filters collected by the speciation samplers, also collect a  $\text{PM}_{10}$  sample. The  
27 IMPROVE and speciation networks use slightly different methods for determination of EC and  
28 OC. The two methods agree on total carbon but differ in the split of total carbon into EC and  
29 OC. The two methods also differ in their correction for positive artifacts due to absorption of  
30 volatile organic compounds on the quartz filters. Neither EC/OC method provides for any

1 correction for negative artifacts due to evaporation of semivolatile organic compounds from the  
2 collected particles.

3 The EPA expects that monitoring agencies will operate continuous PM monitors; and EPA  
4 is in the process of providing guidance regarding appropriate continuous monitoring techniques.  
5 All currently available techniques for continuous measurements of suspended particle mass, e.g.,  
6 the integrating nephelometer, the beta-absorption monitor, and the Tapered Element Oscillating  
7 Microbalance (TEOM), share the problem of dealing with semivolatile PM components: that is,  
8 in order not to include particle-bound water as part of the mass, the particle-bound water must be  
9 removed by heating or dehumidification; however, heating also causes ammonium nitrate and  
10 semivolatile organic compounds to evaporate. The TEOM monitor operates at a constant, but  
11 higher than ambient, temperature to remove particle-bound water; whereas, the FRM is required  
12 to operate at no more than 5 °C above the ambient temperature. Subsequently, much of the  
13 particle-bound water is removed during equilibration at 40% relative humidity. This difference  
14 in techniques for removal of particle-bound water causes differences in the measured mass  
15 concentration between the TEOM and FRMs.

16 Several new techniques for continuous PM mass measurements are currently being field  
17 tested. The Real-Time Total Ambient Mass Sampler (RAMS) measures the total mass of  
18 collected particles including semivolatile species with a TEOM monitor using a “sandwich  
19 filter.” The sandwich contains a Teflon-coated particle-collection filter followed by a charcoal-  
20 impregnated filter to collect any semivolatile species lost from the particles during sampling.  
21 The RAMS uses a Nafion dryer to remove particle-bound water from the suspended particles and  
22 a particle concentrator to reduce the quantity of gas phase organic compounds that must be  
23 removed by the denuder. The Continuous Ambient Mass Monitor (Camm) estimates ambient  
24 particulate matter mass by measurement of the increase in the pressure drop across a membrane  
25 filter caused by particle loading. It also uses a Nafion dryer to remove particle-bound water.  
26 A new differential TEOM offers the possibility of measuring both nonvolatile and semivolatile  
27 PM mass. In addition to continuous mass measurement, a number of techniques for continuous  
28 measurement of sulfate, nitrate, or elements are being tested.

### 2.3.3 Key Points

#### Fine and Coarse Particles

Particle size distributions show that atmospheric particles exist in two classes, fine particles and coarse particles. Fine and coarse particles are defined primarily in terms of their formation mechanisms and size; an they also differ in sources, chemical composition, and removal processes (see Table 2-1). Subsequent chapters will show that fine and coarse particles also differ in aspects of concentration, exposure, dosimetry, toxicology, and epidemiology.

These differences support the setting of separate standards for fine and coarse particles. Fine and coarse particles overlap in the size range between 1 and 3  $\mu\text{m}$  aerodynamic diameter where particulate matter (PM) concentrations are at a minimum. Coarse particles are generally larger than this minimum and are generally formed by mechanical processes. Coarse particles and coarse-mode particles are equivalent terms. Fine particles are generally smaller than the minimum and are generally formed by coagulation and condensation of gases. Fine particles are subdivided into accumulation, Aitkin, and nucleation modes. In earlier texts, nuclei mode referred to the size range now split into the Aitkin and nucleation modes (see Figures 2-4 and 2-5).

#### Measurement of Mass and Composition

Nonvolatile PM. Analytical techniques exist for measurement of the mass and chemical composition of PM retained on a filter (nonvolatile mass) in terms of elements (except carbon) and certain key ions (sulfate, nitrate, hydrogen, and ammonium). Acceptable measurements can be made of the total carbon retained on a filter. However, the split into organic carbon and elemental carbon depends on the operational details of the analytical methods and varies somewhat among methods. Determination of the various organic compounds in the organic carbon fraction remains a challenge.

Semivolatile PM. Important components of atmospheric PM (particle-bound water, ammonium nitrate, and many organic compounds) are termed semivolatile because significant amounts of both the gaseous and condensed phases may exist in the atmosphere in equilibrium. Particle-bound water is not considered a pollutant. Most of the particle-bound water is removed by heating the particles or by equilibration of the collected particles at a low relative humidity

1 (40%) for 24 hours. However, these processes also cause the loss of other semivolatile  
2 components. Semivolatile components also evaporate from the filter during sampling due to the  
3 pressure drop across the filter or due to a reduction in the atmospheric concentration during the  
4 sampling time. Filter collection and equilibration techniques for PM, such as prescribed by the  
5 Federal Reference Methods, lose a fraction of the semivolatile PM. Continuous methods must  
6 dry the PM to remove particle-bound water. If heating is used to dry the particles, more of the  
7 semivolatile components may be removed than are lost in filter sampling. Collection and  
8 retention of ammonium nitrate and semivolatile organic compounds represents a major challenge  
9 in the effort to move to continuous measurement of PM mass. The use of diffusion dryers,  
10 which dehumidify the air stream without heating, represents a promising approach. Uncertainty  
11 in the efficiency of retention of ammonium nitrate and organic compounds on filters also  
12 impacts source category attribution and epidemiologic studies.

#### 13 14 Separation of Fine and Coarse PM

15 Techniques are available to separate fine particles from coarse particles and collect the fine  
16 particles on a filter. No such technique exists for coarse particles. As yet, no consensus exists  
17 on the best technique for collecting a coarse particle sample for determination of mass and  
18 composition. Candidates include multistage impaction, virtual impaction, and difference  
19 (subtracting PM<sub>2.5</sub> mass or composition from PM<sub>10</sub> mass or composition). Advances in the  
20 theory and practice of virtual impaction suggest that it would be possible to design virtual  
21 impactors with much less than the 10% of fine PM collected in the coarse PM sample as is now  
22 the case for the dichotomous samplers used in air quality studies and with penetration curves as  
23 sharp as those used in the current Federal Reference Method for PM<sub>2.5</sub>.

1                   **APPENDIX 2A. TECHNIQUES FOR MEASUREMENT OF**  
2                   **SEMIVOLATILE ORGANIC COMPOUNDS**

3  
4  
5           *Use of Denuder Systems To Measure Semivolatile Organic Compounds*

6           Phase distribution of semivolatile organic species has been the subject of several studies  
7 that have employed denuder technology (see Gundel et al., 1995; Gundel and Lane, 1999) to  
8 directly determine the phase distributions while avoiding some of the positive and negative  
9 sampling artifacts associated with using back-up quartz filters. In an ideal system with a  
10 denuder that is 100% efficient, the gas phase would be collected in the denuder and the particle  
11 phase would be the sum of the material collected on the filter and the adsorbent downstream.  
12 Denuder collection efficiency depends on the denuder surface area (+), the diffusivity (+) and  
13 vapor pressure (-) of the compound, the temperature (-) and flow rate (-) of the air stream, and  
14 the presence of competing species (-), including water vapor (Cui et al., 1998; Kamens and Coe,  
15 1997; Lane et al., 1988). (The + and - symbols in parentheses indicate qualitatively the effect  
16 increasing each parameter would have on efficiency). In a system with a denuder collection  
17 efficiency less than 100%, the collection efficiency must be known to accurately attribute  
18 adsorbed organics from denuder breakthrough to the gas phase and adsorbed organics volatilized  
19 from collected particles to the particle phase. In calculating the overall phase distributions of  
20 SVOC PAH from a denuder system, the collection efficiency for each compound is needed.

21           The efficiency of silicone-grease-coated denuders for the collection of polynuclear  
22 aromatic hydrocarbons was examined by Coutant et al. (1992), who examined the effects of  
23 uncertainties in the diffusion coefficients and in the collisional reaction efficiencies on the  
24 overall phase distributions of SVOC PAH calculated using denuder technology. In their study,  
25 they used a single stage, silicone-grease-coated aluminum annular denuder with a filter holder  
26 mounted ahead of the denuder and an XAD trap deployed downstream of the denuder. In a  
27 series of laboratory experiments, they spiked the filter with a mixture of perdeuterated PAH,  
28 swept the system with ultra-high purity air for several hours, and then analyzed the filter and the  
29 XAD. They found that the effects of these uncertainties, introduced by using a single compound  
30 as a surrogate PAH (in their case, naphthalene) for validation of the denuder collection  
31 efficiency, are less significant than normal variations because of sampling and analytical effects.  
32 Results on field studies using their sampling system have not been published.

1 For measuring particulate phase organic compounds, the denuder-based sampling system  
2 represents an improvement over the filter/adsorbent collection method (Turpin et al., 1993).  
3 Some researchers, however, have reported that denuder coatings themselves can introduce  
4 contamination (Mukerjee et al., 1997) and that the adsorbed species may be difficult to remove  
5 from the coating (Eatough et al., 1993).

6 In a study conducted in southern California (Eatough et al., 1995), the Brigham Young  
7 University Organic Sampling System (BOSS; Eatough et al., 1993) was used for determining  
8 POM composition, and a high-volume version (BIG BOSS; flow rate 200 L/min) was utilized  
9 for determining the particulate size distribution and the chemical composition of SVOC in fine  
10 particles. The BOSS, a multi-channel diffusion denuder sampling system, consists of two  
11 separate samplers (each operating at 35 L/min). The first sampler consists of a multi-parallel  
12 plate diffusion denuder with charcoal-impregnated filter papers as the collection surfaces  
13 followed by a two-stage quartz filter pack and a two-stage charcoal-impregnated filter pack. The  
14 second sampler operating in parallel with the first consists of a two-stage quartz filter pack,  
15 followed by the parallel plate denuder, followed by the two-stage charcoal-impregnated filter  
16 pack. The filter samples collected by the BOSS sampler were analyzed by temperature-  
17 programmed volatilization analysis. The second channel allows calculations of the efficiency of  
18 the denuder in removing gas-phase specifics that would be absorbed by the charcoal impregnated  
19 filter. Eatough et al. (1995) also operated a two-stage quartz filter pack alongside the BOSS  
20 sampler. The BIG BOSS system (Tang et al., 1994) consists of four systems (each with a  
21 flowrate of 200 L/min). Particle size cuts of 2.5, 0.8, and 0.4  $\mu\text{m}$  are achieved by virtual  
22 impaction, and the sample subsequently flows through a denuder, then is split, with the major  
23 flow (150 L/min) flowing through a quartz filter followed by an XAD-II bed. The minor flow is  
24 sampled through a quartz filter backed by a charcoal-impregnated filter paper. The samples  
25 derived from the major flow (quartz filters and XAD-II traps) were extracted with organic  
26 solvents and analyzed by gas chromatography (GC) and GC-mass spectroscopy. The organic  
27 material lost from the particles was found to represent all classes of organic compounds.

28 Eatough et al. (1996) operated the BOSS sampler for a year at the IMPROVE site at  
29 Canyonlands National Park, UT, alongside the IMPROVE monitor and alongside a separate  
30 sampler consisting of a two-stage quartz filter pack. They found that concentrations of  
31 particulate carbon determined from the quartz filter pack sampling system were low on average

1 by 39%, and this was attributed to volatilization losses of SVOC from the quartz filters.

2 In another study conducted with the BOSS in southern California, losses of 35% of the POM, on  
3 average, were found and attributed to losses of the SVOC during sampling (Eatough et al.,  
4 1995).

5 The denuder used in the various BOSS samplers consists of charcoal-impregnated cellulose  
6 fiber filter material. Denuder collection efficiencies of greater than 95% have been reported for  
7 organic gases that adsorb on quartz and charcoal-impregnated filters (Eatough et al., 1999a; Ding  
8 et al., 2002; Lewtas et al., 2001). However, because the mass concentration of gas phase species  
9 that adsorb on quartz and charcoal-impregnated filters is so much greater than the mass of  
10 semivolatile organic material in the particulate phase, it is necessary to measure and account for  
11 the inefficiency of the denuder in the BOSS samplers. To address this problem, Brigham Young  
12 University (BYU) developed a particle-concentrator (PC)-BOSS system (Ding et al., 2002;  
13 Eatough et al., 1999b; Lewtas et al., 2001; Modey et al., 2001; Pang et al., 2001, 2002a,b). The  
14 PC-BOSS includes a virtual impactor upstream of the denuder to improve the denuder collection  
15 efficiency by removing a majority of the gases from the aerosol flow. With this system, denuder  
16 collection efficiencies of greater than 99% have been reported for organic gases, SO<sub>2</sub>(g),  
17 HNO<sub>3</sub>(g) and other species that adsorb on quartz and charcoal-impregnated filters (Pang et al.,  
18 2001). Since the concentrations of semivolatile organic and other gases in the presence of the  
19 concentrated particles is not altered by this process the virtual impaction concentration of  
20 accumulation mode particles (except possibly by slight changes in pressure), it is anticipated that  
21 the gas-particle distribution will not be significantly altered by the concentration process. The  
22 virtual impactor has a 50% cut point at 0.1 μm aerodynamic diameter. As a result, some  
23 particles in the 0.05 to 0.2 μm diameter size range will be removed in the major flow along with  
24 the majority of the gases. Therefore, the mass collection efficiency of the virtual impactor  
25 concentrator will be a function of the particle size distribution in the 0.05 to 0.1 μm size range.  
26 This collection efficiency is measured by comparing the concentration of nonvolatile  
27 components measured in the concentrated sample with that measured in an unconcentrated  
28 sample. The concentration efficiency varies from 50 to 75%. It is relatively constant over  
29 periods of weeks but varies by season and site, presumably as the particle size distribution  
30 changes. Previous studies at Harvard (Sioutas et al., 1995a,b) have shown that the composition  
31 of the sampled aerosol is little changed by the concentration process. The BYU studies listed

1 above have shown that the concentration efficiencies for sulfate, organic carbon (OC) and  
2 elemental carbon (EC) are comparable for a given sampling location. Furthermore, the  
3 concentrations of these species and of fine particulate nitrate determined using the PC-BOSS  
4 have been shown to be comparable to those determined using more conventional samplers for  
5 sulfate or EC or using simpler denuder systems for OC and nitrate.

6 Ding et al. (1998a) developed a method for the determination of total n-nitroso compounds  
7 in air samples and used the method to examine organic compounds formed from NO<sub>x</sub> chemistry  
8 in Provo, UT (Ding et al., 1998b). In their method, n-nitroso compounds are selectively  
9 decomposed to yield nitric oxide, which is then detected using chemiluminescence. From the  
10 samples from Provo, they found that the majority of the n-nitroso and nitrite organic compounds  
11 that were present in fine particulate matter were semivolatile organic compounds that could be  
12 evaporated from the particles during sampling. They found particulate n-nitroso compound  
13 concentrations ranging between <1 and 3 nmoles/m<sup>3</sup> and gas-phase n-nitroso compound  
14 concentrations in the same range. Particulate organic nitrite concentrations were found in the  
15 range of <1 to ≈5 nmoles/m<sup>3</sup>, and gas-phase concentrations as high as 10 nmoles/m<sup>3</sup> were found.

16 Turpin et al. (1993) developed a sampling system that corrects for the loss of semivolatile  
17 organic compounds during sampling by removal of most of the gas phase material from the  
18 particles in a diffusion separator sampling system. Unlike the previously mentioned systems,  
19 wherein the particulate phase is measured directly, in the system of Turpin et al. (1993) the  
20 gas-phase is measured directly. In the laminar flow system, ambient, particle-laden air enters the  
21 sampler as an annular flow. Clean, particle-free air is pushed through the core inlet of the  
22 separator. The clean air and ambient aerosol join downstream of the core inlet section, and flow  
23 parallel to each other through the diffusion zone. Because of the much higher diffusivities for  
24 gases compared to particles, the SVOC in the ambient air diffuses to the clean, core flow. The  
25 aerosol exits the separator in the annular flow, and the core flow exiting the separator now  
26 contains a known fraction of the ambient SVOC. Downstream of the diffusion separator, the  
27 core exit flow goes into a polyurethane foam (PUF) plug, where the SVOC is collected. The  
28 adsorbed gas phase on the PUF plug is extracted with supercritical fluid CO<sub>2</sub> and analyzed by  
29 gas chromatography/mass-selective detection (GC/MSD). The gas-phase SVOC is thus  
30 determined. Ultimately, to determine particulate phase SVOC concentrations, the total  
31 compound concentration will also be measured and the particulate phase obtained by difference.

1 The system was tested for the collection of PAH. The diffusional transport of gas-phase PAHs  
2 and particle concentrations agreed well with theory. Breakthrough was problematic for low  
3 molecular weight PAHs (MW < 160). Detection limits ranged from 20 to 50 pg of injected mass  
4 for all PAHs.

5 Gundel et al. (1995) recently developed a technique for the direct determination of phase  
6 distributions of semivolatile polycyclic aromatic hydrocarbons using annular denuder  
7 technology. The method, called the integrated organic vapor/particle sampler (IOVPS), uses a  
8 cyclone inlet with a 50% cutpoint of 2.5  $\mu\text{m}$  at a sampling rate of 10 L/min. The airstream then  
9 goes through two or three sandblasted glass annular denuders that are coated with ground  
10 adsorbent resin material (XAD-4 was initially examined) that traps vapor-phase organics. The  
11 airstream subsequently passes through a filter, followed by a backup denuder. The denuder  
12 collection efficiency is high and compares well with predictions based on the diffusivity of the  
13 compounds. The denuder can also be extracted to obtain gas-phase concentrations directly  
14 (Gundel and Lane, 1999). Particle-phase PAHs are taken to be the sum of material on the filter  
15 and XAD adsorbent downstream after correction for denuder collection efficiency. The IOVPS  
16 was tested for sampling semivolatile PAH in laboratory indoor air and in environmental tobacco  
17 smoke (ETS). After exposure, the denuders, filters, and sorbent traps were extracted with  
18 cyclohexane (Gundel et al., 1995) and analyzed for PAHs from naphthalene to chrysene using  
19 dual-fluorescence detection (Mahanama et al., 1994). Recoveries from both denuders and filters  
20 were approximately 70% for 30 samples. Detection limits (defined as 3 times the standard  
21 deviation of the blanks) for gas-phase SVOC PAHs ranged from 0.06 ng for anthracene to 19 ng  
22 for 2-methylnaphthalene. The 95% confidence interval for reproduction of an internal standard  
23 concentration was 6.5% of the mean value. Relative precision, from a propagation of errors  
24 analysis or from the 95% confidence interval from replicate analyses of standard reference  
25 material SRM 1649 (urban dust/organics), was 12% on average (8% for naphthalene to 22% for  
26 fluorene). Sources of error included sampling flow rate, internal standard concentration, and  
27 co-eluting peaks. Gundel and Lane (1999) reported that roughly two-thirds of particulate PAH  
28 fluoranthene, pyrene, benz[*a*]anthracene, and chrysene were found on the postfilter denuders, so  
29 that it is likely that considerable desorption from the collected particles took place.

30 Solid adsorbent-based denuder systems have been investigated by other researchers as  
31 well. Bertoni et al. (1984) described the development of a charcoal-based denuder system for

1 the collection of organic vapors. Risse et al. (1996) developed a diffusion denuder system to  
2 sample aromatic hydrocarbons. In their system, denuder tubes with charcoal coating and  
3 charcoal paper precede a filter pack for particulate collection and an adsorption tube to capture  
4 particle blow-off from the filter sample. Breakthrough curves for benzene, toluene, ortho-  
5 xylene, and meta-xylene were developed for 60-, 90-, and 120-cm denuder tubes. The effects of  
6 relative humidity on the adsorption capacities of the denuder system were examined, and it was  
7 found that the capacity of the charcoal was not affected significantly by increases in relative  
8 humidity. The feasibility of outdoor air sampling with the system was demonstrated.

9 Krieger and Hites (1992) designed a diffusion denuder system that uses capillary gas  
10 chromatographic columns as the tubes for SVOC collection. The denuder was followed by a  
11 filter to collect particles, which in turn was followed by a PUF plug to collect organic material  
12 volatilizing off the filter. Denuder samples were analyzed by liquid solvent extraction ( $\text{CH}_2\text{Cl}_2$ )  
13 followed by GC-mass spectrometric analysis. The PUF plugs and filters were extracted with  
14 supercritical fluid extraction using supercritical  $\text{N}_2\text{O}$ . Using this system, an indoor air sample  
15 was found to contain primarily chlorinated biphenyls, ranging from trichlorobiphenyls (vapor  
16 pressures  $10^{-3} - 10^{-4}$  Torr at 25 °C) to octachlorobiphenyls ( $10^{-6} - 10^{-7}$  Torr). This demonstrated  
17 that the sampler collects compounds with a wide range of volatility. They also found that on-  
18 line desorption is successful in maintaining good chromatographic peak shape and resolution.  
19 The entire method, from sample collection to the end of the chromatographic separation, took  
20 2 h.

21 Organic acids in both the vapor and particulate phases may be important contributors to  
22 ambient acidity, as well as representing an important fraction of organic particulate matter.  
23 Lawrence and Koutrakis (1996a,b) used a modified Harvard/EPA annular denuder system  
24 (HEADS) to sample both gas and particulate phase organic acids in Philadelphia, PA, in the  
25 summer of 1992. The HEADS sampler inlet had a 2.1- $\mu\text{m}$  cutpoint impactor (at 10 L/min),  
26 followed by two denuder tubes, and finally a filter pack with a Teflon filter. The first denuder  
27 tube was coated with potassium hydroxide (KOH) to trap gas phase organic acids. The second  
28 denuder tube was coated with citric acid to remove ammonia and thus to avoid neutralizing  
29 particle phase acids collected on the filter. The KOH-coated denuder tube was reported to  
30 collect gas phase formic and acetic acids at better than 98.5% efficiency and with precisions of  
31 5% or better (Lawrence and Koutrakis, 1994). It was noted that for future field measurements of

1 particulate organic acids, a Na<sub>2</sub>CO<sub>3</sub>-coated filter should be deployed downstream of the Teflon  
2 filter to trap organic acids that may evaporate from the Teflon filter during sampling.

### 3 4 ***Role of the Collection Media***

5 The role of the collection media was recently examined in a study conducted in Seattle  
6 (Lewtas et al., 2001). In that study, the influence of denuder sampling methods and filter  
7 collection media on the measurement of SVOC associated with PM<sub>2.5</sub> was evaluated. Activated  
8 carbon and XAD collection media were used in diffusion denuders and impregnated back-up  
9 filters in two different samplers, the Versatile Air Pollution Sampler (VAPS) and the PC-BOSS.  
10 XAD-coated glass annular denuders and charcoal-impregnated cellulose fiber (CIF) filter  
11 denuders also were used. CIF filters also were compared to XAD-coated quartz filters as backup  
12 filter collection media. Lewtas et al. (2001) found that the two denuder types resulted in an  
13 equivalent measurement of particulate organic carbon and particle mass. The carbon-coated  
14 denuders in the BOSS sampler were more efficient than the XAD-coated denuders for the  
15 collection of the more highly volatile organic compounds (MHVOC). Lewtas et al. (2001)  
16 concluded that this MHVOC that is collected in the carbon-coated BOSS denuder does not  
17 contribute substantially to the particle mass or to the SVOC measured as OC on quartz filters.  
18 However, this MHVOC would be captured in the carbon impregnated filters placed behind the  
19 quartz filters, so that, in the XAD denuder configuration, the captured MHVOC would cause a  
20 higher OC concentration and an overestimation of the SVOC.

21 Some of the recent research in denuder technology also has focused on reduction in the  
22 size of the denuder, optimization of the residence time in the denuder, understanding the effect  
23 of diffusion denuders on the positive quartz filter artifact, identifying changes in chemical  
24 composition that occur during sampling, determining the effects of changes in temperature and  
25 relative humidity, and identifying possible losses by absorption in coatings.

### 26 27 ***Reducing the Size of Denuders***

28 The typical denuder configuration is an annular diffusion denuder tube of significant length  
29 (e.g., 26.5 cm for 10 L/min [Koutrakis et al., 1988a,b]). A more compact design based on a  
30 honeycomb configuration was shown to significantly increase the capacity (Koutrakis et al.,  
31 1993). However, in intercomparisons with an annular denuder/filter pack system (Koutrakis

1 et al., 1988), significant losses of ammonia and nitric acid were observed for the honeycomb  
2 configuration and were attributed to the large inlet surface area and long sample residence time  
3 of the honeycomb design relative to the annular denuder system. Sioutas et al. (1996a)  
4 subsequently designed a modified glass honeycomb denuder/filter pack sampler (HDS) with an  
5 inlet that minimizes vapor losses on the inlet surfaces. The modified HDS has reduced inlet  
6 surfaces and decreased residence time for sampled gases ( $\text{NH}_3$  and  $\text{HNO}_3$ ) compared to its  
7 predecessor (Sioutas et al., 1994d). Sioutas et al. (1996b) also tested various inlet materials  
8 (glass, PFA, and polytetrafluoroethylene [PTFE]) in laboratory tests and found that a PTFE  
9 Teflon coated inlet minimized loss of sampled gases (1 to 8% loss of  $\text{HNO}_3$  observed, and -4 to  
10 2% loss of  $\text{NH}_3$  observed). The highest inlet losses were observed for  $\text{HNO}_3$  lost to PFA  
11 surfaces (14 to 25%). The modified HDS was tested in laboratory and field tests and found to  
12 agree within 10% with the annular denuder system.

### 13 14 ***Residence Time in the Denuder***

15 The efficiency of a diffusion denuder sampler for the removal of gas phase material can be  
16 improved by increasing the residence time of the sampled aerosol in the denuder. However, the  
17 residence time can only be increased within certain limits. Because the diffusion denuder  
18 reduces the concentration of gas-phase semivolatile organic material, semivolatile organic matter  
19 present in the particles passing through the denuder will be in a thermodynamically unstable  
20 environment and will tend to outgas SVOC during passage through the denuder. The residence  
21 time of the aerosol in the denuder, therefore, should be short enough to prevent significant loss  
22 of particulate phase SVOC to the denuder. Various studies have suggested that the residence  
23 time in the denuder should be less than about 2 s (Gundel and Lane, 1999; Kamens and Coe,  
24 1997; Kamens et al., 1995). The residence times in the various denuder designs described by  
25 Gundel and Lane (1999) are from 1.5 to 0.2 s. The equilibria and evaporation rates are not as  
26 well understood for organic components as they are for  $\text{NH}_4\text{NO}_3$  (Zhang and McMurry, 1987,  
27 1992; Hering and Cass, 1999).

### 28 29 ***Effect of Diffusion Denuders on the Positive Quartz Filter Artifact***

30 The adsorption of organic compounds by a second quartz filter has been shown to be  
31 reduced, but not eliminated, in samples collected in the Los Angeles Basin if a multi-channel

1 diffusion denuder with quartz filter material as the denuder collection surface preceded the  
2 quartz filters (Fitz, 1990). This artifact can be further reduced by the use of activated charcoal as  
3 the denuder surface and the use of a particle concentrator to reduce the amount of gas phase  
4 organic compounds relative to condensed phase organic compounds (Cui et al., 1997, 1998;  
5 Eatough, 1999). Other experiments (Cotham and Bidleman, 1992; Cui et al., 1998; Eatough  
6 et al., 1995, 1996) have shown that the quartz filter artifact can result both from the collection of  
7 gas phase organic compounds and from the collection of semivolatile organic compounds lost  
8 from particles during sampling. Thus, results available to date suggest that both a “positive” and  
9 a “negative” artifact can be present in the determination of particulate phase organic compounds  
10 using two tandem quartz filters.

11 The importance of the adsorption of organic vapors on filters or PM relative to the  
12 volatilization of organic compounds from PM collected on a filter continues to be a topic of  
13 active debate. The relative importance of positive and negative artifacts will be different for  
14 denuded and undenuded filters; will depend on face velocity, sample loading, and the vapor  
15 pressures of the compounds of interest; and may vary with season and location because of  
16 variations in the composition of volatile and semivolatile organic material. Evidence exists for  
17 substantial positive and negative artifacts in the collection of organic PM.

### 18 19 ***Changes in Chemical Composition During Sampling***

20 The use of sampling systems designed to correctly identify the atmospheric gas and  
21 particulate phase distributions of collected organic material has been outlined above.  
22 An additional sampling artifact that has received little consideration in the collection of  
23 atmospheric samples is the potential alteration of organic compounds as a result of the sampling  
24 process. These alterations appear to result from the movement of ambient air containing  
25 oxidants and other reactive compounds past the collected particles. The addition of NO<sub>2</sub>  
26 (<1ppm) or O<sub>3</sub> (<200 ppb) to the sampled air stream (0 to 5 °C) for a high-volume sampler  
27 reduced the concentrations of benzo[*a*]pyrene and benzo[*a*]anthracene from a few % to 38%,  
28 with the observed reduction increasing with increased concentration of the added gases  
29 (Brorström et al., 1983). Spiking a filter with an amine resulted in an increase in measured  
30 concentrations of nitrosamines in both the filter and a following XAD sorbent bed for a  
31 mid-volume sampler (Ding et al., 1998a,b). Similar results have been obtained for the exposure

1 of a deuterated amine on a filter to NO<sub>x</sub> (Pellizzari and Krost, 1984). When Tenax columns  
2 spiked with deuterated styrene and cyclohexene were exposed to ppm concentrations of ozone or  
3 halogens, oxygenated and halogenated compounds were formed (Pellizzari and Krost, 1984).  
4 Similar oxidation of aldehydes and peroxyacetyl nitrate (PAN) during sampling has been  
5 observed (Grosjean and Parmar, 1990). Collected PAH compounds can be oxygenated or  
6 nitrated on a filter (Davis et al., 1987; Lindskog and Brorstrom-Lunden, 1987), but 1-nitropyrene  
7 has been shown to be resistant to additional nitration (Grosjean, 1983). These various chemical  
8 transformations of collected organic compounds can be eliminated by removal of the gas phase  
9 oxidants, NO<sub>x</sub>, HNO<sub>3</sub>, etc., by reaction or adsorption prior to collection of the particles (Ding,  
10 1998a,b; Grosjean and Parmar, 1990; Parmar and Grosjean, 1990; Pellizzari and Krost, 1984;  
11 Williams and Grosjean, 1990). The BOSS denuder should be effective in eliminating most of  
12 the chemical transformation artifacts because reactive gases are removed by the charcoal  
13 denuder that precedes the particle collection filter.

#### 14 15 ***Temperature and Relative Humidity Effects***

16 The problems of sampling artifacts associated with SVOC adsorption and evaporation are  
17 compounded by temperature and relative humidity effects (Pankow and Bidleman, 1991;  
18 Pankow et al., 1993; Falconer et al., 1995; Goss and Eisenreich, 1997). Effects of temperature  
19 on the partitioning of PAH were examined by Yamasaki et al. (1982), who found that the  
20 partition coefficient ( $PAH_{\text{vapor}}/PAH_{\text{part}}$ ) was inversely related to temperature and could be  
21 described using the Langmuir adsorption concept. The dissociation of ammonium nitrate aerosol  
22 is also a function of temperature. Bunz et al. (1996) examined the dissociation and subsequent  
23 redistribution of NH<sub>4</sub>NO<sub>3</sub> within a bimodal distribution using a nine-stage low-pressure Berner  
24 impactor followed by analysis by ion chromatography and found a strong temperature  
25 dependency on the redistribution. Bunz et al. (1996) found that at lower temperatures (below  
26 10 °C) there was little change in the aerosol size distribution. At temperatures between 25 and  
27 45 °C, however, the lifetime of NH<sub>4</sub>NO<sub>3</sub> particles decreases by more than a factor of 10, and size  
28 redistribution, as measured by average ending particle diameter, increased more for higher  
29 temperatures than for lower temperatures.

30 The effects of relative humidity on the sorption of SVOC on particles are not well  
31 understood. In a series of laboratory experiments, Goss and Eisenreich (1997) examined the

1 sorption of both nonpolar (hydrocarbons and chlorinated hydrocarbons) and polar (ethyl ether  
2 and acetone) volatile organic compounds onto combustion soot particles as a function of  
3 temperature and relative humidity. The soot particles used in their experiments were collected  
4 from oil furnaces and contained 60% (w/w) iron sulfate (water-soluble fraction) and 9% (w/w)  
5 elemental and organic carbon. They found that, for all compounds, the sorption of VOC onto  
6 soot particles decreased with increasing relative humidity over the range of 10 to 95%. They  
7 also observed hysteresis in the relative humidity dependency, with sorption coefficients at a  
8 given relative humidity higher when the RH is being increased than when the RH is being  
9 decreased. The sorption coefficients were fit with an exponential function to the RH so that the  
10 slope of the regression line would provide a measure of the influence of relative humidity.  
11 Based on the magnitude of the slope, they concluded that the RH-dependency of sorption was  
12 stronger for water-soluble organic compounds.

13 In another study by Jang and Kamens (1998), humidity effects on gas-particle partitioning  
14 of SVOC were examined using outdoor environmental chambers and the experimentally  
15 determined partitioning coefficients were compared to theoretical values. They examined the  
16 partitioning of SVOC onto wood soot, diesel soot, and secondary aerosols and concluded that  
17 “the humidity effect on partitioning was most significant for hydrophobic compounds adsorbing  
18 onto polar aerosols.” Although these two studies seem to be contradictory, on closer  
19 examination, it is difficult to compare the two studies for several reasons. The experiments  
20 conducted by Jang and Kamens (1998) were conducted in outdoor chambers at ambient  
21 temperatures and humidities. Their model was for absorptive partitioning of SVOC on  
22 *liquid-like* atmospheric particulate matter. In contrast, the results of Goss and Eisenreich (1997)  
23 were obtained from a gas chromatographic system operated at 70 °C higher than ambient  
24 conditions. The model of Goss and Eisenreich (1997) was for adsorptive partitioning of VOC on  
25 *solid-like* atmospheric particulate matter. In the study of Jang and Kamens (1998), calculated  
26 theoretical values for water activity coefficients for diesel soot were based on an inorganic salt  
27 content of 1 to 2%; whereas, the combustion particles studied by Goss and Eisenreich (1997)  
28 contained 60% water-soluble, inorganic salt content. Jang and Kamens (1998) obtained their  
29 diesel soot from their outdoor chamber, extracted it with organic solvent (mixtures of hexane and  
30 methylene chloride), and measured the organic fraction. The resulting salt content of 2% of the

1 particulate matter studied in Jang and Kamens (1998) is enough to affect water uptake but  
2 presumably not to affect the sorption partitioning of organics.

#### 3 4 ***Impactor Coatings***

5       Impactors are used as a means to achieve a size cutpoint and as particle collection surfaces.  
6 Particles collected on impactors are exposed to smaller pressure drops than filter-collected  
7 particles, making them less susceptible to volatile losses (Zhang and McMurry, 1987).  
8 However, size resolution can be affected by bounce when samples are collected at low  
9 humidities (Stein et al., 1994). There are other sources of error inherent in some of the currently  
10 acceptable practices that could potentially affect particulate mass concentration measurements  
11 and that will surely become even more important as more emphasis is placed on chemical  
12 speciation. Allen et al. (1999a) reported that the practice of greasing impaction substrates may  
13 introduce an artifact from the absorption of semivolatile species from the gas phase by the grease  
14 because the grease could artificially increase the amount of PAHs and other organic compounds  
15 attributed to the aerosol. Allen et al. (1999b) offer several criteria to ensure that this absorption  
16 artifact is negligible, including selecting impaction oils in which analytes of interest are  
17 negligibly soluble and ensuring that species do not have time to equilibrate between the vapor  
18 and oil phases (criterion is met for nonvolatile species). They recommend using oiled impaction  
19 substrates only if the absorption artifact is negligible as determined from these criteria.  
20 Application of greases and impaction oils for preventing or reducing bounce when sampling with  
21 impactors is not suitable for carbon analysis because the greases contain carbon (Vasilou et al.,  
22 1999).

23       Kavouras and Koutrakis (2001) investigated the use of polyurethane foam (PUF) as a  
24 substrate for conventional inertial impactors. The PUF impactor substrate is not rigid like the  
25 traditional impactor substrate so particle bounce and reentrainment artifacts are reduced  
26 significantly. Kavouras and Koutrakis (2001) found that the PUF impaction substrate resulted in  
27 a much smaller 50% cut point at the same flow rate and Reynolds number. Moreover, the lower  
28 50% cut point was obtained at a lower pressure drop than with the conventional substrate, which  
29 could lead to a reduction of artifact vaporization of semivolatile components.

## APPENDIX 2B. ANALYTICAL TECHNIQUES

### 2B.1 INORGANIC ELEMENTS

#### 2B.1.1 Energy Dispersive X-Ray Fluorescence (EDXRF)

EDXRF has usually been the method of choice for analysis of trace elements on filters. EDXRF is preferred for aerosol analysis over wavelength dispersive XRF because it allows fast and simultaneous analysis over the total spectrum, allowing for the analysis of numerous elements simultaneously. EDXRF can accommodate small sample sizes and requires little sample preparation or operator time after the samples are placed into the analyzer. It also leaves the sample intact after analysis; so, further analysis is possible. XRF irradiates a uniform particle deposit on the surface of a membrane filter with 1 to 50 keV x-rays that eject inner shell electrons from the atoms of each element in the sample (Dzubay and Stevens, 1975; Jaklevic et al., 1977; Billiet et al., 1980; Potts and Webb, 1992; Piorek, 1994; Bacon et al., 1995; deBoer et al., 1995; Holynska et al., 1997; Török et al., 1998; Watson et al., 1999). When a higher energy electron drops into the vacant lower energy orbital, a fluorescent x-ray photon is released. The energy of this photon is unique to each element, and the number of photons is proportional to the concentration of the element. Concentrations are quantified by comparing photon counts for a sample with those obtained from thin-film standards of known concentration (Dane et al., 1996). The previous 1996 PM AQCD included a detailed discussion of EDXRF.

Emitted x-rays with energies less than ~4 keV (affecting the elements sodium, magnesium, aluminum, silicon, phosphorus, sulfur, chlorine, and potassium) are absorbed in the filter, in a thick particle deposit, or even by large particles in which these elements are contained. Very thick filters also scatter much of the excitation radiation or protons, thereby lowering the signal-to-noise ratio for XRF and PIXE. For this reason, thin membrane filters with deposits in the range of 10 to 50  $\mu\text{g}/\text{cm}^2$  provide the best accuracy and precision for XRF and PIXE analysis (Davis et al., 1977; Haupt et al., 1995).

#### 2B.1.2 Synchrotron Induced X-ray Fluorescence (S-XRF)

S-XRF is a form of EDXRF in which the exciting x-rays are derived from a synchrotron. Bremsstrahlung x-rays are generated when energetic electrons (generally several GeV in

1 energy) are forced by a magnetic field to make a bend in their path. The advantages of the  
2 technique are that an extremely high flux of x-rays may be obtained and that the x-rays are 100%  
3 polarized in the plane of the electron beam. The former allows for x-ray beams generally of  
4 50 to 500  $\mu\text{m}$  in diameter. However, the beams can be focused into x-ray microprobes, with spot  
5 sizes on the order of one  $\mu\text{m}$  diameter. The x-ray polarization allows for removal of most of the  
6 background normally found under the characteristic x-ray peaks, greatly improving sensitivity  
7 compared to other XRF techniques. The primary disadvantages are the limited number of  
8 synchrotrons, and that few synchrotrons have S-XRF capabilities. Thus, the technique has been  
9 relatively little used for PM, and then generally for special problems such as the smoke from the  
10 Kuwaiti oil fires (Cahill et al., 1992, Reid et al., 1994). However, with the increasing  
11 availability of S-XRF facilities dedicated to PM analysis, the first of which was the Advanced  
12 Light Source opened at Lawrence Berkeley National Laboratory last year, utilization of S-XRF  
13 for PM analysis is increasing.

### 14 15 **2B.1.3 Proton (or Particle) Induced X-ray Emission (PIXE)**

16 PIXE differs from XRF analysis in the excitation source for producing fluorescence. The  
17 filter deposit is bombarded with high-energy protons to remove inner shell electrons and the  
18 resulting characteristic x-rays are analyzed as in XRF (Johansson, 1970, Cahill, 1981, 1985;  
19 Zeng et al., 1993). Small accelerators, generally Van de Graaffs, generate intense beams of low  
20 energy protons, generally of a few MeV in energy. These have the ability to remove electrons  
21 from inner shells of atoms of any element. Thus, PIXE can see a very wide range of elements in  
22 a single analysis. The cross section for producing x-rays using protons of a few MeV in energy  
23 tends to favor lighter elements, Na through Ca, but sensitivities for equivalent PIXE and  
24 multi-wavelength XRF analysis are roughly comparable. The technique has been widely used in  
25 the U.S. (Flocchini et al., 1976, Malm et al., 1994) and around the world, as many universities  
26 have the small accelerators needed for the method. Like S-XRF, the proton beams can be  
27 focused into  $\mu\text{m}$  size beams, but these have been relatively little used for PM. However, the mm  
28 size beams used in both S-XRF and PIXE are well suited to analyzing the limited mass and small  
29 deposits that result from detailed particle size measurements by impactors (Perry et al., 1999).

#### 2B.1.4 Proton Elastic Scattering Analysis (PESA)

With the routine availability of elemental analyses for all elements sodium and heavier, organic components remain the major unmeasured species for mass balance. For programs like IMPROVE (Malm et al., 1994), parallel filters are collected for separate organic and elemental carbon determinations. Aerosol programs that use PIXE can directly measure hydrogen simultaneously by scattering protons from Teflon filters that lack hydrogen (Cahill et al., 1989, 1992). Generally, results from organic matter by carbon combustion from quartz filters and organic matter by hydrogen from Teflon filters are in agreement, assuming certain assumptions about the chemical states of sulfates and nitrates are met (Malm et al., 1994, Cahill et al., 1996).

#### 2B.1.5 Total Reflection X-ray Fluorescence (TRXRF)

One of the limitations of the EDXRF method is the minimum detection limit, which may be high due to high background values (Streit et al., 2000). By implementation of x-ray optical geometries that use the total reflection of the primary radiation on flat surfaces, scattering on the substrate is reduced, so that detection limits can be reduced. This is the basis for the total reflection x-ray fluorescence (TRXRF) method (Aiginger and Strelt, 1997). This modification to the EDXRF technique improves detection limits and avoids the need to correct for matrix effects. Despite its apparent advantages, TRXRF has not yet become widely in use for atmospheric aerosol analysis but has been used in the analysis of marine aerosol (Stahlschmidt et al., 1997) and at a high elevation site (Streit et al., 2000). Streit et al. sampled ambient air at the High Alpine Research Station (3580 m above sealevel) in the Bernese Alps, Switzerland, using a nine-stage, single-jet, low-pressure, cascade impactor equipped with quartz impactor plates coated with silicon oil diluted in 2-propanol. The typical sample volume for a weekly sample was 10 m<sup>3</sup>. The quartz plates were analyzed directly by TRXRF. Streit et al. reported that the minimum detection limits, defined by the 3 $\sigma$  values of the blanks, ranged from 25 ng for S, decreased monotonically with increasing atomic number down to 5 pg for Rb, and decreased after that. The use of TRXRF is expected to increase as EDXRF users become aware of the method. A relatively low-cost, add-on unit has been developed that would allow EDXRF users to test the TRXRF technique (Aiginger, 1991).

## 2B.1.6 Instrumental Neutron Activation Analysis (INAA)

INAA irradiates a sample in the core of a nuclear reactor for few minutes to several hours, depending on the elements being quantified (Dams et al., 1970; Zoller and Gordon, 1970; Nadkarni, 1975; Landsberger, 1988; Olmez, 1989; Ondov and Divita, 1993). The neutron bombardment chemically transforms many elements into radioactive isotopes. The energies of the gamma rays emitted by these isotopes identify them and, therefore, their parent elements. The intensity of these gamma rays is proportional to the amount of the parent element present in the sample. Different irradiation times and cooling periods are used before counting with a germanium detector. In source apportionment studies, it is possible to use a combination of XRF and INAA to develop a relatively complete set of elemental measurements. Between these two analytical techniques, good sensitivity is possible for many elements, including most of the toxic metals of interest. In general, XRF provides better sensitivity for some metals (e.g., Ni, Pb, Cu, and Fe); whereas INAA provides better sensitivity for others (Sb, As, Cr, Co, Se, and Cd). Both methods provide similar detection limits for still other elements (V, Zn, and Mn). INAA does not quantify some of the abundant species in ambient particulate matter such as silicon, nickel, tin, and lead. While INAA is technically nondestructive, sample preparation involves folding the sample tightly and sealing it in plastic, and the irradiation process makes the filter membrane brittle and radioactive. These factors limit the use of the sample for subsequent analyses.

INAA has been used to examine the chemical composition of atmospheric aerosols in several studies either as the only method of analysis or in addition to XRF (e.g., Yatin et al., 1994; Gallorini, 1995). INAA has higher sensitivity for many trace species, and it is particularly useful in analyzing for many trace metals. Landsberger and Wu (1993) analyzed air samples collected near Lake Ontario for Sb, As, Cd, In, I, Mo, Si, and V using INAA. They demonstrated that using INAA in conjunction with epithermal neutrons and Compton suppression produces very precise values with relatively low detection limits.

Enriched rare-earth isotopes have been analyzed via INAA and used to trace sources of particulate matter from a coal-fired power plant (Ondov et al., 1992), from various sources in the San Joaquin Valley (Ondov, 1996), from intentionally tagged (iridium) diesel emissions from sanitation trucks (Suarez et al., 1996; Wu et al., 1998), and from iridium-tagged emissions from school buses (Wu et al., 1998).

1 An intercomparison was conducted in which 18 pairs of filters were sent to participants in  
2 the Coordinated Research Program (CRP) on Applied Research on Waste Using Nuclear Related  
3 Analytical Techniques (Landsberger et al., 1997). As part of that study, participants used PIXE,  
4 INAA, XRF, or AAS to analyze the samples. Many of the results for XRF and PIXE in the  
5 coarse fraction were observed to be biased low compared to INAA. The authors speculated that  
6 there is a systematic error because of self-attenuation of the x-rays resulting from the particle  
7 size effect.

### 9 **2B.1.7 Atomic Absorption Spectrophotometry (AAS)**

10 AAS is applied to the residue of a filter extracted in a strong solvent to dissolve the solid  
11 material; the filter or a portion of it is also dissolved during this process (Ranweiler and Moyers,  
12 1974; Fernandez, 1989; Jackson and Mahmood, 1994; Chow et al., 2000a). A few milliliters of  
13 this extract are injected into a flame where the elements are vaporized. Elements absorb light at  
14 certain wavelengths in the visible spectrum, and a light beam with wavelengths specific to the  
15 elements being measured is directed through the flame to be detected by a monochromator. The  
16 light absorbed by the flame containing the extract is compared with the absorption from known  
17 standards to quantify the elemental concentrations. AAS requires an individual analysis for each  
18 element, and a large filter or several filters are needed to obtain concentrations for a large variety  
19 of elements. AAS is a useful complement to other methods, such as XRF and PIXE, for species  
20 such as beryllium, sodium, and magnesium which are not well-quantified by these methods.  
21 Airborne particles are chemically complex and do not dissolve easily into complete solution,  
22 regardless of the strength of the solvent. There is always a possibility that insoluble residues are  
23 left behind and that soluble species may co-precipitate on them or on container walls.

24 AAS was used to characterize the atmospheric deposition of trace elements Zn, Ni, Cr, Cd,  
25 Pb, and Hg to the Rouge River watershed by particulate deposition (Pirrone and Keeler, 1996).  
26 The modeled deposition rates were compared to annual emissions of trace elements that were  
27 estimated from the emissions inventory for coal and oil combustion utilities, iron and steel  
28 manufacturing, metal production, cement manufacturing, and solid waste and sewage sludge  
29 incinerators. They found generally good agreement between the trend observed in atmospheric  
30 inputs to the river (dry + wet deposition) and annual emissions of trace elements, with  $R^2$ s  
31 varying from  $\approx 0.84$  to 0.98. Both atmospheric inputs and emissions were found to have

1 followed downward trends for Pb. For the period of 1987 to 1992, steady increases were  
2 observed for Cd (major sources are municipal solid waste incineration, coal combustion, sludge  
3 incineration, and iron and steel manufacturing), Cr and Ni (major sources are iron and steel  
4 production and coal combustion), and Hg (major sources are coal, the contribution from which  
5 had decreased from 53 to 45%, and municipal, solid, and medical waste incineration, the  
6 contribution from which has increased).

### 7 8 **2B.1.8 Inductively Coupled Plasma with Atomic Emission Spectroscopy** 9 **(ICP-AES)**

10 ICP-AES introduces an extracted sample into an atmosphere of argon gas seeded with free  
11 electrons induced by high voltage from a surrounding Tesla coil (Fassel and Kniseley, 1974;  
12 McQuaker et al., 1979; Lynch et al., 1980; Harman, 1989; Tyler, 1992; Baldwin et al., 1994).  
13 The high temperatures in the induced plasma raise valence electrons above their normally stable  
14 states. When these electrons return to their stable states, a photon of light is emitted that is  
15 unique to the element that was excited. This light is detected at specified wavelengths to identify  
16 the elements in the sample. ICP-AES acquires a large number of elemental concentrations using  
17 small sample volumes with acceptable detection limits for atmospheric samples. As with AAS,  
18 this method requires complete extraction and destruction of the sample.

### 19 20 **2B.1.9 Inductively Coupled Plasma with Mass Spectroscopy (ICP-MS)**

21 ICP-MS has been applied in the analysis of personal exposure samples (Tan and Horlick,  
22 1986; Gray and Williams, 1987a,b; Nam et al., 1993; Munksgaard and Parry, 1998; Campbell  
23 and Humayun, 1999). Ion species generated from ICP and from the sample matrix can produce a  
24 significant background at certain masses resulting in formation of polyatomic ions that can limit  
25 the ability of ICP-MS to determine some elements of interest. Cool plasma techniques have  
26 demonstrated the potential to detect elements at the ultra-trace level (Nham et al., 1996) and to  
27 minimize common molecular ion interferences (Sakata and Kawabata, 1994; Turner, 1994;  
28 Plantz, 1996). Detection limits of ICP-MS using a one-second scan are typically in the range of  
29  $10^{-3}$  ng/m<sup>3</sup>, which is an order of magnitude lower than other elemental analysis methods. The  
30 instrument can also be set up to analyze a wide dynamic range of aerosol concentrations.

1 Isotope analysis can also be performed with ICP-MS. Intercomparison studies are needed to  
2 establish the comparability of ICP-MS with other non-destructive filter analysis methods.

3 Keeler and Pirrone (1996) used ICP-MS to determine trace elements Cd, Mn, V, As, Se,  
4 and Pb in atmospheric fine particulate (PM<sub>2.5</sub>) and total suspended particulate samples collected  
5 in two Detroit sites. The results were used in a deposition model with additional measurements  
6 using AAS to estimate the dry deposition flux of trace elements to Lake Erie.

### 7 8 **2B.1.10 Scanning Electron Microscopy (SEM)**

9 Mamane et al. (2001) investigated the use of computer-controlled scanning electron  
10 microscopy (CCSEM) as a way of supplementing XRF analysis and providing automated  
11 analysis of particle size, chemistry, and particle classification. An ambient coarse particulate  
12 sample from Baltimore was collected on a polycarbonate filter for this analysis. CCSEM  
13 analyses were conducted for 2819 particles in 78 randomly selected fields of view during an  
14 unattended 8-h run. Mamane et al. confirmed the stability of the CCSEM instrument over  
15 several hours of operation. The physical properties of the sample such as particle diameter, mass  
16 loading per field, and particle number per field were well represented by analyzing  
17 approximately 360 particles with little additional information gained by analyzing more  
18 particles. Teflon filters are not well suited for SEM analyses. Analysis of fine PM is expected  
19 to pose analytical challenges not addressed in the present study (Mamane et al., 2001).

20 Nelson et al. (2000) applied Raman chemical imaging and SEM (Raman/SEM) to study the  
21 size, morphology, elemental and molecular composition, and molecular structure of fine  
22 particulate matter. In their study, filter compatibility was examined, and Raman/SEM chemical  
23 imaging was conducted for several standard materials as well as for ambient PM<sub>2.5</sub> samples.  
24 Polycarbonate was determined to be a suitable substrate for both SEM and Raman chemical  
25 imaging analysis.

26 Conner et al. (2001) used CCSEM with individual X-ray analysis to study the chemical and  
27 physical attributes of indoor and outdoor aerosols collected around a retirement home in  
28 Baltimore. The CCSEM technique was demonstrated to be capable of identifying spherical  
29 particles typical of combustion or other high temperature (presumably industrial) processes as  
30 well as pollens and spores. Indoor particles originating from cosmetics were also identified.

## 2B.2 ORGANIC AND INORGANIC CARBON

Large scale efforts to characterize carbonaceous aerosol require cost effective methods that can analyze samples rapidly. Commercial thermal/optical (TO) instruments were developed to serve this need. The US EPA IMPROVE and STN networks have employed these instruments to accumulate large datasets, including measurements taken over the past 18 years by the IMPROVE network and over the past 3 years by STN. In addition to the protocols developed for IMPROVE and STN networks, a number of alternative TO-based protocols and techniques have been employed by the academic research community. Protocols vary in temperature range and step size, in the duration of heating at each step, in the timing for introduction of oxygen for the conversion of black carbon into CO<sub>2</sub>, and in the assignment of organic carbon (OC) and elemental carbon (EC) fractions. Figure 2B-2 shows examples of two protocols in current use. These operational differences have complicated efforts to compare and combine data sets from studies using different TO protocols.

### *Thermal-Optical Reflectance*

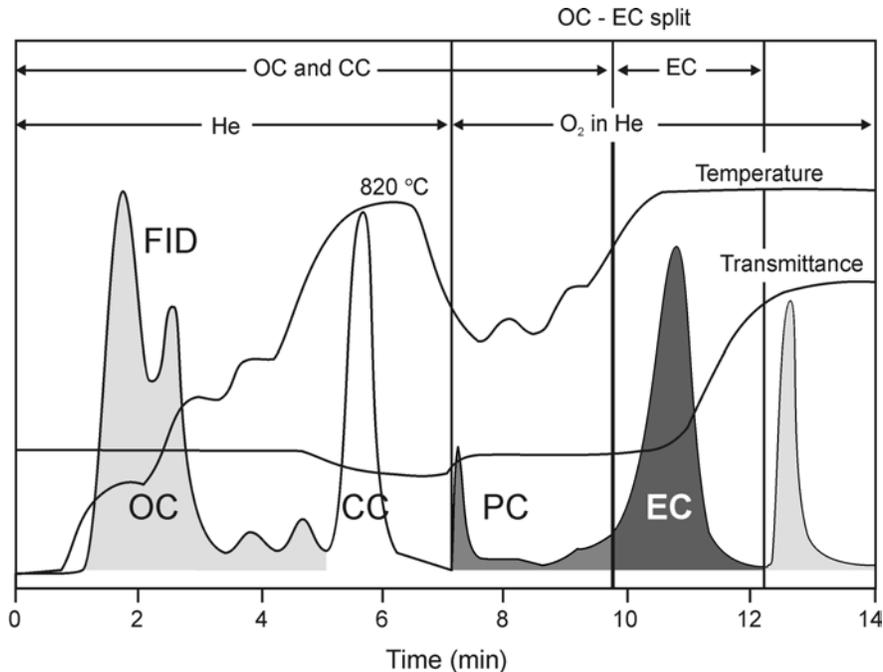

The thermal optical reflectance (TOR) method of carbon analysis developed by Huntzicker et al. (1982) has been adapted by several laboratories for the quantification of organic and elemental carbon in PM collected on quartz-fiber filters. Although the principle applied by these laboratories is identical to that of Huntzicker et al. (1982), the details differ with respect to calibration standards, analysis time, temperature ramping, and volatilization/combustion temperature. The IMPROVE network employs a version of the TOR method for its OC/EC analyses.

In the most commonly used version of the TOR method (Chow et al., 1993), a punch from the filter sample is heated to temperatures ranging from ambient to 550 °C in a pure helium atmosphere. In principle, the organic carbon fraction of the PM contained by the filter punch will vaporize, leaving behind only refractory elemental carbon. The organic carbon that evolves at each temperature step is first oxidized to CO<sub>2</sub>, then converted to methane and finally quantified with a flame ionization detector (FID). The filter punch is incubated at 550 °C for a period sufficient to allow the flame ionization signal to return to its baseline value. The punch is then exposed to a 2% oxygen and 98% helium atmosphere and heated from 550 °C to 800 °C with several temperature ramping steps. The reflectance from the deposit side of the filter punch

1 is monitored throughout the analysis. This reflectance decreases during OC volatilization in the  
2 helium atmosphere owing to the pyrolysis of involatile organic material present in the filter  
3 punch. When oxygen is added, the reflectance increases as light-absorbing carbon is combusted  
4 and removed. It is assumed that the first light-absorbing carbon compounds to combust are  
5 pyrolysis artifacts from the first phase of the analysis. Therefore, the organic carbon mass is  
6 defined as that fraction that evolves up to the introduction of oxygen plus the oxidized carbon  
7 that evolves up to the point when the filter reflectance signal is restored to its pre-analysis value.  
8 Once the original reflectance level is re-attained, all further carbon evolving from the sample  
9 punch is assigned to the elemental carbon fraction. Accordingly, “organic carbon” (OC) is  
10 carbon that does not absorb light at the laser wavelength (632.8 nm) typically used by TOR  
11 instruments, and all other carbon is defined as “elemental carbon” (EC).

### 13 *Thermal-Optical Transmission*

14 The primary difference between TOR and thermal optical transmission methods is in the  
15 choice of absorption detection — light transmission through the filter punch, rather than its  
16 reflectance, is monitored throughout the analysis. The TOT method of Birch and Cary (1996)  
17 also uses a pure helium atmosphere for volatilizing organic carbon, but the second stage involves  
18 a higher oxygen/helium (10%) gas mixture to oxidize the black carbon remaining on the filter  
19 punch. The temperature is raised to approximately 820 °C in the helium phase, during which  
20 both organic and carbonate carbon are volatilized from the filter. In the second stage, the oven  
21 temperature is reduced then raised to about 860 °C. During this stage, pyrolysis correction and  
22 the EC measurement is made. Figure 2B-1 is an example of a TOT thermogram, showing  
23 temperature, transmittance, and FID response traces. The peaks that correspond to the  
24 concentrations of CO<sub>2</sub> that evolve from the filter punch during the course of the analysis are  
25 assigned to OC, carbonate carbon (CC), pyrolytic carbon (PC), and EC. The high temperature in  
26 the first stage of the TOT thermal profile is included for the purpose of decomposing carbonate  
27 carbon and for volatilization of very high-boiling organic compounds. However, many organic  
28 carbon compounds will pyrolyze at this temperature to generate PC. The ability to quantify PC  
29 is particularly important in high OC/EC regions such as wood smoke-impacted air sheds. Wood  
30 smoke aerosol contains many complex compounds that generate substantial PC. Significant  
31 error in the EC fraction can result in the absence of a careful PC correction.

**Figure 2B-1. This thermogram, for a sample containing rock dust (a carbonate source) and diesel exhaust, shows three traces that correspond to temperature, filter transmittance, and FID detector response. Peaks correspond to organic (OC), carbonate (CC), pyrolytic (PC), and elemental (EC) carbon. The final peak is a methane calibration peak.**

Source: Birch and Cary (1996).

1 Informal intercomparisons among different filter transmission methods have shown high  
 2 correlations of absorption, but differences of up to a factor of two in absolute values (Watson  
 3 et al., 1988a,b). These differences are functions of the type of filter, filter loading, the chemical  
 4 and physical nature of the deposit, the wavelengths of light used, calibration standards, and light  
 5 diffusing methods. At the current time, there is no agreement on which combination most  
 6 accurately represents light absorption in the atmosphere.

7 The National Institute for Occupational Safety and Health (NIOSH) Method 5040 is based  
 8 on the TOT method (Birch and Cary, 1996). The NIOSH protocol consists of a two-stage  
 9 process with the first stage being conducted in a pure helium atmosphere at temperatures of 250,  
 10 500, 650, and 850 °C for a total of 4.5 minutes and the second stage conducted in a 2%  
 11 oxygen/98% helium mix at temperatures of 650, 750, 850, and 940 °C for 4 minutes.

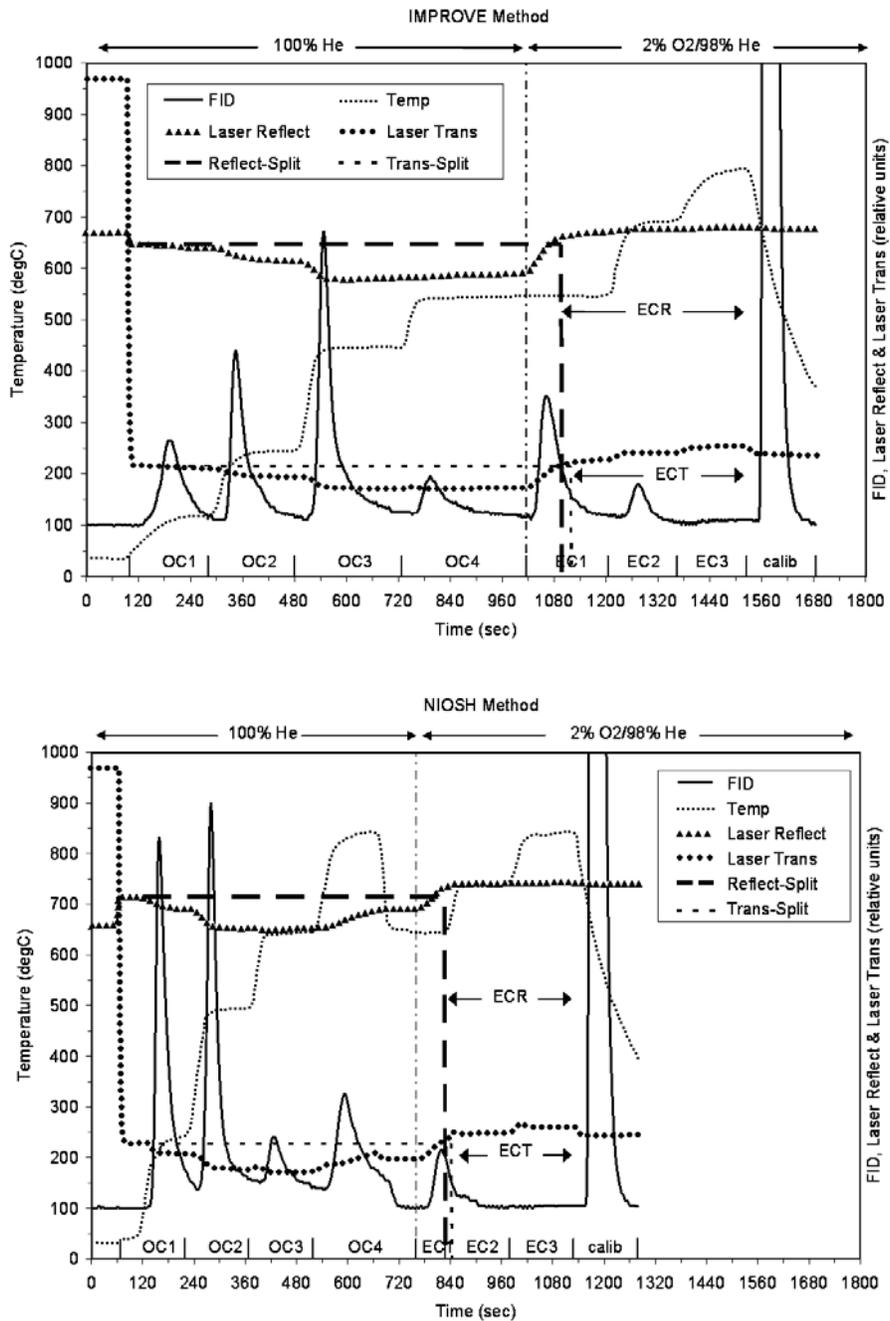

1 A pyrolysis base correction is made based on the transmittance measurement. The U.S. EPA  
2 adopted a modified version of the NIOSH Method 5040 protocol for use in its Speciation Trends  
3 Network (STN).

#### 4 5 *IMPROVE versus NIOSH protocols*

6 Although the IMPROVE protocol and the NIOSH protocol in use by the STN network  
7 yield closely comparable total carbon (TC) values, the differences in thermal profiles and  
8 operational definitions of organic versus black carbon result in very different mass assignments  
9 to these fractions. Other methodological differences may make data comparisons difficult,  
10 including the different choice of absorption detection, e.g. reflectance versus transmission, the  
11 different temperature ranges and incubation periods and the different approaches used to account  
12 for background OC. Examples of thermograms obtained with the IMPROVE and NIOSH  
13 protocols are shown in Figure 2B-2.

14 Using both the IMPROVE and NIOSH protocols, Chow et al. (2000) analyzed 60 quartz  
15 filter samples on a prototype reflectance/transmittance analyzer that represented a wide variety  
16 of aerosol compositions and concentrations. The two TC data sets possessed no statistically  
17 significant differences. However, marked differences were found in the fraction of TC that is  
18 attributed to EC as determined by the IMPROVE versus NIOSH thermal evolution protocols.  
19 The IMPROVE EC measurements were typically higher than the NIOSH EC measurements.  
20 When the NIOSH protocol was modified to exclude the helium-only 850 °C temperature step,  
21 however, the OC/EC ratios came into agreement between the two methods. Because OC and EC  
22 are operationally defined parameters, Chow et al. (2000) pointed out that it is important to retain  
23 ancillary information when reporting EC and OC by these analytical methods, so that  
24 comparisons can be made among measurements taken at different sites using these two methods.

25 The NIOSH and IMPROVE protocols both require correction for positive organic artifacts  
26 due to absorption of background organic vapor by the heat-treated quartz filters used for OC/EC  
27 measurements. Both the IMPROVE and STN science teams have evaluated the presence of  
28 carbon artifacts in their measurements. The IMPROVE team has established that heat-treated  
29 quartz filters adsorb organic carbon vapors up to a saturation threshold over the course of a few  
30 days in the field. The STN science team has observed that positive carbon artifacts can vary  
31 with sampler type. Total carbon artifacts for the samplers used by the STN range from 9.5 to

**Figure 2B-2. Examples of thermograms obtained by (a) the IMPROVE protocol, and by (b) the NIOSH protocol. Flame ionization detection is used in both examples. FID denotes the observed signal intensity. The intervals denoted ECR/ECT, i.e., elemental carbon reflectance/transmittance, refer to the time and temperature intervals during which EC is oxidized and filter “blackness” is monitored by laser reflectance or transmission at the He-Ne wavelength, 633 nm.**

### 8 *Pyrolytic Carbon (PC) and Other Confounders*

9 In a methods comparison study, Countess (1990) determined that it is necessary to  
10 minimize or correct for PC and that OC found in wood smoke and automobile exhaust samples  
11 which pyrolyze to create interferences during the course of some thermal optical protocols.  
12 Pyrolysis of organic compounds occurs during analysis by both TO methods, although the  
13 greater temperature to which samples are exposed in the NIOSH protocol is likely to produce  
14 larger quantities of pyrolysis-derived EC. During the initial heating phase, pyrolysis is indicated  
15 by an increase in optical density (blackness) by the filter sample. Both methods distinguish  
16 artifact pyrolysis-derived EC from ambient EC at the point when the transmittance or reflectance  
17 signal is restored to the pre-heating level. The assumption made is that heating does not alter the  
18 absorption properties of the material collected on the filter. This assumption is reasonable if the  
19 only light absorbing species of carbon is strictly a graphite-like elemental carbon that is unlikely  
20 to undergo a change in its absorption properties over the temperature ranges used by TO  
21 methods. The effects of heat-induced changes to the light absorption and chemical properties of  
22 atmospheric organic compounds on TO analysis are being evaluated by NIST. NIST has  
23 identified three assumptions that must be met in order for TO methods to reliably measure EC:  
24 (1) absorptivity of carbonaceous PM remains constant up to the point of pyrolysis; (2) once  
25 formed, pyrolyzed carbon (char) absorbs at the analytic wavelength and its absorptivity remains  
26 constant within the high temperature step; (3) pyrolyzed OC has the same absorptivity as EC that  
27 is native to the sample. Using urban dust, forest fire emissions and ambient laboratory aerosol,  
28 they observed changes in the absorptivities of these materials during heating before and during  
29 the formation of pyrolysis artifacts, up to the OC/EC split point. NIST, therefore, recommends  
30 that standard TOR/T protocols be developed that account for these changes.

1 Light-absorbing carbon includes a large number of compounds that may be altered, not  
2 only in their light-absorbing properties but also in their oxidation chemistry. The materials  
3 responsible for defining the original blackness of the filter sample may be altered during the  
4 initial heating phase of TO analysis, so that the mix present during the oxidation cycle may not  
5 be representative of the original, atmospherically-derived black carbon. An error in determining  
6 the mass of EC would arise, for example, if a heavy, but weakly light-absorbing compound were  
7 transformed into a material that possesses a higher absorption coefficient and higher resistance to  
8 oxidation than absorbing compounds collected from the atmosphere. The pyrolyzed form of this  
9 compound would resist oxidation past the OC-EC split point in the analysis, leading to a falsely  
10 high EC fraction.

11 Chow et al. (2000) noted that neither the IMPROVE nor NIOSH methods were able to  
12 accurately detect further blackening on optically dense, i.e., very black, filters that are typical of  
13 source profile samples. Predictions of artifact pyrolysis carbon by TOR and TOT differed  
14 widely. Note that both transmittance and reflectance methods rely on derivations of optics laws  
15 (i.e., the Beer-Lambert and Lambert Laws) that predict a linear transmittance/reflectance signal  
16 response with species concentration, but only for optically thin samples (Strobel and Heineman,  
17 1989). Very black filters exceed this limitation; thus, the signal response of these methods may  
18 not be a linear or otherwise predictable function of black carbon concentration.

19 Another important source of error in any TO measurement of aerosol OC/EC arises when  
20 samples contain transition metal oxides, such as iron oxide. Many transition metal oxides are  
21 found in crustal material. Fung et al.(2002) report that such oxides can serve as oxidizing agents  
22 for BC at high temperatures. The consequence of such an effect is an elevation of the signal  
23 usually assigned to OC and corresponding reduction in apparent BC.

#### 24 *Thermal Manganese Oxidation*

25 The thermal manganese oxidation (TMO) method (Mueller et al., 1982; Fung, 1990) uses  
26 manganese dioxide in contact with the sample throughout the analysis as the oxidizing agent.  
27 Temperature is relied upon to distinguish between organic and elemental carbon. Carbon  
28 evolving at 525 °C is classified as organic carbon, and carbon evolving at 850 °C is classified as  
29 elemental carbon. TMO does not correct for pyrolyzed OC, which may lead to overestimation of  
30 EC. This method has been used in the SCENES (Subregional Cooperative Electric Utility,  
31

1 Department of Defense, National Park Services, and Environmental Protection Agency Study);  
2 (Sutherland and Bhardwaja, 1987; Mueller et al., 1986) visibility network, as well as in the  
3 SCAQS (Southern California Air Quality Study) (Chow et al., 1994a,b; Watson et al., 1993,  
4 1994a,b).

#### 6 *OC/EC Methods Intercomparisons*

7 Chow et al. (1993) document several variations of the thermal (T), thermal/optical  
8 reflectance (TOR), thermal/optical transmission (TOT), and thermal manganese oxidation  
9 (TMO) methods for organic and elemental carbon. Comparisons among the results of the  
10 majority of these methods show that they yield comparable quantities of total carbon in aerosol  
11 samples, but the distinctions between organic and elemental carbon are quite different (Cadle  
12 and Groblicki, 1982; Cadle and Mulawa, 1990; Countess, 1990; Hering et al., 1990; Birch, 1998;  
13 Schmid et al., 2001). For the sum of organic and elemental carbon, these methods reported  
14 agreement within 5% to 15% for ambient and source samples (Houck et al., 1989; Kusko et al.,  
15 1989; Countess, 1990; Shah and Rau, 1990) and within 3% on carefully prepared standards.  
16 Evaluation of these methods thus is a matter of assessing how they differentiate between organic  
17 and elemental carbon. The EC/TC ratio for samples is method dependent.

18 An international methods intercomparison study on the analysis of carbonaceous aerosols  
19 on quartz fiber filters was organized by the Vienna University of Technology and involved  
20 seventeen laboratories and nine different thermal and optical methods (Schmid et al., 2001).  
21 All laboratories were sent punches from three 150-mm quartz fiber filters that had been exposed  
22 for 24 h near a high traffic street in Berlin.

23 Five laboratories employed the German official standard VDI 2465 methods. Two of these  
24 laboratories used the VDI 2465/1 method that determines extractable organic carbon, non-  
25 extractable organic carbon, and elemental carbon by way of a solvent-based extraction protocol.  
26 Other laboratories participating in the intercomparison used variations of the VDI 2465 standard  
27 that rely upon differences in thermal stability to accomplish the separation of carbonaceous  
28 aerosol fractions. A range of thermal protocols, total carbon determination techniques and CO<sub>2</sub>  
29 detection schemes were employed by the participating laboratories.

30 Good agreement of the TC results was obtained by all laboratories with only two outliers in  
31 the complete data set. The relative standard deviation between laboratories for the TC results,

1 were 6.7, 10.6, and 8.8% for the three samples. In contrast, the EC results were much more  
2 variable. The relative standard deviation between laboratories for the EC results, were 36.6,  
3 24.4, and 45.5% for the three samples. The VDI methods, especially the VDI 2465/2, were  
4 found to give generally higher amounts of EC than the thermal-optical methods. This trend was  
5 detected for all samples. The authors recognized that uncorrected thermal methods are prone to  
6 positive artifacts by charring during pyrolysis. They also noted that when using solvent  
7 extraction methods, the dissolution of polymeric aerosol constituents may not be successful.  
8 Both of these effects would lead to overestimation of the EC fraction. When the laboratories  
9 were grouped according to their methods, the relative standard deviation between laboratories  
10 was much smaller. This study demonstrates that the TC measurement can yield similar results  
11 from a variety of methods, but the EC measurement is highly dependent upon the method used.  
12 The problems associated with the determination of EC are exacerbated by the lack of a standard  
13 reference material and consistent definitions of EC.

#### 14 15 *Measuring Black Carbon (BC) Instead of EC*

16 Light absorbing or black carbon (BC) can be measured by optical techniques (Penner and  
17 Novakov, 1996). Both EC and BC define a similar fraction of aerosol; but EC is defined in  
18 terms of both the thermal and light-absorption properties of the sample, whereas BC is based on  
19 solely on its light-absorption properties. The aethalometer, the integrating sphere sunphotometer  
20 and photoacoustic spectroscopy (described in Section 2B.3) are example techniques for  
21 determining BC.

22 Hitzenberger et al. (1996) investigated the feasibility of using an integrating sphere  
23 photometer as an adequate measurement system for the BC content and the absorption  
24 coefficient. In another study (Hitzenberger et al., 1999), the integrating sphere method was  
25 compared to an aethalometer (Hansen et al., 1984), the thermal method of Cachier et al. (1989),  
26 and the thermal/optical method of Birch and Cary (1996). The absorption coefficients that were  
27 obtained from both the integrating sphere and the aethalometer were comparable. The BC mass  
28 concentrations obtained from the aethalometer were 23% of those obtained from the integrating  
29 sphere. Compared to the thermal method, the integrating sphere overestimated the BC mass  
30 concentrations by 21%. Compared to the thermal/optical method, the integrating sphere was  
31 within 5% of the 1:1 line. However, the data were not well correlated.

1           The Carbonaceous Species Methods Comparison Study (CSMCS), as mentioned in the  
2 1996 PM AQCD (U.S. Environmental Protection Agency, 1996a) was conducted in Los Angeles  
3 in 1986. Hansen and McMurry (1990) compared the thermal manganese method with the  
4 aethalometer for aerosol elemental carbon. The first involved collection of impactor samples  
5 backed by a quartz fiber after-filter followed by EC analysis by oxidation in helium over a MnO<sub>2</sub>  
6 catalyst; the other conducted real-time measurements using an aethalometer (an optical  
7 absorption technique). They found good agreement between these two very different methods.  
8 The CSMCS interlaboratory precision for total carbon was 4.2% (Turpin et al., 2000). However,  
9 because the split between OC and EC is operationally defined, there was substantial  
10 interlaboratory variability in OC and EC (e.g., 34% for EC [Turpin et al., 1990]).

11  
12           ***EC/OC Summary.*** With the limitations and precautions described above, laboratory  
13 analyses for the carbonaceous properties of collected particles have matured to the point where  
14 they can be performed with commercially-available instruments following established standard  
15 operating procedures. However, carbon analysis continues to be a subject of active research  
16 within the atmospheric sciences community and EPA, and carbon speciation methods  
17 comparisons are being undertaken during such studies as the Atlanta Supersite. The state of the  
18 art for carbonaceous PM measurements continues to advance; and, although progress is being  
19 made, the definitions of OC, EC and BC continue to be operationally defined in reference to the  
20 method employed. Reports of EC/OC measurements should therefore include mention of the  
21 method with which the species were determined. Finally, if possible, all ancillary data should be  
22 retained, to allow later comparison to other methods.

## 23 24 25 **2B.3 CONTINUOUS METHODS**

### 26 **2B.3.1 Continuous Measurement of Mass**

#### 27 ***Tapered Element Oscillating Microbalance (TEOM)***

28           The advantages of continuous PM monitoring and the designation of the TEOM as an  
29 equivalent method for PM<sub>10</sub>, have led to the deployment of the TEOM at a number of air  
30 monitoring sites. The TEOM also is being used to measure PM<sub>2.5</sub>. The TEOM differs from the  
31 federal reference methods for particulate mass in that it does not require equilibration of the

1 samples at a specified temperature and relative humidity. The TEOM samples at a constant  
2 temperature and is typically heated to some temperature higher than the ambient temperature  
3 (Meyer et al., 1995; Meyer and Rupprecht, 1996); whereas the FRM samples at the ambient  
4 temperature. Thus, the TEOM does not provide data equivalent to the FRM because of losses of  
5 volatile species. Volatilization losses in the TEOM sampler can be reduced by operating the  
6 instrument at 30 °C, rather than the typical 50 °C specified, or by using a Nafion diffusion dryer  
7 instead of heating to dehumidify the particles (with a 30 °C temperature).

8 This difference in operation and implications for fine particle measurements was  
9 examined by researchers at Commonwealth Scientific and Industrial Research Organisation  
10 (CSIRO) Atmospheric Research in Australia (Ayers et al., 1999). That group compared 24-h  
11 mean PM<sub>2.5</sub> mass concentrations as determined by a TEOM and by two manual, gravimetric  
12 samplers (a low-volume filter sampler and a MOUDI sampler) in four Australian cities, on 15  
13 days in the winter half-year. The TEOM was operated at 50 °C at one location and at 35 °C at  
14 the other three locations. A systematically low TEOM response in comparison to the integrated  
15 gravimetric methods was observed. In a comprehensive study, Allen et al. (1997) reported  
16 results in which TEOM data collected at 10 urban sites in the United States and Mexico were  
17 compared with 24 h integrated mass concentrations for both PM<sub>10</sub> and PM<sub>2.5</sub>. They collected a  
18 large data set that included both winter and summer seasons. Allen et al. (1997) concluded that,  
19 especially for urban areas, a significant fraction of PM<sub>10</sub> could be semivolatile compounds that  
20 could be lost from the heated filter in the TEOM leading to a systematic difference between the  
21 TEOM and the EPA FRM for PM<sub>10</sub>. They suggested that this difference is likely to be larger for  
22 PM<sub>2.5</sub> than it is for PM<sub>10</sub> (Allen et al., 1997).

23 In a similar study conducted in Vancouver, British Columbia, the effect of equilibration  
24 temperature on PM<sub>10</sub> concentrations from the TEOM was examined. Two collocated TEOM  
25 monitors operated at 30 and 50 °C, respectively, were operated in the Lower Fraser Valley in  
26 British Columbia for a period of approximately 17 months (Mignacca and Stubbs, 1999).  
27 A third TEOM operating at 40 °C was operated for 2 months during this period. They found  
28 that, on average, the 1-h average PM<sub>10</sub> from the TEOM operating at 30 °C was consistently  
29 greater than that from the TEOM operated at 50 °C. For the period during which the third  
30 TEOM was operated (at 40 °C), the PM<sub>10</sub> from that instrument was between those values for the  
31 other two instruments. They also found that the differences in masses were proportional to the

1 PM<sub>10</sub> loading, and more strongly correlated to the PM<sub>10</sub> from the TEOM operated at the lower  
2 temperature. They recommended that the TEOM monitors be operated at 40 °C as opposed to  
3 operating at 50 °C in summer and 30 °C in winter, in order to avoid introducing a methodological  
4 seasonal bias.

5 A new sample equilibration system (SES) was developed to reduce losses of semivolatile  
6 species from the PM<sub>2.5</sub> TEOM by conditioning the sample stream to lower humidity and  
7 temperature (Meyer et al., 2000). The SES utilizes humidity sensors and a Nafion dryer  
8 designed for low particle loss. The dryer fits between the flow splitter that follows the size-  
9 selective inlet and the sensor unit. A dry purge gas flows over the exterior of the Nafion tubing  
10 and allows for self-regeneration. A TEOM with PM<sub>2.5</sub> inlet and equipped with an SES was  
11 operated at 30 °C alongside another TEOM operating at 50 °C without the SES in Albany, NY,  
12 over a 6-day period during a summertime high-temperature, high-relative-humidity episode. The  
13 SES maintained the sample air relative humidity under 30%, and the TEOM with the SES  
14 generally measured more mass than the other TEOM. The TEOM with SES also was operated  
15 alongside an FRM-type sampler for the period of June 6 through September 25, 1999. The  
16 correlation between the FRM and TEOM/SES showed a slope of 1.0293 and R<sup>2</sup> of 0.9352;  
17 whereas the correlation between the FRM and the TEOM without SES and operating at 50 °C  
18 showed a slope of 0.8612 and R<sup>2</sup> of 0.8209. The SES can be installed on existing TEOM  
19 monitors.

### 21 ***Beta-Gauge Techniques***

22 The use of absorption of beta radiation as a indicator of particle mass has been used  
23 effectively to measure the mass of equilibrated particulate matter collected on Teflon filters  
24 (Jaklevic et al., 1981a; Courtney et al., 1982). The technique also has been used to provide near  
25 real-time measurements with time intervals on the order of an hour (Wedding and Weigand,  
26 1993). However, real-time beta gauge monitors experience the same problems as other  
27 continuous or near real-time particulate matter mass monitoring techniques. Particle-bound  
28 water must be removed to reduce the sensitivity of the indicated mass to relative humidity.  
29 However, the simplest technique, mild heating, will remove a portion of the ammonium nitrate  
30 and the semivolatile organic compounds as well as the particle-bound water.

1 An intercomparison study of two beta gauges at three sites indicated that the Wedding  
2 beta gauge and the Sierra Anderson (SA) 1200 PM<sub>10</sub> samplers were highly correlated,  $r > 0.97$   
3 (Tsai and Cheng, 1996). The Wedding beta gauge was not sensitive to relative humidity but  
4 yielded results approximately 7% lower. This suggests that the mild heating in the beta gauge  
5 causes losses comparable to those caused by equilibration, although the differences could result  
6 from slight differences in the upper cut points. The Kimoto beta gauge that was operated at  
7 ambient temperature was sensitive to relative humidity yielding significantly higher mass  
8 concentrations relative to the SA 1200 for  $RH > 80\%$  than for  $RH < 80\%$  even though the  
9 correlation with the SA 1200 was reasonable ( $r = 0.94$  for  $RH > 80\%$  and  $0.83$  for  $RH < 80\%$ ).

### 11 *Piezoelectric Microbalance*

12 Piezoelectric crystals have mechanical resonances that can be excited by applying an  
13 alternating electrical voltage to the crystal. As the resonance frequencies are well defined, such  
14 crystals (quartz in particular) have found applications as secondary time and frequency standards  
15 in clocks and watches. As for all mechanical resonators, the resonance frequency is a function  
16 of mass. Therefore, by monitoring the resonance frequency in comparison with a second crystal,  
17 one can continuously measure the mass deposited on the crystal (Sem et al., 1977; Bowers and  
18 Chuan, 1989; Ward and Buttry, 1990; Noel and Topart, 1994). Comparison with a second  
19 crystal largely compensates for the effect of temperature changes on the resonance frequency.

20 The piezoelectric principle has been used to measure particle mass by depositing the  
21 particles on the crystal surface either by electrostatic precipitation or by impaction (Olin and  
22 Sem, 1971). The collection efficiency of either mechanism has to be determined as function of  
23 particle size to achieve quantitative measurements. In addition, the mechanical coupling of large  
24 particles to the crystal is uncertain. Both single and multi-stage impactors have been used (Olin  
25 and Sem, 1971; Fairchild and Wheat, 1984). Quartz crystals have sensitivities of several  
26 hundred hertz per microgram. This sensitivity results in the ability to measure the mass  
27 concentration of a typical  $100 \mu\text{g}/\text{m}^3$  aerosol to within a few percent in less than one minute  
28 (Olin and Sem, 1971).

## 1 ***Coarse Particle Mass***

2 The RAMS and CAMM are only appropriate for fine particle measurements ( $PM_{2.5}$  or  
3  $PM_{10}$ ). However, the TEOM, beta gauge, and piezoelectric microbalance may be used to measure  
4 either  $PM_{2.5}$  or  $PM_{10}$  (or a sample with any specified upper 50% size cut). A pair of such  
5 samplers may be used to measure thoracic coarse PM mass concentration ( $PM_{10-2.5}$ ) by difference  
6 between the  $PM_{10}$  and  $PM_{2.5}$  concentrations. However, concerns have been raised concerning the  
7 quality of the data from such difference calculations and the resulting potential biases in  
8 exposure assessment and risk determinations (Wilson and Suh, 1997; White, 1998). Misra et al.  
9 (2001) describe the development and evaluation of a continuous coarse particle monitor (CCPM)  
10 that may provide direct measurements of coarse mode PM mass concentrations at short time  
11 intervals (on the order of 5-10 min). The basis of the CCPM is enrichment of the coarse particle  
12 concentrations through use of virtual impaction while maintaining fine particle concentrations at  
13 ambient levels. The resulting aerosol mixture is analyzed using a standard TEOM for which the  
14 response is now dominated by the enriched coarse PM mass. The coarse PM concentrations  
15 determined from the CCPM were compared to those obtained with a MOUDI, operating with  
16 only the 10- and 2.5-micron cutpoint stages, and a Partisol dichotomous sampler. The CCPM  
17 coarse particulate concentrations were highly correlated with both the MOUDI ( $R^2 = 0.88$ ) and  
18 the Partisol ( $R^2 = 0.88$ ) coarse PM concentrations. By operating the CCPM at a coarse particle  
19 enrichment factor of 25, the coarse PM concentration can be determined *a priori* without  
20 determination of the fine particle concentration, so long as the fine-to-coarse particle  
21 concentration ratios are not unusually high (i.e., 4-6). Misra et al. (2001) also concluded from  
22 field experiments that the coarse particulate concentrations determined from the CCPM were  
23 independent of the ambient fine-to-coarse particulate concentration ratio due to the decrease in  
24 particle mass median diameter that should accompany fine-to-coarse particulate concentration  
25 ratios during stagnation conditions.

### 26 27 **2B.3.2 Continuous Measurement of Organic and/or Elemental Carbon**

28 Testing and refinement of models that simulate aerosol concentrations from gas and  
29 particle emissions require air quality measurements of approximately 1-h time resolution to  
30 reflect the dynamics of atmospheric transport, dispersion, transformation, and removal. Below  
31 instruments are described that have been used to collect and analyze atmospheric organic PM

1 with better than 2-h resolution. These instruments were all present at the Atlanta Supersite  
2 experiment during the summer of 1999, and an intercomparison of results is underway.

### 3 4 ***Automated Carbon Analyses***

5 Turpin et al. (1990) describe an *in situ*, time-resolved analyzer for particulate organic and  
6 elemental carbon that can operate on a time cycle as short as 90 min. This analyzer collects  
7 particulate matter on a quartz fiber filter mounted in a thermal-optical transmittance carbon  
8 analyzer (Turpin et al., 1990). A second quartz fiber filter behind a Teflon filter in a second  
9 sampling port may also be analyzed to provide an estimate of the positive sampling artifact (i.e.,  
10 gas adsorption on the quartz sampling filter). The organic material in the collected PM is  
11 thermally desorbed from the filter at 650 °C and oxidized at 1000 °C over a MnO<sub>2</sub> catalyst bed.  
12 The evolved CO<sub>2</sub> is converted to methane over a nickel catalyst, and the methane is measured in  
13 a flame ionization detector. Then the elemental carbon is oxidized at 350 °C in a 98% He-2% O<sub>2</sub>  
14 atmosphere. Correction is made for pyrolytic conversion of some of the organic particulate  
15 matter. The instrument was operated with a 2-h resolution during SCAQS in 1987 (Turpin and  
16 Huntzicker, 1991;1995), as well as during CSMCS in 1986 (Turpin et al., 1990). By using  
17 elemental carbon as a tracer for primary, combustion-generated organic carbon, these authors  
18 estimated the contributions of primary sources (i.e., material emitted in particulate form) and  
19 secondary sources (i.e., particulate material formed in the atmosphere) to the total atmospheric  
20 particulate organic carbon concentrations in these locations.

21 An automated carbon analyzer with 15-min to 1-h resolution is now commercially  
22 available (Rupprecht et al., 1995) and has been operated in several locations including the  
23 Atlanta Supersite. It collects samples on a 0.1- $\mu$ m impactor downstream of an inlet with a  
24 2.5- $\mu$ m cutpoint. Use of an impactor eliminates gas adsorption that must be addressed when  
25 filter collection is used. However, this collection system may experience substantial particle  
26 bounce and loss of a sizable fraction of EC since some EC is in particles < 0.2  $\mu$ m. It is possible  
27 that ongoing research, in which particle size is increased by humidification prior to impaction,  
28 may result in an improvement in collection efficiency. In the analysis step, carbonaceous  
29 compounds are removed by heating in filtered ambient air. Carbonaceous material removed  
30 below 340 °C is reported as organic carbon, and material removed between 340 and 750 °C is  
31 reported as elemental carbon. Turpin et al. (2000) comment that it would be more appropriate to

1 report carbon values obtained by this method as “low-” and “high-temperature” carbon, because  
2 some organics are known to evolve at temperatures greater than 340 °C (e.g., organics from  
3 woodsmoke).

#### 4 5 *Aethalometer for EC*

6 As discussed earlier, black carbon (BC), a carbon fraction very similar to EC, is most  
7 commonly measured using an aethalometer, a commercially available, automated, time-resolved  
8 instrument (i.e., 5- to 15-min sample duration) that measures the light attenuation of aerosol  
9 particles collected on a filter tape (Hansen et al., 1984). The concentration of elemental carbon  
10 is derived from the light absorption measured on a filter using an estimate of the specific  
11 absorption ( $m^2/g$ ) of elemental carbon on the filter; the specific absorption value is derived from  
12 laboratory and atmospheric tests and is specified by the manufacturer. The specific absorption  
13 value could be expected to vary with location, season, and source mix. Comparisons in  
14 atmospheric experiments at some locations with EC values measured by thermal methods  
15 confirm that the aethalometer provides a statistically meaningful estimate of EC concentration  
16 (Allen et al., 1999c; Liousse et al., 1993). For instance, Allen et al. (1999c) found the following  
17 statistical relationship for Uniontown, PA, during summer 1990: black carbon (aethalometer)  
18 =  $0.95 \cdot EC \text{ (thermal)} - 0.2$  ( $r^2 = 0.925$ ,  $n$  not specified but appears to be  $>50$ , EC range from 0 to  
19  $9 \mu g/m^3$ ). Another source of error in aethalometer measurements arises from the sampling  
20 procedure. Particles are trapped within a three-dimensional filter matrix. Therefore, scattering  
21 of transmitted and reflected light may erroneously be attributed to absorption, thus causing errors  
22 in the BC calculation. Ballach et al. (2001) investigated immersing the filter in oil of a similar  
23 refractive index as a means to minimize the interferences due to light scattering effects from the  
24 filter, similar to a procedure common in microscopy. BC measurements determined using the oil  
25 immersion technique were compared to those from an integrating sphere, a polar photometer,  
26 and Mie calculations. Aerosols tests included several pure carbon blacks from different  
27 generating procedures that were used to calibrate the immersion technique, pure ammonium  
28 sulfate aerosol, and external and internal mixtures of ammonium sulfate with varying amounts of  
29 carbon blacks. The oil immersion technique was also tested on ambient air samples collected at  
30 two different sites in the cities of Frankfurt am Main and Freiburg, Germany. Optical  
31 measurements, both of blank and loaded filters, show that the oil immersion technique

1 minimizes scattering losses. Ballach et al. (2001) found that site-related effects were reduced  
2 and that there was reasonably good agreement with the other optical techniques as well as with  
3 the Mie calculations.

#### 4 5 ***Photoacoustic Measurement of EC***

6 Measurement of aerosol light absorption utilizing photoacoustic spectroscopy has been  
7 examined as a continuous method for measuring elemental carbon mass concentrations (Petzold  
8 and Niessner, 1996; Arnott et al., 1999; 2000). Like the aethalometer, this method measures  
9 light absorption; however, unlike most other light absorption methods, the photoacoustic  
10 technique does not require a filter. The photoacoustic spectrometer of Arnott and coworkers was  
11 demonstrated during the Northern Front Range Air Quality Study and compared to an  
12 aethalometer (Moosmuller et al., 1998). Neither the aethalometer nor the photoacoustic  
13 spectrometer measure elemental carbon mass directly. Because the photoacoustic spectrometer  
14 measures the absorption coefficient directly, the specific absorption efficiency must be known or  
15 assumed in order to determine elemental carbon mass. Assuming a light absorption efficiency of  
16  $10 \text{ m}^2 \text{ g}^{-1}$ , Arnott et al. (1999) reported a lower detection limit for light absorption of  $0.4 \text{ M m}^{-1}$   
17 corresponding to a mass concentration of elemental carbon of approximately  $40 \text{ ngm}^{-3}$ .

### 18 19 **2B.3.3 Continuous Measurements of Nitrate and Sulfate**

#### 20 ***Nitrate***

21 An integrated collection and vaporization cell was developed by Stolzenburg and Hering  
22 (2000) that provides automated, 10-min resolution monitoring of fine particulate nitrate. In this  
23 system, particles are collected by a humidified impaction process and analyzed in place by flash  
24 vaporization and chemiluminescent detection of the evolved nitrogen oxides. In field tests in  
25 which the system was collocated with two FRM samplers, the automated nitrate sampler results  
26 followed the results from the FRM, but were offset lower. The system also was collocated with  
27 a HEADS and a SASS speciation sampler (MetOne Instruments). In all these tests, the  
28 automated sampler was well correlated to other samplers with slopes near 1 (ranging from 0.95  
29 for the FRM to 1.06 for the HEADS) and correlation coefficients ranging from 0.94 to 0.996.

30 During the Northern Front Range Air Quality Study in Colorado (Watson et al., 1998),  
31 the automated nitrate monitor captured the 12-minute variability in fine particle nitrate

1 concentrations with a precision of approximately  $\pm 0.5 \mu\text{g}/\text{m}^3$  (Chow et al., 1998). A comparison  
2 with denuded filter measurements followed by ion chromatographic analysis (Chow and Watson,  
3 1999) showed agreement within  $\pm 0.6 \mu\text{g}/\text{m}^3$  for most of the measurements, but exhibited a  
4 discrepancy of a factor of two for the elevated nitrate periods. More recent intercomparisons  
5 took place during the 1997 Southern California Ozone Study (SCOS97) in Riverside, CA.  
6 Comparisons with 14 days of 24-hour denuder-filter sampling gave a correlation coefficient of  
7  $R^2 = 0.87$  and showed no significant bias (i.e., the regression slope is not significantly different  
8 from 1). As currently configured, the system has a detection limit of  $0.7 \mu\text{g}/\text{m}^3$  and a precision  
9 of  $0.2 \mu\text{g}/\text{m}^3$ .

### 11 ***Sulfate***

12 Continuous methods for the quantification of aerosol sulfur compounds first remove  
13 gaseous sulfur (e.g.,  $\text{SO}_2$ ,  $\text{H}_2\text{S}$ ) from the sample stream by a diffusion tube denuder followed by  
14 the analysis of particulate sulfur (Cobourn et al., 1978; Durham et al., 1978; Huntzicker et al.,  
15 1978; Mueller and Collins, 1980; Tanner et al., 1980). Another approach is to measure total  
16 sulfur and gaseous sulfur separately by alternately removing particles from the sample stream.  
17 Particulate sulfur is obtained as the difference between the total and gaseous sulfur (Kittelson  
18 et al., 1978). The total sulfur content is measured by a flame photometric detector (FPD) by  
19 introducing the sampling stream into a fuel-rich hydrogen-air flame (e.g., Stevens et al., 1969;  
20 Farwell and Rasmussen, 1976) that reduces sulfur compounds and measures the intensity of the  
21 chemiluminescence from electronically excited sulfur molecules ( $\text{S}_2^*$ ).

22 Because formation of  $\text{S}_2^*$  requires two sulfur atoms, the intensity of the  
23 chemiluminescence is theoretically proportional to the square of the concentration of molecules  
24 that contain a single sulfur atom. In practice, the exponent is between one and two and depends  
25 on the sulfur compound being analyzed (Dagnall et al., 1967; Stevens et al., 1971). Calibrations  
26 are performed using both particles and gases as standards. The FPD can also be replaced by a  
27 chemiluminescent reaction with ozone that minimizes the potential for interference and provides  
28 a faster response time (Benner and Stedman, 1989, 1990).

29 Capabilities added to the basic system include *in situ* thermal analysis and sulfuric acid  
30 speciation (Cobourn et al., 1978; Huntzicker et al., 1978; Tanner et al., 1980; Cobourn and  
31 Husar, 1982). Sensitivities for particulate sulfur as low as  $0.1 \mu\text{g}/\text{m}^3$ , with time resolution

1 ranging from 1 to 30 min, have been reported. Continuous measurements of particulate sulfur  
2 content have also been obtained by on-line x-ray fluorescence analysis with resolution of 30 min  
3 or less (Jaklevic et al., 1981b). During a field-intercomparison study of five different sulfur  
4 instruments, Camp et al. (1982) reported four out of five FPD systems agreed to within  $\pm 5\%$   
5 during a one-week sampling period.

## 8 **2B.4 OTHER CONTINUOUS MEASUREMENTS**

### 9 *Continuous Ion Chromatography of Water-Soluble Ions*

10 Dasgupta and Slanina have independently developed particle collection systems that  
11 grow particles by increasing the relative humidity and collect the particles in an aqueous solution  
12 suitable for injection into an ion chromatography (Simon and Dasgupta, 1995; Khlystov et al.,  
13 1995). Automation of these systems yield semi-continuous monitors for those ions that can be  
14 determined using ion chromatography. A similar system using a particle size magnifier has been  
15 reported by Weber et al. (2001).

### 17 *Determination of Aerosol Surface Area in Real Time*

18 Aerosol surface area is an important aerosol property for health effects research.  
19 However, methods for on-line measurement of surface area are not widely available. Woo et al.  
20 (2001b) used three continuous aerosol sensors to determine aerosol surface area. They used a  
21 condensation particle counter (CPC, TSI, Inc., Model 3020), an aerosol mass concentration  
22 monitor (MCM, TSI, Inc., Model 8520), and an electrical aerosol detector (EAD, TSI, Inc.,  
23 Model 3070) for measuring particle charge concentration. The three sensor signals were  
24 inverted to obtain the aerosol size distribution, using a log-normal size distribution model (by  
25 minimizing the difference between the measured signals and the theoretical values based upon a  
26 size distribution model, the instrument calibration, and its theoretical responses). The log-  
27 normal function was then integrated to calculate the total surface area concentration. Woo et al.  
28 (2001b) demonstrated that this method can give near real-time measurements of aerosol surface  
29 area.

1     ***Light Scattering***

2             A variety of types of nephelometers that integrate aerosol light scattering over various  
3 solid angles are available (McMurry, 2000). When used to measure visibility, e.g., to provide  
4 pilots with realtime data on visual range, it is desirable to include the light scattering due to  
5 particle-bound water. However, when used as an indicator of fine particle mass, it is desirable to  
6 exclude particle-bound water. This is frequently done by heating the ambient aerosol to a low  
7 reference relative humidity of 40%. However, this heating has the potential of also causing the  
8 loss of semivolatile components of the aerosol. The evaporation of ammonium nitrate aerosol in  
9 a heated nephelometer has been examined. Bergin et al. (1997) conducted laboratory  
10 experiments at low relative humidity (~10%) and as a function of temperature (27-47 °C), mean  
11 residence time in the nephelometer, and initial particle size distribution. The evaporation of  
12 ammonium nitrate aerosol was also modeled for comparison and was found to describe  
13 accurately the decrease in aerosol scattering coefficient as a function of aerosol physical  
14 properties and nephelometer operating conditions. Bergin et al. (1997) determined an upper  
15 limit estimate of the decrease in the aerosol light scattering coefficient at 450 nm due to  
16 evaporation for typical field conditions. The model estimates for their worst-case scenario  
17 suggest that the decrease in the aerosol scattering coefficient could be roughly 40%. Under most  
18 conditions, however, they estimate that the decrease in aerosol scattering coefficient is generally  
19 expected to be less than 20%.

20

# 3. CONCENTRATIONS, SOURCES, AND EMISSIONS OF ATMOSPHERIC PARTICULATE MATTER

## 3.1 INTRODUCTION

This chapter discusses topics covered in Chapter 5 (Sources and Emissions of Atmospheric Particles) and Chapter 6 (Environmental Concentrations) of the previous document, Air Quality Criteria for Particulate Matter or “1996 PM AQCD” (U.S. Environmental Protection Agency, 1996) and presents updates to these materials where available.

Information about concentrations, the composition, and the spatial and temporal variability of ambient particles across the United States is presented in Section 3.2. Ambient concentration data obtained during the first three years of operation of the recently deployed nationwide network of Federal Reference Method PM<sub>2.5</sub> monitors in twenty-seven metropolitan statistical areas (MSAs) are presented and analyzed in Appendix 3A. Initial data from the pilot method evaluation study for the national speciation network are presented in Appendix 3B. Results of field studies that have characterized the composition of organic compounds in ambient particles are summarized in Appendix 3C to complement the data for the inorganic composition of ambient particles presented in Appendix 6A of the 1996 PM AQCD and Appendix 3B of this document. Data for characterizing the daily and seasonal variability of PM<sub>2.5</sub> concentrations are discussed in Section 3.2.1; the intra-day variability of PM<sub>2.5</sub> concentrations is discussed in Section 3.2.2; relationships among different size fractions are discussed in Section 3.2.3; interrelationships and correlations among PM components are discussed in Section 3.2.4; and the spatial variability of various PM components is discussed in Section 3.2.5.

Unlike gaseous criteria pollutants (SO<sub>2</sub>, NO<sub>2</sub>, CO, O<sub>3</sub>), which are well-defined chemical entities, atmospheric particulate matter (PM) is composed of a variety of particles differing in size and chemical composition. Therefore, sources of each component of the atmospheric aerosol must be considered in turn. Differences in the composition of particles emitted by different sources also will lead to spatial and temporal heterogeneity in the composition of the atmospheric aerosol. The nature of the sources and the composition of the emissions from these sources are discussed in Section 3.3. The chemistry of formation of secondary PM from gaseous precursors is discussed in Section 3.3.1. Estimates of contributions of various sources to

1 ambient PM levels given by source apportionment studies also are presented in Section 3.3.2.  
2 More detailed information about the composition of emissions from various sources is given in  
3 Appendix 3D. The determination of “policy-relevant background” (PRB) concentrations,  
4 including contributions from natural local sources and the long-range transport of PM from  
5 sources outside the United States, is discussed in Section 3.3.3. Reviews of transport of PM and  
6 its precursors within the United States can be found in the North American Research Strategy for  
7 Tropospheric Ozone (NARSTO) Fine Particle Assessment (NARSTO, 2002). More detailed  
8 information regarding sulfur and nitrogen species can be found in Hidy (1994). Further  
9 information about PM concentrations observed at relatively remote monitoring sites (RRMS),  
10 i.e., monitoring sites located in relatively remote areas that are not obviously influenced by local  
11 anthropogenic sources, is given in Appendix 3E. Because PM is composed of both primary and  
12 secondary constituents, emissions of both the primary components and the gaseous precursors of  
13 secondary PM must be considered. Nationwide emissions estimates of primary PM and  
14 precursors to secondary PM are discussed in Section 3.3.4, and uncertainties in emissions  
15 estimates in Section 3.3.5.

16 The organization of topics in this chapter (ambient measurements, source characterization  
17 and apportionment, and emissions inventories) reflects, in a broad sense, the order in which these  
18 topics are addressed in scientific studies and, arguably, the increasing levels of uncertainty that  
19 are associated with these topics.

## 22 **3.2 PATTERNS AND TRENDS IN AMBIENT PM CONCENTRATIONS**

23 Considerable data exists for characterizing  $PM_{10}$  mass concentrations and trends, and those  
24 available at the time were presented in the 1996 PM AQCD. In contrast, data sets for  
25 characterizing  $PM_{2.5}$  and  $PM_{10-2.5}$  mass or trends were not as extensive. Sources of data for  $PM_{2.5}$   
26 (fine) and  $PM_{10-2.5}$  (coarse) discussed in the 1996 PM AQCD include EPA’s Aerometric  
27 Information Retrieval System (AIRS; U.S. Environmental Protection Agency, 2000a);  
28 Interagency Monitoring of Protected Visual Environments (IMPROVE; Eldred and Cahill, 1994;  
29 Cahill, 1996); the California Air Resources Board (CARB) Data Base (California Air Resources  
30 Board, 1995); the Harvard Six-Cities Data Base (Spengler et al., 1986; Neas, 1996); and the  
31 Harvard-Philadelphia Data Base (Koutrakis, 1995). The Inhalable Particulate Network (IPN)

1 (Inhalable Particulate Network, 1985; Rodes and Evans, 1985) provided TSP, PM<sub>15</sub>, and PM<sub>2.5</sub>  
2 data but only a small amount of PM<sub>10</sub> data.

3 New sources of PM data include the recently deployed nationwide PM<sub>2.5</sub> compliance-  
4 monitoring network, which provides mass measurements using a Federal Reference Method  
5 (FRM). This section summarizes data obtained by this network from 1999 to 2001 and provides  
6 an approximate characterization of nationwide PM<sub>10-2.5</sub> concentrations by comparing PM<sub>10</sub> to  
7 PM<sub>2.5</sub> measurements at sites where both types of compliance monitors are located. Various  
8 aspects of these data are presented in greater detail in Appendix 3A. In addition, a small number  
9 of recent studies in which daily mass and composition measurements are available for extended  
10 periods are discussed in this section. The results of quality-assured aerosol composition data  
11 obtained by X-ray fluorescence (XRF) and by analyses of organic carbon (OC) and elemental  
12 carbon (EC) for thirteen urban areas from the methods evaluation study for the national PM<sub>2.5</sub>  
13 speciation network are presented in Appendix 3B. The terms organic carbon (OC) and elemental  
14 carbon (EC) are subject to some ambiguity, and the meanings of these terms discussed in Section  
15 2.2.7 and Appendix 2.B.2 are applied here.

16 Organic compounds contribute from 10 to 70% of the dry fine particle mass in the  
17 atmosphere (see Appendix 3C). However, concentrations and the composition of organic PM  
18 are poorly characterized, and its formation mechanisms are poorly understood. Particulate  
19 organic matter is an aggregate of hundreds of individual compounds spanning a wide range of  
20 chemical and thermodynamic properties (Saxena and Hildemann, 1996). Some of the organic  
21 compounds are “semivolatile” (i.e., they have atmospheric concentrations and saturation vapor  
22 pressures such that both gaseous and condensed phases exist in equilibrium in the atmosphere).  
23 The presence of semivolatile or multiphase organic compounds complicates the sampling  
24 process. Organic compounds originally in the gas phase may be absorbed on glass or quartz  
25 filter fibers and create a positive artifact. Conversely, semivolatile compounds originally present  
26 in the condensed phase may evaporate from particles collected on glass, quartz, or Teflon filters  
27 creating a negative artifact. In addition, no single analytical technique is currently capable of  
28 analyzing the entire range of organic compounds present in atmospheric PM. Rigorous  
29 analytical methods are able to identify only 10 to 20% of the organic PM mass on the molecular  
30 level (Rogge et al., 1993), and only about 50% of the condensed phase compounds can be  
31 identified in smog chamber studies of specific compounds (Forstner et al., 1997a,b).

1 Measurement techniques and associated artifacts are discussed in Section 2.2.3.2. Information  
2 on the identification and concentration of the many different organic compounds identified in  
3 atmospheric samples obtained during the 1990s is given in Appendix 3C.

4 Summary tables giving the results of 66 field studies that obtained data for the composition  
5 of particles in the  $PM_{2.5}$ ,  $PM_{10-2.5}$ , or  $PM_{10}$  size ranges were presented in Appendix 6A of the  
6 1996 PM AQCD. The summary tables included data for mass, organic carbon, elemental  
7 carbon, nitrate, sulfate, and trace elements. Data from the studies were presented for the eastern,  
8 western, and central United States. It should be noted that these studies took place at various  
9 times and lasted for various durations over a 20-year period, and there may have been significant  
10 changes in the concentrations of many species between the times when these studies were  
11 conducted and now. These changes resulted from a number of factors (e.g., pollution controls,  
12 technological advances, land use changes, etc).

13 There were a number of discernible differences in the composition of particles across the  
14 United States evident in the data sets listed in Appendix 6A in the 1996 PM AQCD (cf.,  
15 Figures 6-85a to 6-85c). However, these differences can only be discussed in the context of the  
16 uncertainties in the measurements of the main components (sulfate, organic carbon, elemental  
17 carbon, crustal material, ammonium, and nitrate). Sulfate, followed by crustal materials, has the  
18 smallest uncertainty associated with its measurement among all the components listed. Sulfate  
19 constituted about 38% of  $PM_{2.5}$  in the aerosol composition studies in the eastern United States  
20 and was the major identifiable component of  $PM_{2.5}$ . However, it constituted only about 11% of  
21  $PM_{2.5}$  in the studies listed for the western United States. The contribution of crustal materials to  
22  $PM_{2.5}$  ranged from about 4% in the East to about 15% in the West. The contribution of  
23 unidentified material (possibly consisting mostly of water of hydration) ranged from 23% in the  
24 East to 0% in the West. The contribution of elemental carbon to  $PM_{2.5}$  ranged from about 4% in  
25 the East to about 15% in the West. Organic compounds constituted about 21% of  $PM_{2.5}$  in the  
26 eastern United States, reaching to about 39% for the studies listed in the western United States.  
27 However, uncertainties for organic carbon, elemental carbon, ammonium, and nitrate are larger  
28 than for sulfate and crustal material. Concentrations of organic carbon were multiplied by  
29 a factor of 1.4 when calculating mass to account for the presence of oxygen, nitrogen, and  
30 hydrogen in the organic compounds. This factor may vary among different areas and may  
31 represent the lowest reasonable estimate for an urban aerosol (Turpin and Lim, 2001).

1 In addition, the samples collected in the studies were subject to a number of sampling artifacts  
2 involving the adsorption of gases and the evaporation of volatile components that either formed  
3 on the filters or were present in the ambient particles. The values reported for organic carbon  
4 and elemental carbon in filter samples depend strongly on the specific analysis method used  
5 (Chow et al., 2002) as discussed extensively in Chapter 2.

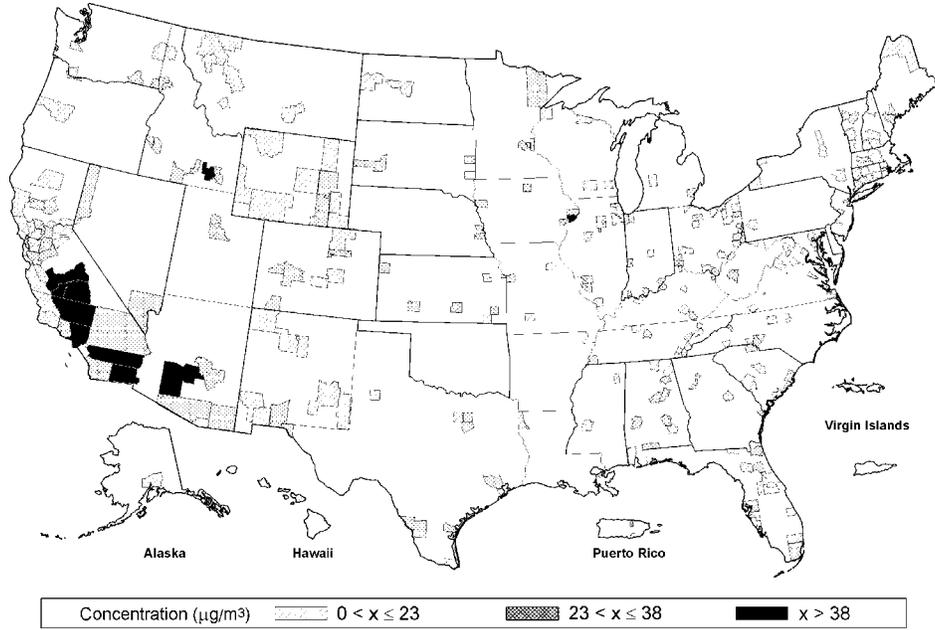

6 Crustal materials constitute from 52% of  $PM_{10-2.5}$  in the eastern United States to 70% of  
7  $PM_{10-2.5}$  in the western United States as indicated by the studies in Appendix 6A of the 1996 PM  
8 AQCD. The fraction of unidentified material in  $PM_{10-2.5}$  varied from 41% in the eastern United  
9 States to 27% in the western United States. However, in the vast majority of these studies, no  
10 attempt was made to characterize organic components or nitrate in the  $PM_{10-2.5}$  size fraction.  
11 It should also be remembered that a small fraction (typically about 10%) of  $PM_{2.5}$  is entrained  
12 into the flow of the channel of the dichotomous sampler that collects the  $PM_{10-2.5}$  sample and that  
13 there may be errors invoked during the procedure used to account for this entrainment. Even if  
14 analyses of total OC were available, they would not be able to distinguish between primary  
15 biological particles (PBP), which include microorganisms and fragments of living things, and  
16 organic compounds of miscellaneous origin in surface deposits on filters. A clear distinction  
17 should be made between PBP and primary OC emitted by organisms such as waxes coating the  
18 surfaces of leaves, seeds, fruits, stems, pollen, fungi, and on insects. Indeed, the fields of view  
19 of many photomicrographs of PM samples obtained by scanning electron microscopy, are  
20 dominated by large numbers of pollens, plant and insect fragments, and microorganisms.  
21 Bioaerosols such as pollens, fungal spores, and most bacteria are expected to be found mainly in  
22 the coarse size fraction. However, allergens from pollens can also be found in respirable  
23 particles (Monn, 2001; Taylor et al., 2002). Matthias-Maser (1998) summarized information  
24 about the size distribution of PBP in and around Mainz, Germany, in what is perhaps the most  
25 complete study of this sort. Matthias-Maser found that PBP constituted up to 30% of total  
26 particle number or volume in the size range from about 0.35  $\mu m$  to about 50  $\mu m$  on an annual  
27 basis. Additionally, whereas the contribution of PBP to the total aerosol volume did not change  
28 appreciably with season, the contribution of PBP to total particle number ranged from about 10%  
29 in December and March to about 25% in June and October.

30 Data for the chemical composition of particles in a number of national parks and remote  
31 areas have been collected for a number of years by the IMPROVE network. Concentrations

1 have been reported for sulfate, nitrate, light absorbing carbon, organic carbon, and soil  
2 components. With the collection of compositional data by the speciation network, more synoptic  
3 (i.e., concurrent) coverage will be obtained for these constituents from relatively remote to urban  
4 environments across the United States.

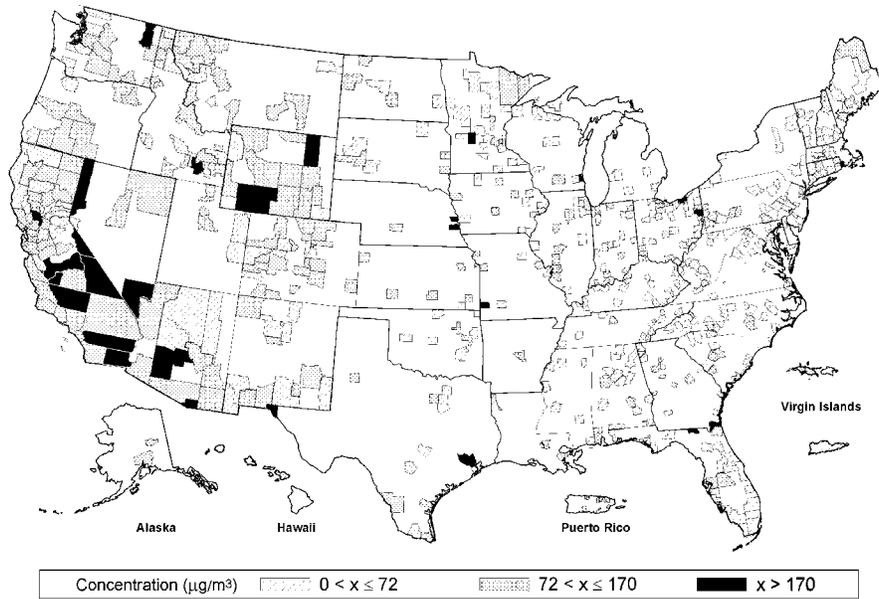

### 6 ***PM<sub>10</sub> Concentrations and Trends***

7 Nationwide PM<sub>10</sub> annual mean concentrations on a county-wide basis from the AIRS  
8 database for calendar years 1999, 2000, and 2001 are shown in Figure 3-1a. Concentrations in  
9 most areas of the country were below the level of the PM<sub>10</sub> annual standard of 50 µg/m<sup>3</sup> from  
10 1999 through 2001. Further information about the attainment status of different areas can be  
11 found in the U.S. Environmental Protection Agency's Air Quality Trends Reports. The median  
12 annual mean PM<sub>10</sub> concentration for this three year period was about 23 µg/m<sup>3</sup>; and the  
13 95<sup>th</sup> percentile value was about 38 µg/m<sup>3</sup>. Concentrations flagged as natural events (e.g.,  
14 resulting from high winds, wildfires, volcanic eruptions) or exceptional events (e.g.,  
15 construction, prescribed burning) are not included in the calculations. The procedures for  
16 calculating the annual means at the site level follow 40 Code of Federal Regulations (CFR)  
17 Part 50 Appendix K (requiring 75 percent completeness per quarter for all three years). The  
18 98<sup>th</sup> percentile concentrations from the monitor showing the highest value in a given county over  
19 the three year period are shown in Figure 3-1b. In these and in similar maps for PM<sub>2.5</sub> and  
20 PM<sub>10-2.5</sub>, cut points were chosen at the 50<sup>th</sup> and 95<sup>th</sup> percentile concentrations. These cut points  
21 were chosen as they represent the standard metrics for characterizing important aspects of human  
22 exposure used by the U.S. Environmental Protection Agency. Of course, any other percentiles or  
23 statistics that are believed to be useful for characterizing human exposures could also be used.  
24 As shown by the blank areas on the maps, the picture is not complete because some monitoring  
25 locations did not record valid data for all four quarters or recorded fewer than 11 samples in one  
26 or more quarters or counties simply did not have monitors. Similar considerations apply to the  
27 maps shown later for PM<sub>2.5</sub> and PM<sub>10-2.5</sub>. It should also be noted that the area of counties can be  
28 much greater in the West than in the East. As a result, the density of monitors may appear to be  
29 greater in the West and air quality may appear to be worse over much larger areas in the West  
30 than in the East. Concentrations are shown at the county level because this is the typical scale

**Figure 3-1a. 1999-2001 county-wide average annual mean  $PM_{10}$  concentrations ( $\mu\text{g}/\text{m}^3$ ) for counties with  $PM_{10}$  monitors.**

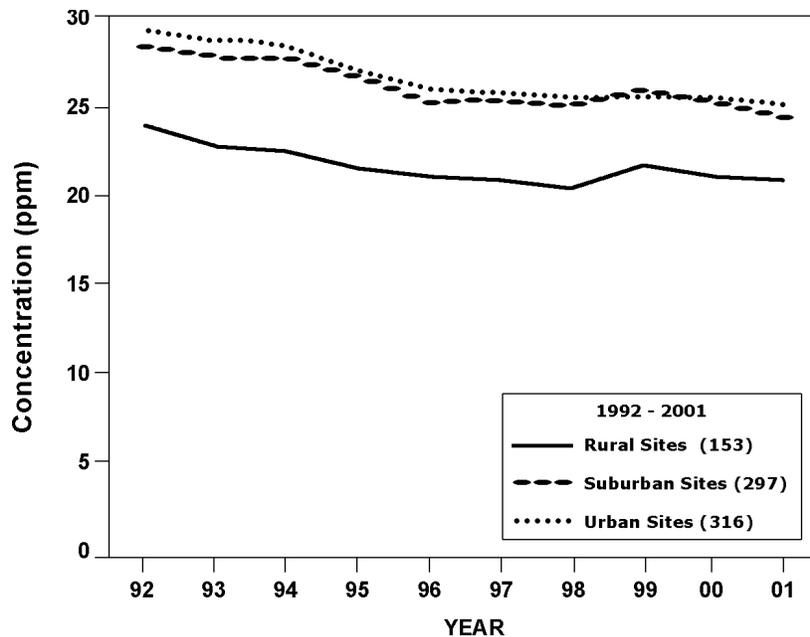

**Figure 3-1b. 1999-2001 highest county-wide 98<sup>th</sup> percentile 24-h average  $PM_{10}$  concentrations ( $\mu\text{g}/\text{m}^3$ ) for counties with  $PM_{10}$  monitors.**

Source: Aerometric Information Retrieval System (AIRS; U.S. Environmental Protection Agency, 2002b).

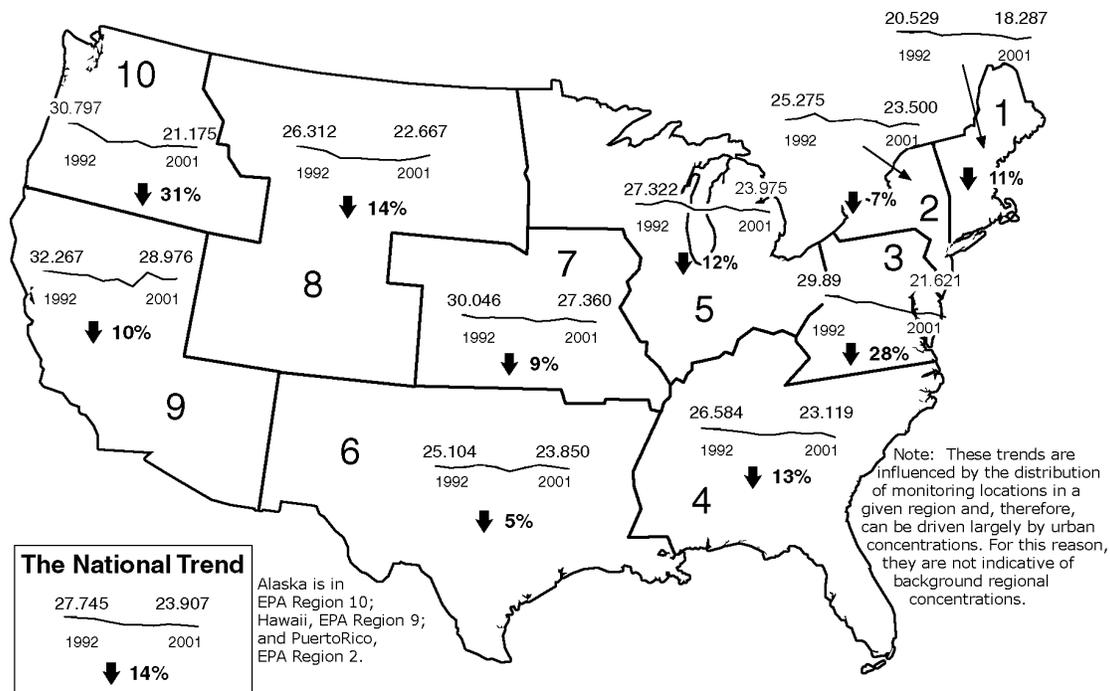

1 used in many health outcome studies. MSA or multi-county scales have also been used in a  
2 number of studies, e.g., Schwartz et al. (1996), or the NMMAPS study.

3 Nationwide trends in annual mean PM<sub>10</sub> concentrations from 1992 through 2001 (based on  
4 data obtained at 119 rural sites, 297 suburban sites, and 316 urban sites reporting to AIRS) are  
5 shown in Figure 3-2 (U.S. Environmental Protection Agency, 2002a). Although average  
6 concentration levels differ among types of sites with higher levels at urban and suburban sites  
7 the nationwide data set shows a decrease of 14% that occurred mainly during the first half of the  
8 record. PM<sub>10</sub> concentrations basically leveled off during the last few years of the record but  
9 there were indications of transient increases followed by decreases. Figure 3-3 shows the annual  
10 mean PM<sub>10</sub> trend summarized by EPA region. Decreases in annual average PM<sub>10</sub> concentrations  
11 from 1990 to 1999 were largest in the Northwest (9.6 µg/m<sup>3</sup>) and smallest in the south-central  
12 United States (1.3 µg/m<sup>3</sup>). Analyses of available TSP measurements obtained since 1950  
13 indicate that mean TSP concentrations appear to have declined by about two- to three-fold in  
14 urban areas between 1950 and 1980 (Lipfert, 1998).

1 ***PM<sub>2.5</sub> Concentrations and Trends***

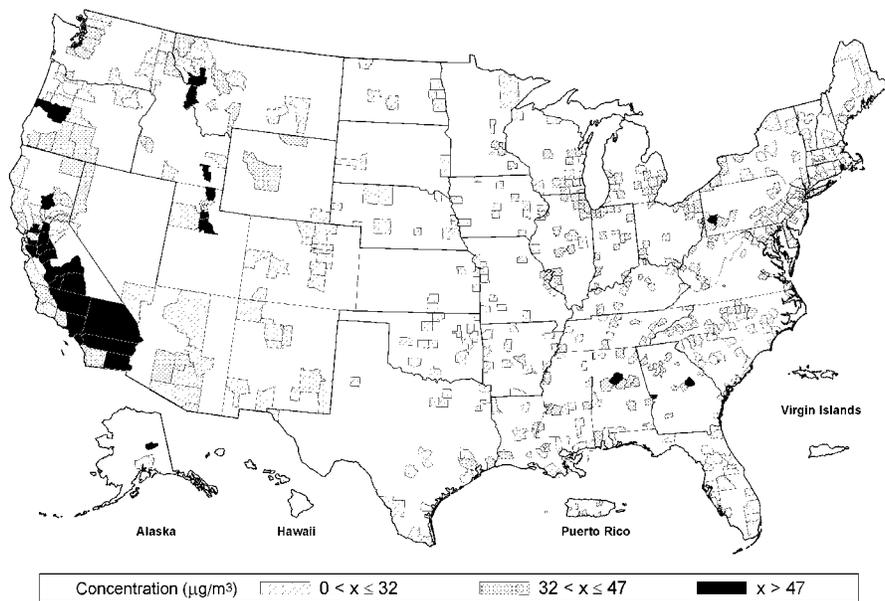

2 Nationwide annual mean PM<sub>2.5</sub> concentrations obtained from data collected during 1999,  
 3 2000, and 2001 are shown in Figure 3-4a; and 98<sup>th</sup> percentile concentrations are shown in  
 4 Figure 3-4b. Quantities shown in Figure 3-4a and 3-4b were calculated for individual counties.  
 5 Annual mean concentrations shown in Figure 3-4a were calculated on the basis of the latest  
 6 8 consecutive quarters containing at least 11 samples per quarter, and results from the highest  
 7 monitor were used to produce Figure 3-4b. Data meeting these completeness criteria were  
 8 obtained at 897 sites in 592 counties. The median PM<sub>2.5</sub> concentration nationwide was about  
 9 13 µg/m<sup>3</sup>. Annual mean PM<sub>2.5</sub> concentrations were above 17 µg/m<sup>3</sup> at 5% of the sites, mainly in  
 10 California and in the southeastern United States. The 98<sup>th</sup> percentile 24-h average concentrations  
 11 (as defined earlier for PM<sub>10</sub>) were below 47 µg/m<sup>3</sup> at 95% of the sites sampled. Most of the sites  
 12 with levels above this value are located in California.

Source: Aerometric Information Retrieval System (AIRS; U.S. Environmental Protection Agency, 2002b).

1 Annual average PM<sub>2.5</sub> concentrations obtained as part of several health studies conducted  
2 in various locations in the United States and Canada from the late 1980s to the early 1990s are  
3 shown in Figure 3-5 (Bahadori et al., 2000a). These studies include the Harvard six-cities study  
4 (Steubenville, OH; Watertown, MA; Portage, WI; Topeka, KS; St. Louis, MO; and Kingston-  
5 Harriman, TN); Particle Total Exposure Assessment Methodology (PTEAMS; Riverside, CA);  
6 Metropolitan Acid Aerosol Characterization Study (MAACS; Philadelphia, PA; Washington,  
7 DC; and Nashville, TN); South Boston Air Quality and Source Apportionment Study (Boston,  
8 MA); and NPMRMN (Phoenix, AZ). The remaining sites were part of the 24-cities study  
9 (Spengler et al., 1996).

10 Sufficient data are not yet available to permit the calculation of nationwide trends of PM<sub>2.5</sub>  
11 and PM<sub>10-2.5</sub>; however, some general emerging patterns can be discerned. Darlington et al.  
12 (1997) proposed that the consistent reductions in PM<sub>10</sub> concentrations found in a wide variety of  
13 environments ranging from urban to rural may have resulted from common factors or controls  
14 that affected fine particles more strongly than coarse particles. This is because fine particles  
15 have longer atmospheric lifetimes than coarse particles and can be transported over longer  
16 distances and, hence, can affect larger areas. Apart from the IMPROVE network of monitoring  
17 sites located mainly in national parks, the longest time series of PM<sub>2.5</sub> concentration and  
18 composition data have been obtained by the California Air Resources Board (CARB). Their  
19 data show that annual average PM<sub>2.5</sub> concentrations decreased by about 50% in the South Coast  
20 Air Basin, 35% in the San Joaquin Valley, 30% in the San Francisco Bay Area, and 35% in the  
21 Sacramento Valley from 1990 to 1995 (Dolislager and Motallebi, 1999). PM<sub>2.5</sub> data were  
22 collected continuously from 1994 to 1998 as part of the children's health study in 12 southern  
23 California communities (Taylor et al., 1998). Data obtained at all sites show decreases in PM<sub>2.5</sub>  
24 ranging from 2% at Santa Maria to 37% at San Dimas/Glendora from 1994 through 1998. These  
25 decreases were accompanied by decreases in major components such as nitrate, sulfate,  
26 ammonium, and acids. Based on the analysis of PM<sub>2.5</sub> data sets collected prior to 1990, Lipfert  
27 (1998) found that PM<sub>2.5</sub> concentrations appear to have decreased by about 5% per year from  
28 1970 to 1990 in a number of urban areas. These declines were also found to be consistent with  
29 decreases in emissions from combustion sources over that time period.

**Figure 3-5. Collection of annual distribution of 24-h average PM<sub>2.5</sub> concentrations observed in U.S. and Canadian health studies conducted during the 1980's and early 1990's.**

Source: Bahadori et al. (2000a).

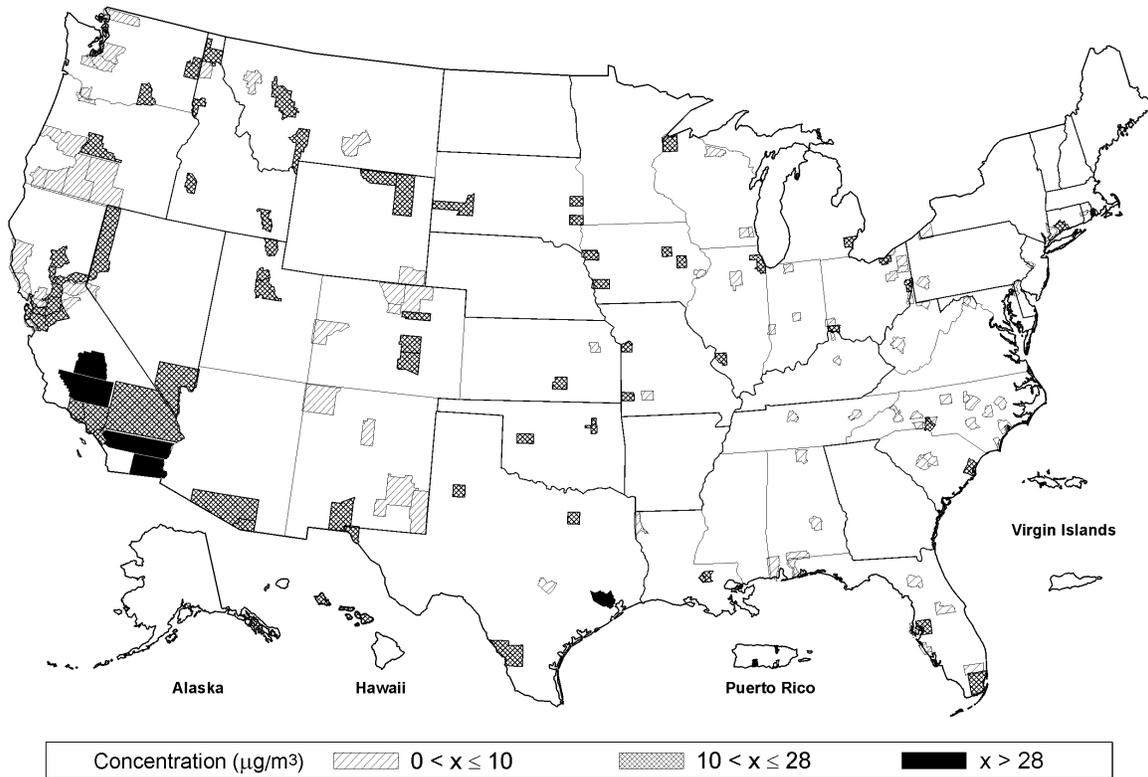

## ***PM<sub>10-2.5</sub> Concentrations***

By using AIRS data for 1999, 2000, and 2001 obtained by the PM<sub>10</sub> and PM<sub>2.5</sub> compliance networks, it is possible to construct a picture of the distribution of coarse PM across the country. This is accomplished by pairing data from 208 compliance monitoring sites in 196 counties where PM<sub>10</sub> and PM<sub>2.5</sub> monitors are collocated and subtracting the mass concentrations of PM<sub>2.5</sub> from PM<sub>10</sub>. Annual mean concentrations were calculated on the basis of the latest 8 consecutive quarters containing at least 11 samples per quarter. Nationwide annual mean PM<sub>10-2.5</sub> concentrations calculated by this approach are shown in Figure 3-6a. Annual mean PM<sub>10-2.5</sub> concentrations ranged from about 1 to about 50 µg/m<sup>3</sup>; the nationwide median concentration was about 10 µg/m<sup>3</sup>; and 5% of the sites had mean concentrations greater than 28 µg/m<sup>3</sup>. The higher values occur mainly in the western United States, particularly in California. The highest county-wide 98<sup>th</sup> percentile PM<sub>10-2.5</sub> concentrations based on this same data set are shown in Figure 3-6b. Highest values in the western United States are caused by dust raised locally either by natural means or by anthropogenic activity. It is not clear what the contribution of PBP to these values may be. Elevated dust levels are also found in southern Florida as the result of dust storms in North Africa (Section 3.3.3) and trans-Atlantic transport. In many areas, combined errors in the PM<sub>2.5</sub> and PM<sub>10</sub> measurements may be similar to or even greater than the calculated PM<sub>10-2.5</sub> concentrations. Because of this and other potential problems with this approach (Section 3.2.1), these results should be viewed with caution.

### **3.2.1 Seasonal Variability in PM Concentrations**

#### ***PM<sub>2.5</sub>***

Aspects of the spatial and temporal variability of PM<sub>2.5</sub> concentrations for 1999, 2000, and 2001 in a number of metropolitan areas across the United States are presented in this and following subsections. Data for multiple sites in 27 urban areas across the United States have been obtained from the AIRS data base and analyzed for their seasonal variations and for their spatial correlations and spatial uniformity in concentrations. Selection of these 27 MSAs was based on the criteria that data be available for at least 15 days in each calendar quarter of either a three year period (1999, 2000, and 2001) or a two year period (2000 and 2001) at three or more sites within that MSA. In addition, a maximum of 11 sites per MSA were included for analysis.

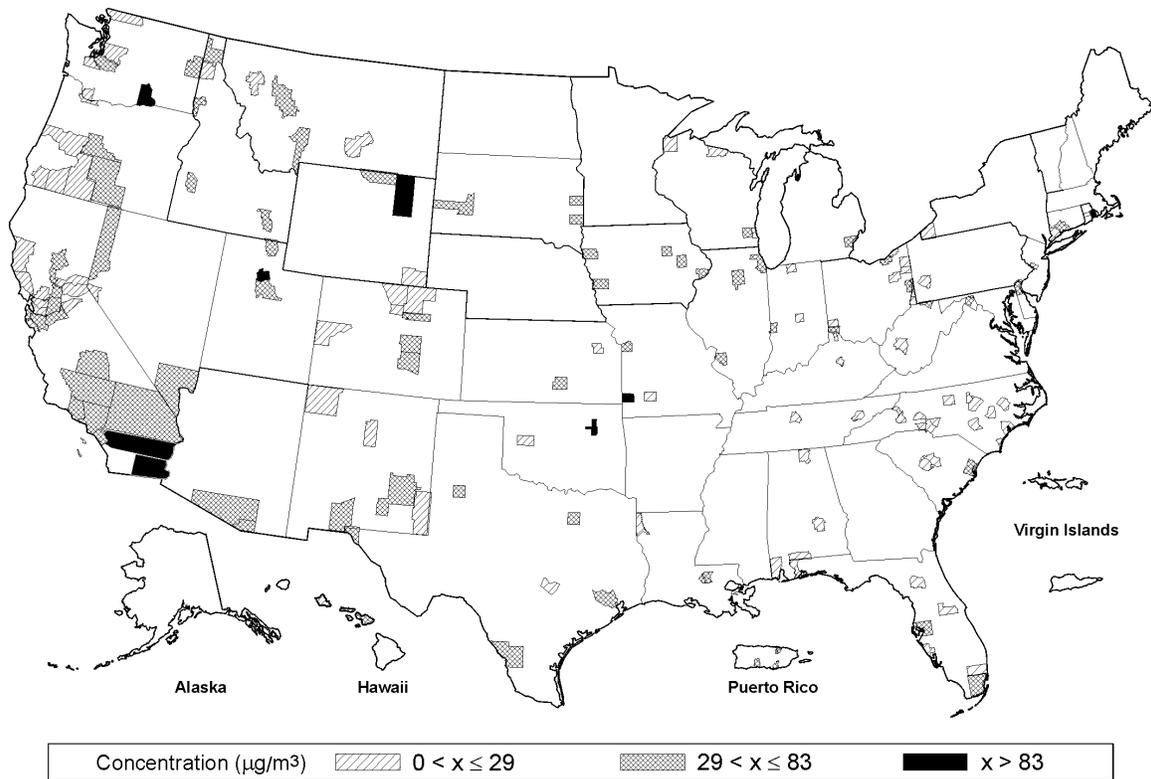

**Figure 3-6a. 1999-2000 estimated county-wide average annual mean  $PM_{10-2.5}$  concentrations ( $\mu\text{g}/\text{m}^3$ ) for counties with collocated  $PM_{2.5}$  and  $PM_{10}$  monitors.**

Source: Aerometric Information Retrieval System (AIRS; U.S. Environmental Protection Agency, 2002b).

1 (In the Chicago and St. Louis MSAs, the 11 sites having the most observations were selected  
 2 from a greater number of qualifying sites.) A number of aspects of the spatial and temporal  
 3 variability of the 1999  $PM_{2.5}$  data set were presented in Rizzo and Pinto (2001) based in part on  
 4 analyses given in Fitz-Simons et al. (2000).

5 Information regarding the seasonal variability in  $PM_{2.5}$  concentrations in four MSAs  
 6 (Philadelphia, PA; Cleveland, OH; Dallas, TX; and Los Angeles-Long Beach, CA) in the  
 7 United States is summarized in Figures 3-7a through 3-7d. These four urban areas were chosen  
 8 to illustrate some general features of the spatial and temporal variability found in the  
 9 United States. The figures show lowest, lower quartile, median, upper quartile, and highest  
 10 concentrations for each calendar quarter of 1999, 2000, and 2001 for the Cleveland, OH MSA  
 11 and for 2000 and 2001 for Philadelphia, Dallas and Los Angeles MSAs. For each monitoring

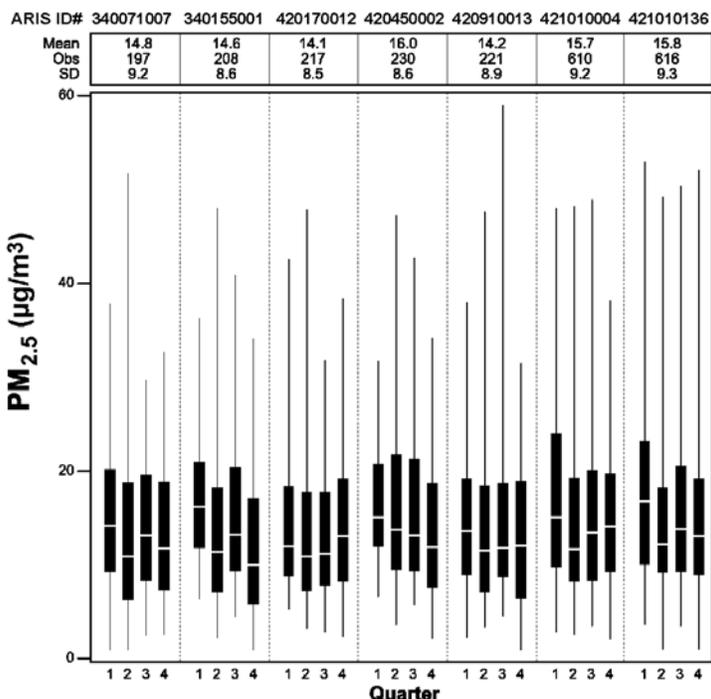

**Figure 3-6b. 1999-2000 estimated county-wide highest 98<sup>th</sup> percentile 24-h  $PM_{10-2.5}$  concentrations ( $\mu\text{g}/\text{m}^3$ ) for counties with collocated  $PM_{2.5}$  and  $PM_{10}$  monitors.**

Source: Aerometric Information Retrieval System (AIRS; U.S. Environmental Protection Agency, 2002b).

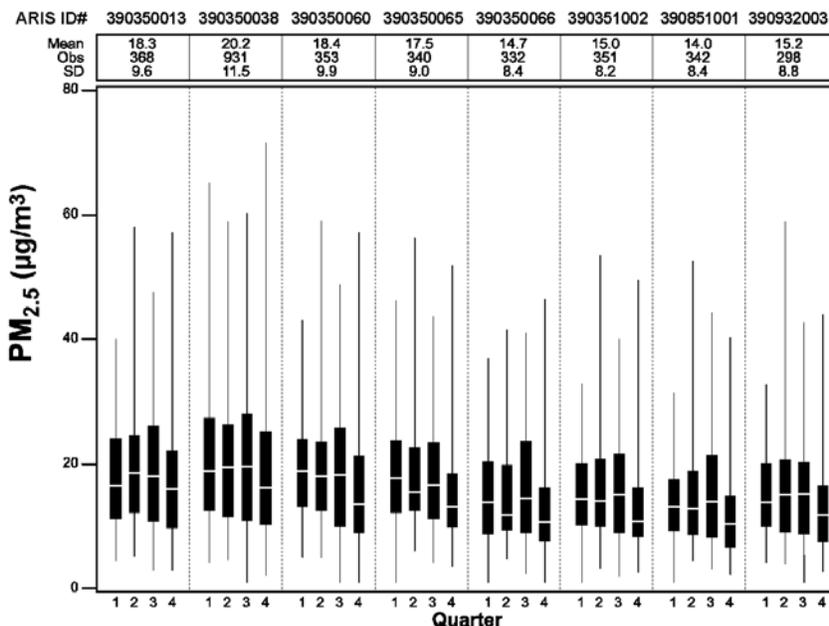

1 site, the AIRS ID numbers, annual mean concentrations, the number of observations, and  
 2 standard deviations are also shown. Data for multiple sites within these MSAs are shown to  
 3 provide an indication of the degree of inter-site variability. Data for these MSAs and an  
 4 additional twenty-three MSAs, criteria used for site selection, and additional descriptions of the  
 5 data are given in Appendix 3A.

6 Annual mean  $PM_{2.5}$  concentrations at individual monitoring sites in the MSAs examined  
 7 ranged from about  $6 \mu\text{g}/\text{m}^3$  to about  $30 \mu\text{g}/\text{m}^3$ . The lowest values were found in rural portions of  
 8 the MSAs examined, typically near the perimeter of the MSA. The two highest mean  
 9 concentrations were found in the Riverside and Los Angeles-Long Beach MSAs in southern  
 10 California while the three lowest means were found in the Northwest (Portland, OR; Boise, ID;  
 11 Seattle, WA). MSAs situated along the Eastern seaboard (Washington, DC; Philadelphia, PA;

**a. Philadelphia, PA (2000 - 2001)**

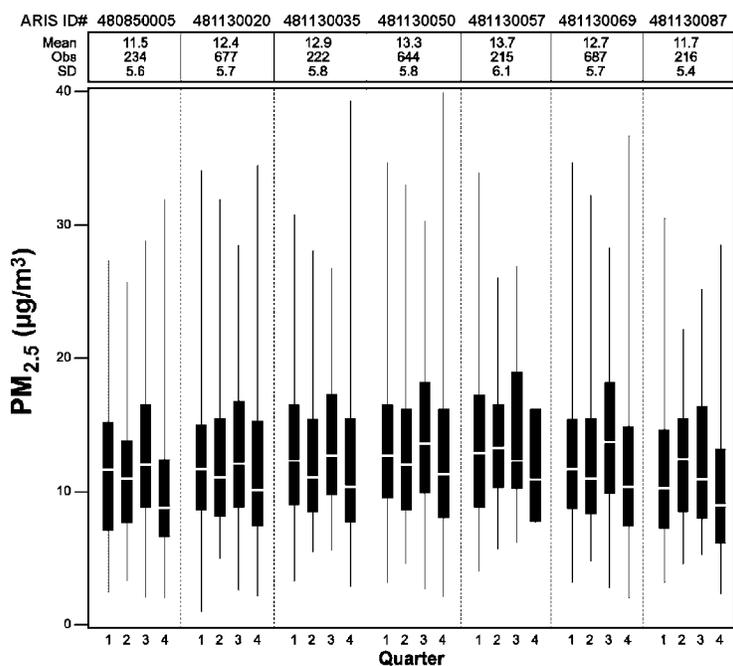

**b. Cleveland, OH (1999 - 2001)**

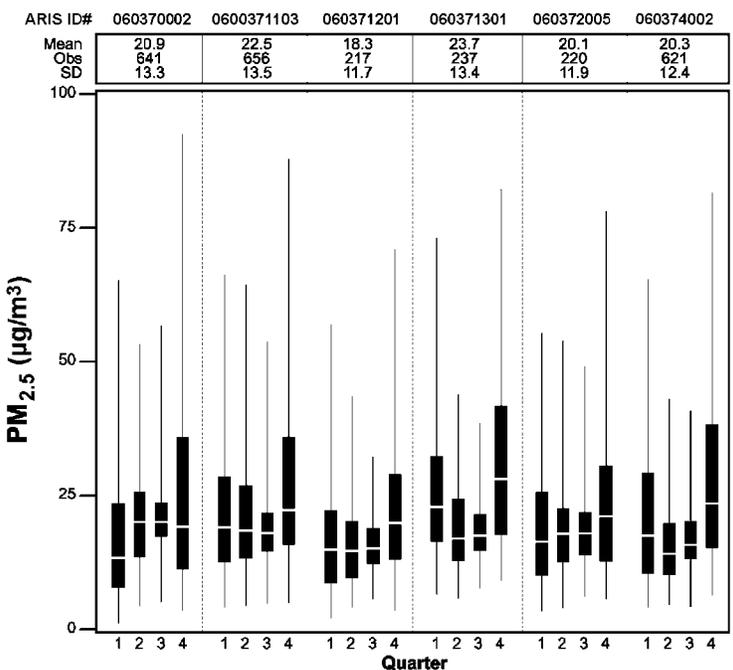

**Figure 3-7a,b. Quarterly distribution of 24-h average PM<sub>2.5</sub> concentrations for selected monitors in the (a) Philadelphia, PA and (b) Cleveland, OH. Values for the lowest, lower quartile, median, upper quartile and highest concentrations are shown in the figures. The AIRS site ID number, annual mean concentration (µg/m<sup>3</sup>), number of observations, and standard deviation of the data are shown above the figures for each site.**

**c. Dallas, TX (2000 - 2001)**

**d. Los Angeles, CA (2000 - 2001)**

**Figure 3-7c,d. Quarterly distribution of 24-h average PM<sub>2.5</sub> concentrations for selected monitors in the (c) Dallas, TX and (d) Los Angeles, CA MSAs. Values for the lowest, lower quartile, median, upper quartile and highest concentrations are shown in the figures. The AIRS site ID number, annual mean concentration (µg/m<sup>3</sup>), number of observations, and standard deviation of the data are shown above the figures for each site.**

1 Norfolk, VA) tend to have lower mean PM<sub>2.5</sub> concentrations than MSAs in the north-central  
2 United States (Steubenville, OH; Cleveland, OH; Pittsburgh, PA; Chicago, IL; Detroit, MI;  
3 Gary, IN; Appendix 3A). In addition, average PM<sub>2.5</sub> concentrations tended to be lower in 1999,  
4 2000, and 2001 in urban areas given in Appendix 3A compared to the concentrations observed  
5 during pollution-health outcome studies conducted in those five urban areas where these overlap  
6 (Figure 3-5). It should be noted that there are no data demonstrating the comparability of the  
7 monitors used in the studies shown in Figure 3-5 and the FRM.

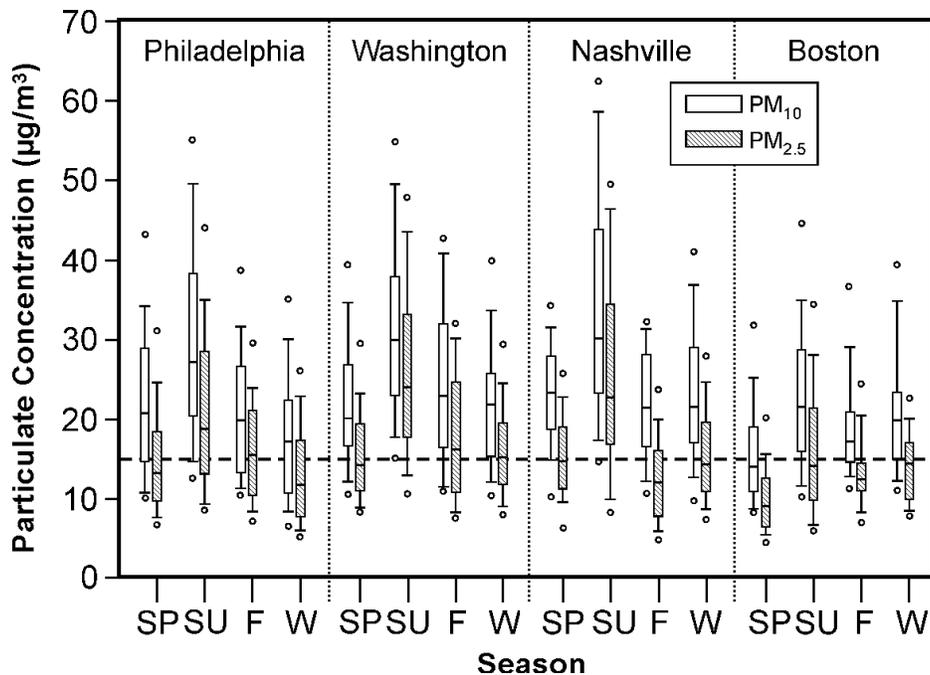

8 The patterns of seasonal variability observed in the MSAs examined are complex. In the  
9 Philadelphia, PA MSA, highest median concentrations occur at all but one site in the first quarter  
10 (cf., Figure 3-7a). First quarter maxima are also observed at all sites in the Detroit, MI and  
11 Chicago, IL MSAs (cf., Figures 3A-11 and 3A-14). The Cleveland, OH, MSA (Figure 3-7b) by  
12 contrast does not have a clear seasonal pattern. In several MSAs examined in the south and  
13 eastern United States (Atlanta, GA; Baton Rouge, LA; Birmingham, AL; Columbia, SC;  
14 and Washington, DC), highest median concentrations occur at all sites during the third calendar  
15 quarter (i.e., summer months; cf., Appendix 3A). Sites in Dallas, TX, (Figure 3-7c) as in the  
16 other southern cities mentioned above, generally exhibit third quarter median concentration  
17 maxima. Highest median concentrations occur during the fourth calendar quarter in MSAs in the  
18 western United States as in the Los Angeles, CA MSA (Figure 3-7d) although there are  
19 exceptions at individual sites in the Riverside, CA MSA (Figure 3A-26).

20 Lowest median concentrations occur mainly during the first or fourth quarters at most sites  
21 in the eastern United States as well as in Cleveland, OH and Dallas, TX (Figures 3-7b and 3-7c)  
22 while some occur during the second quarter (Philadelphia, PA; Figure 3-7a). Moving westward,  
23 the seasonal pattern is not as distinct: lowest median concentrations occur in any quarter, but  
24 usually in the second or third quarter as in the Chicago, Detroit, and Los Angeles-Long Beach  
25 (Figure 3-7d) MSAs. With the exception of Los Angeles, CA and Riverside, CA, sites in the  
26 West show lowest median concentrations in the second quarter. In most of the MSAs examined,  
27 seasonal variations follow a similar pattern at all of the sites within the MSA, but in a few MSAs  
28 there are noticeable differences in the seasonal pattern between sites. The large-scale differences  
29 in seasonal variability between MSAs tend to follow differences in the major categories of PM  
30 sources affecting the monitoring sites. Local heating by wood burning during the colder months  
31 is practiced more widely in the western United States than in the eastern United States.

1 Prolonged winter stagnation events are also more common in western mountain valleys during  
2 winter than in sections of the eastern United States located in relatively flat topography. Hence,  
3 winter maxima and greater variability in  $PM_{2.5}$  concentrations across sites are expected in the  
4 West due to the influence of the local sources. On the other hand, photochemical production of  
5 secondary PM, especially sulfate, occurs over wide areas in relatively homogeneous air masses  
6 during the summer months in the eastern United States. Because sulfates (along with associated  
7 cations and water) constitute the major fraction of summertime  $PM_{2.5}$  in the East, there is greater  
8 uniformity in third quarter PM concentrations within eastern MSAs (cf., Appendix 3A).

9 Maximum twenty-four hour average concentrations shown in the box plots in Figures 3-7a  
10 to 3-7d and in Figures 3A-1 to 3A-27 do not necessarily follow the same seasonal pattern as the  
11 median concentrations. There is no clear relation between the maximum and the median  
12 concentrations evident in the Philadelphia, PA data set (Figure 3-7a). In Cleveland, OH  
13 (Figure 3-7b), maximum concentrations occur during the second or fourth quarters, and highest  
14 median concentrations generally occur during the third or first quarters. In Dallas, TX  
15 (Figure 3-7c), maximum concentrations generally occur during the fourth quarter, but highest  
16 median concentrations tend to occur during the second or third quarter. In the Los Angeles-Long  
17 Beach MSA (Figure 3-7d), the maximum and highest median concentrations occur together in  
18 the fourth quarter with the exception of one site. Peak individual concentrations likely reflect  
19 the occurrence of transient events such as forest fires (mainly in the West) or episodes of  
20 secondary PM production (mainly in the East). However, chemical analyses of filter samples or  
21 other evidence should be used to determine specific causes in particular locations.

22 There have been a few studies that have characterized  $PM_{2.5}$  and  $PM_{10}$  concentrations in  
23 major urban areas. The Metropolitan Aerosol Acidity Characterization Study (MAACS)  
24 (Bahadori et al., 2000b) characterized the levels and the spatial and temporal variability of  $PM_{2.5}$ ,  
25  $PM_{10}$ , and acidic sulfate concentrations in four cities in the eastern United States (Philadelphia,  
26 PA; Washington, D.C.; Nashville, TN; and Boston, MA). Seasonal variations in  $PM_{2.5}$  and  $PM_{10}$   
27 concentrations obtained during the course of this study are shown in Figure 3-8. The data for the  
28 four cities included in MAACS are presented in a box plot showing the lowest, lowest tenth  
29 percentile, lowest quartile, median, highest quartile, highest tenth percentile, and highest  $PM_{2.5}$   
30 and  $PM_{10}$  values. Mean and highest  $PM_{2.5}$  and  $PM_{10}$  concentrations are found during the summer  
31

**Figure 3-8. Seasonal concentrations of  $PM_{2.5}$  and  $PM_{10}$  measured in the four MAACS cities. The data show the lowest, lowest tenth percentile, lowest quartile, median highest quartile, highest tenth percentile, and highest  $PM_{2.5}$  24-h average values. The dashed line shows the level of the annual  $PM_{2.5}$  standard.**

Source: Bahadori et al. (2000b).

1 in all four cities (in contrast with Figure 3-7a) although the seasonal pattern in Boston appears to  
 2 be more nearly bimodal with an additional winter peak.

3

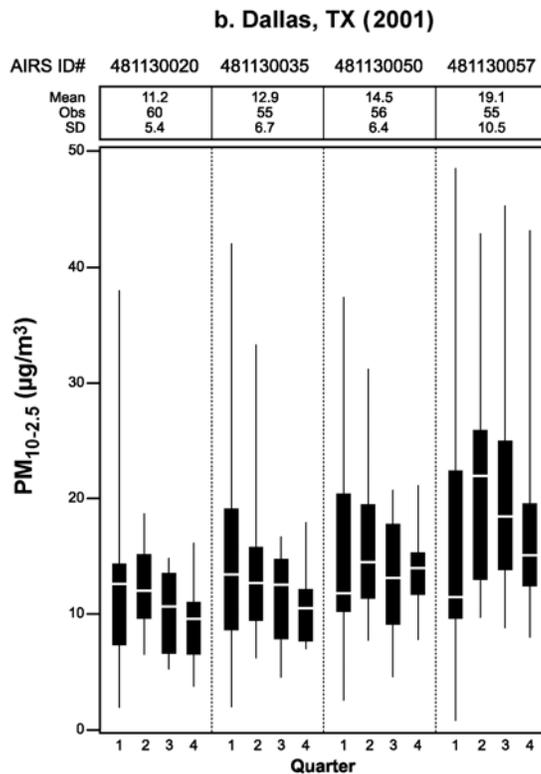

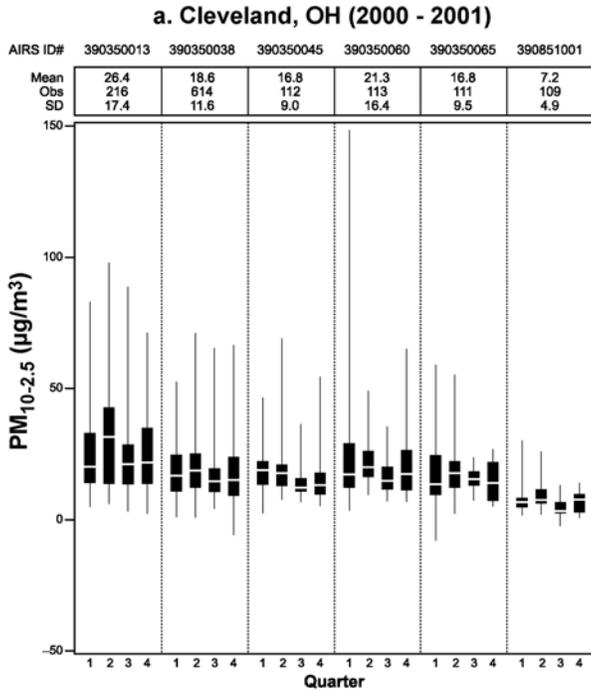

4  **$PM_{10-2.5}$**

5 Of the 27 MSAs selected for analysis of  $PM_{2.5}$  data (Appendix 3A), 17 have multiple sites  
 6 satisfying the  $PM_{10-2.5}$  data completeness criteria. A subset of 53 qualifying sites were selected  
 7 for analysis of  $PM_{10-2.5}$  data. Each qualifying site has 11 or more observations per calendar  
 8 quarter for twelve consecutive quarters (1999-2001, 2 MSAs), eight quarters (1999 + 2000 or  
 9 2000 + 2001, 7 MSAs) or four quarters (2000 or 2001, 8 MSAs). In addition, data from sites  
 10 within the same MSA represent the same year (or years) of observations, so that intersite  
 11 comparisons within an MSA are based on the same reporting period. However, comparisons

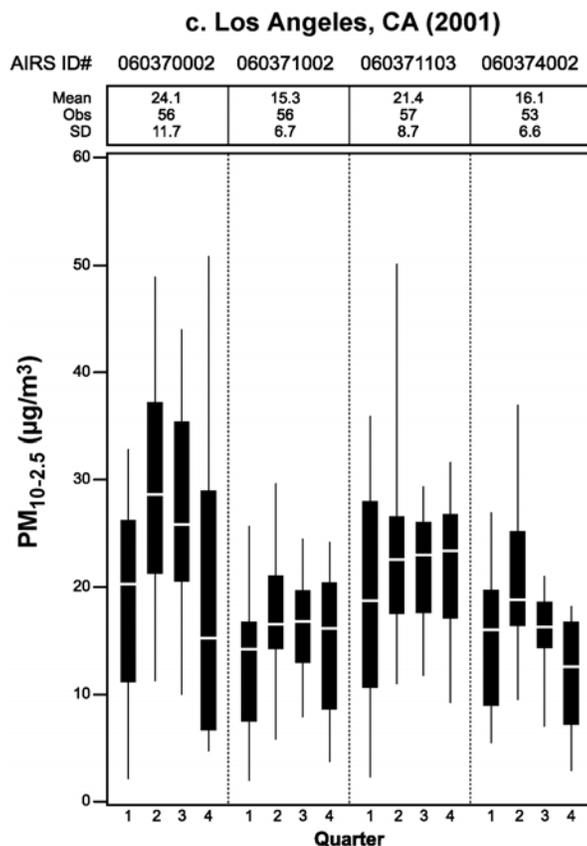

1 between different MSAs can involve different annual reporting periods. As can be seen by  
2 comparing Figures 3-7a,b,c,d and Figures 3-9a,b,c the number of observations used for  
3 summarizing  $PM_{10-2.5}$  data is much lower than that measured for  $PM_{2.5}$ . Unfortunately, fewer  
4 qualifying MSAs for  $PM_{10-2.5}$  result in geographical coverage that is more spotty than with  $PM_{2.5}$ .  
5 Five of the seven MSAs representing the eastern United States for  $PM_{2.5}$ , for example, did not  
6 meet completeness criteria for  $PM_{10-2.5}$ , leaving only Tampa, FL, and Columbia, SC, to represent  
7 the East. Secondly, it can readily be seen, e.g., for Cleveland, OH (Figure 3-9a) and in  
8 Figures 3A-28 through 3A-44, that a number of  $PM_{10-2.5}$  concentrations are negative.  
9 For example, in 2001, approximately one-fourth of all  $PM_{10-2.5}$  concentrations at the three  
10 qualifying sites in the Gary, IN MSA were negative. (The negative estimates have been included  
11 in the calculation of mean concentrations.) There are a number of reasons for the negative  
12 concentration estimates, many of which arise because the ratios of  $PM_{2.5}$  to  $PM_{10}$  are based on  
13 two independent measurements. Measurement imprecision plays a role when the ratios are large  
14 and concentrations are small. Differences in the behavior of semivolatile components in the two  
15 samplers could occur; and the results may also reflect errors in sampler placement, field,  
16 laboratory, or data processing procedures. For the reasons cited above, caution should be  
17 exercised when attempting to interpret results for  $PM_{10-2.5}$  based on current network collocated  
18  $PM_{2.5}$  and  $PM_{10}$  monitors.

19 Annual mean  $PM_{10-2.5}$  concentrations at individual monitoring sites range from about  
20  $6 \mu\text{g}/\text{m}^3$  (Portland, OR) to about  $33 \mu\text{g}/\text{m}^3$  (Riverside, CA). (Gary, IN sites were excluded  
21 because of numerous negative  $PM_{10-2.5}$  concentrations, and one site in Riverside, CA, affected by  
22 a local dust event was excluded.) The three highest annual mean concentrations are observed in  
23 Riverside, CA; Los Angeles-Long Beach, CA; and Salt Lake City, UT; and the lowest  
24 (excluding Gary) were observed in Portland, OR. For the remaining MSAs, there does not  
25 appear to be a significant geographical trend associated with the annual mean  $PM_{10-2.5}$   
26 concentration. Within MSAs, the lowest concentrations are frequently observed at sites near the  
27 perimeter of the MSA although it must be noted that the number of sites is limited.

28 Within each MSA, collocated  $PM_{2.5}$  and  $PM_{10-2.5}$  concentrations, averaged over the same  
29 years, were compared. The mean  $PM_{2.5}:PM_{10-2.5}$  ratio was calculated for each of the 17 MSAs  
30 using as many sites as possible. The median mean  $PM_{2.5}:PM_{10-2.5}$  ratio for the 17 MSAs was 1.2.  
31 For eight MSAs (Columbia, SC; Chicago, IL; Louisville, KY; Gary, IN; Tampa, FL;

Source: AIRS Database.

1 Steubenville, WV; Portland, OR; Milwaukee, WI) the mean  $PM_{2.5}$  concentration exceeded the  
 2 mean  $PM_{10-2.5}$  concentration. For an additional eight MSAs, the  $PM_{2.5}$  and  $PM_{10-2.5}$  concentration  
 3 means were the same (within one SD). Salt Lake City was the only MSA for which the mean  
 4  $PM_{10-2.5}$  concentration exceeded the mean  $PM_{2.5}$  concentration.

5 Information regarding the seasonal variability in  $PM_{10-2.5}$  concentrations in three MSAs  
 6 (Cleveland, OH; Dallas, TX; Los Angeles-Long Beach, CA) is summarized in Figures 3-9a  
 7 through 3-9c. The figures show lowest, lower quartile, median, upper quartile, and highest  
 8 concentrations for each calendar quarter of 2000 and 2001 for the Cleveland, OH MSA (six

1 sites); and of 2001 for the Dallas, TX and Los Angeles, CA MSAs (four sites each). Data for  
2 these and an additional 13 MSAs, as well as additional descriptions of the data, are given in  
3 Appendix 3A. The seasonal pattern for  $PM_{10-2.5}$  median concentrations is different from that of  
4  $PM_{2.5}$  (Figures 3-7a,b,c,d, and Appendix 3A). Most seasonal median maxima in  $PM_{10-2.5}$  occur  
5 during the second or third calendar quarters, i.e., spring and summer months (45% and 36% of  
6 all sites, respectively) as seen, for example, at most sites in Figures 3-9. Contributions from  
7 bioaerosols during the spring blooming season, which mostly affect  $PM_{10-2.5}$  concentrations,  
8 might be a significant contributing factor in the second quarter  $PM_{10-2.5}$  median maxima in some  
9 regions of the United States. Lowest median concentrations occur mainly in the first or fourth  
10 quarters (62% and 23% of all sites, respectively). Cleveland, OH, (Figure 3-9a) and Tampa, FL,  
11 where lowest medians generally are observed in the third quarter are exceptions (Figure 3A-29).  
12 At no site was the lowest median  $PM_{10-2.5}$  concentration observed in the second quarter. By  
13 comparison with  $PM_{10-2.5}$ , seasonal  $PM_{2.5}$  median maxima mostly occurred in the first or third  
14 quarters and  $PM_{2.5}$  median minima are mostly observed in the second and fourth quarters. With  
15 few exceptions, collocated  $PM_{2.5}$  and  $PM_{10-2.5}$  seasonal medians at individual sites peak in  
16 different quarters. Likewise, at a given site, the lowest median concentrations for  $PM_{2.5}$  and  
17  $PM_{10-2.5}$  rarely occur in the same quarter. In MSAs with several  $PM_{10-2.5}$  sites, the seasonal  
18 patterns are typically reproduced at all sites within the MSA. In the Dallas, TX MSA, the  
19 maximum and minimum estimated  $PM_{10-2.5}$  concentrations both occur in the first quarter at all  
20 four sites.

21 The ratio of  $PM_{2.5}/PM_{10-2.5}$  seasonal median concentrations peak in the first quarter for  
22 MSAs in the central and north-central United States and tend to peak in the fourth quarter for  
23 western states. The largest ratios of  $PM_{2.5}/PM_{10-2.5}$  seasonal median concentrations are observed  
24 in the central and north-central MSAs (Chicago, Cleveland, Detroit, and St. Louis); whereas  
25 smaller ratios are found in the western and southern United States.

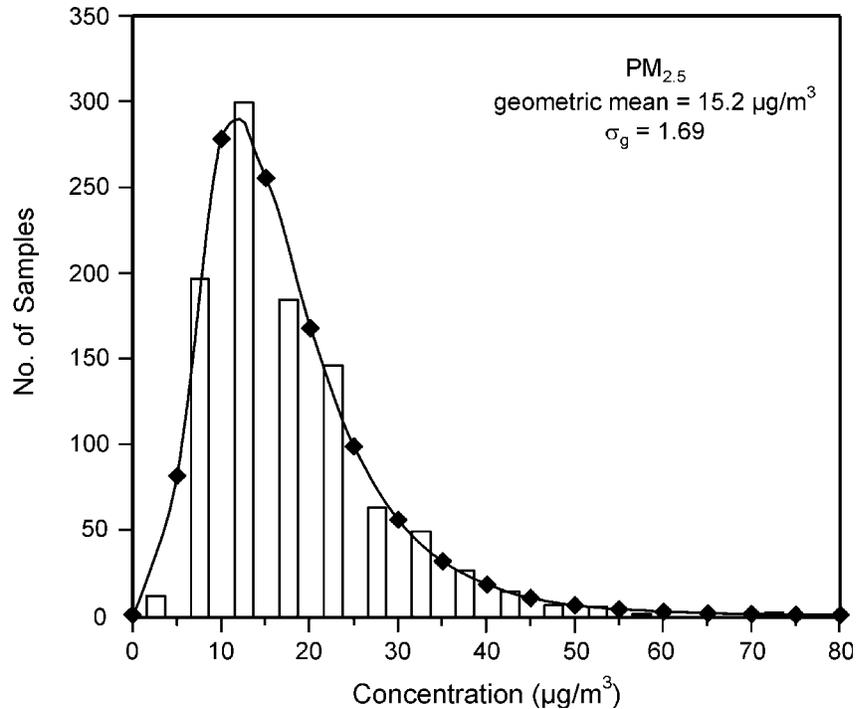

26 As can be seen from Figure 3-9a and Figures 3A-40 and 3A-43, the maxima for  $PM_{10-2.5}$   
27 concentrations exceeded  $100 \mu\text{g}/\text{m}^3$  in Cleveland, OH, and Salt Lake City, UT, and  $500 \mu\text{g}/\text{m}^3$  in  
28 Riverside, CA. This latter value is related to a dust storm. In several urban areas (Cleveland,  
29 OH; Detroit, MI; Chicago, IL; Dallas, TX; and Riverside, CA) maxima in  $PM_{10-2.5}$  concentrations  
30 were larger than those for  $PM_{2.5}$ . However, there is no clear geographic pattern.

1 The results described above should be viewed with caution because of inherently large  
2 errors in the technique used to derive them.

### 3 4 ***Frequency Distributions for PM<sub>2.5</sub> Data***

5 Frequency distributions for PM<sub>2.5</sub> concentrations obtained in Philadelphia from 1992  
6 through 1995 are shown in Figure 3-10 (data obtained by Bahadori et al., 2000b). Also shown,  
7 are concentrations predicted from the log-normal distribution, using geometric mean values and  
8 standard deviations derived from the data. In Philadelphia, the highest PM<sub>2.5</sub> values were  
9 observed when winds were from the southwest during sunny but hazy high pressure conditions.  
10 In contrast, the lowest values were found after significant rainstorms during all seasons of the  
11 year. Mean ± SD day-to-day concentration differences in the data set are  $6.8 \pm 6.5 \mu\text{g}/\text{m}^3$  for  
12 PM<sub>2.5</sub> and  $8.6 \pm 7.5 \mu\text{g}/\text{m}^3$  for PM<sub>10</sub>. Maximum day-to-day concentration differences are  
13  $54.7 \mu\text{g}/\text{m}^3$  for PM<sub>2.5</sub> and  $50.4 \mu\text{g}/\text{m}^3$  for PM<sub>10</sub>.

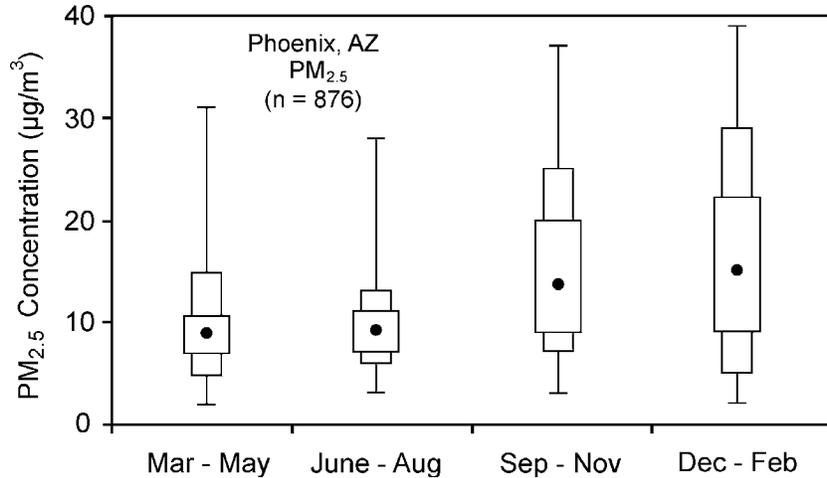

14 Different patterns are observed in data collected elsewhere in the United States. PM<sub>2.5</sub>  
15 concentrations obtained in Phoenix, AZ, from 1995 through 1997 (Zweidinger et al., 1998) are  
16 summarized in Figure 3-11; and frequency distributions of PM<sub>2.5</sub> concentrations obtained in  
17 Phoenix are shown in Figure 3-12. Mean ±SD day-to-day concentration differences in this data  
18 set are  $2.9 \pm 3.0 \mu\text{g}/\text{m}^3$ ; the maximum day-to-day concentration difference was  $23 \mu\text{g}/\text{m}^3$ . PM<sub>2.5</sub>  
19 and PM<sub>10-2.5</sub> data were obtained with dichotomous samplers at a number of sites in California on  
20 a sampling schedule of every 6 days from 1989 through 1998. Histograms showing the  
21 frequency distribution of the entire set of PM<sub>2.5</sub> and PM<sub>10-2.5</sub> concentrations obtained by the  
22 CARB network of dichotomous samplers from 1989 to 1998 are shown in Figures 3-13 and  
23 3-14. Also shown are log-normal distributions generated by using geometric means and  
24 standard deviations derived from the data as input. Although the data for both size fractions  
25 appear to be reasonably well simulated by the function, data obtained at individual locations may  
26 not be. Data showing the seasonal variability of PM<sub>2.5</sub> obtained at Riverside-Rubidoux are  
27 summarized in box plot form in Figure 3-15. The frequency distribution of PM<sub>2.5</sub> concentrations  
28 obtained at Riverside-Rubidoux from 1989 to 1994 is shown in Figure 3-16. It can be seen that  
29 the data are not as well fit by a log-normal distribution as are data shown in Figure 3-10, partly  
30 as the result of a significant number of days when PM<sub>2.5</sub> concentrations exceed  $100 \mu\text{g}/\text{m}^3$ .

**Figure 3-10. Frequency distribution of 24-h average PM<sub>2.5</sub> concentrations measured at the Presbyterian home (PBY) monitoring site in southwestern Philadelphia from 1992 to 1995. Log-normal distribution fit to the data shown as solid line.**

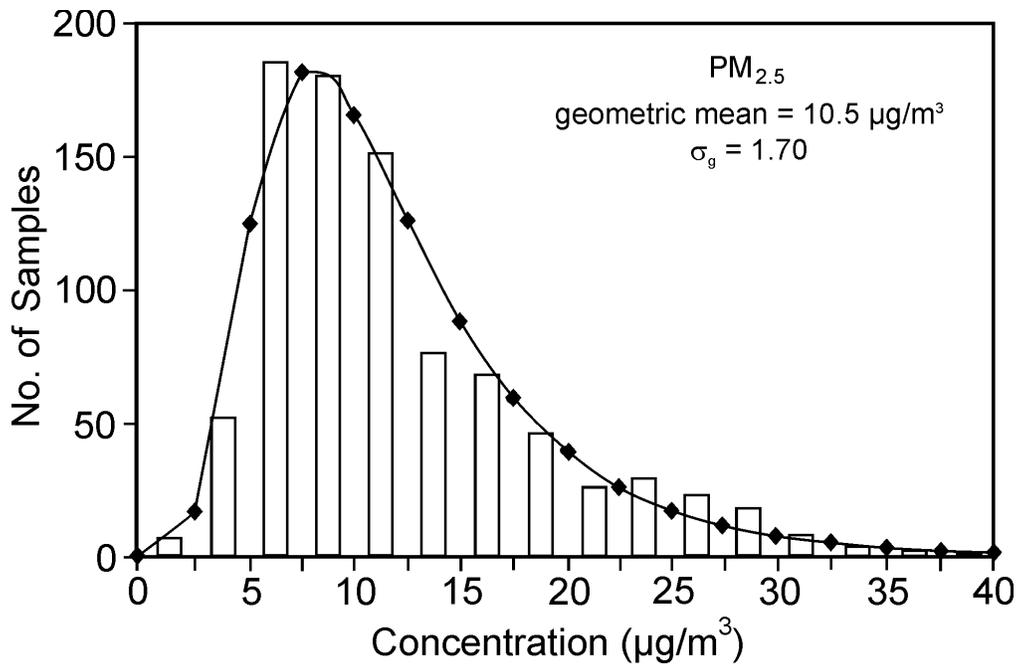

Source: Bahadori et al. (2000b).

1 An examination of the data from the four MAACS cities, Phoenix, AZ, and Riverside, CA,  
 2 indicates that substantial differences exist in aerosol properties between the eastern cities  
 3 (MAACS) and the western cities (Phoenix, AZ; Riverside, CA). Fine-mode particles account for  
 4 most of the PM<sub>10</sub> mass observed in the MAACS cities and appear to drive the daily and seasonal  
 5 variability in PM<sub>10</sub> concentrations in the East; whereas coarse-mode particles represent a larger  
 6 fraction of PM<sub>10</sub> mass in Phoenix and Riverside and drive the seasonal variability in PM<sub>10</sub> seen in  
 7 the West. The average ratio of PM<sub>2.5</sub> to PM<sub>10</sub> concentrations is much larger in the MAACS cities  
 8 of Philadelphia, PA (0.72); Washington, DC (0.74); and Nashville, TN (0.63) than in either  
 9 Phoenix, AZ (0.34) or Riverside, CA (0.49). Differences between median and maximum  
 10 concentrations in any size fraction are much larger at the Riverside site than at either the  
 11 MAACS or Phoenix sites. Many of these differences could reflect the more sporadic nature of

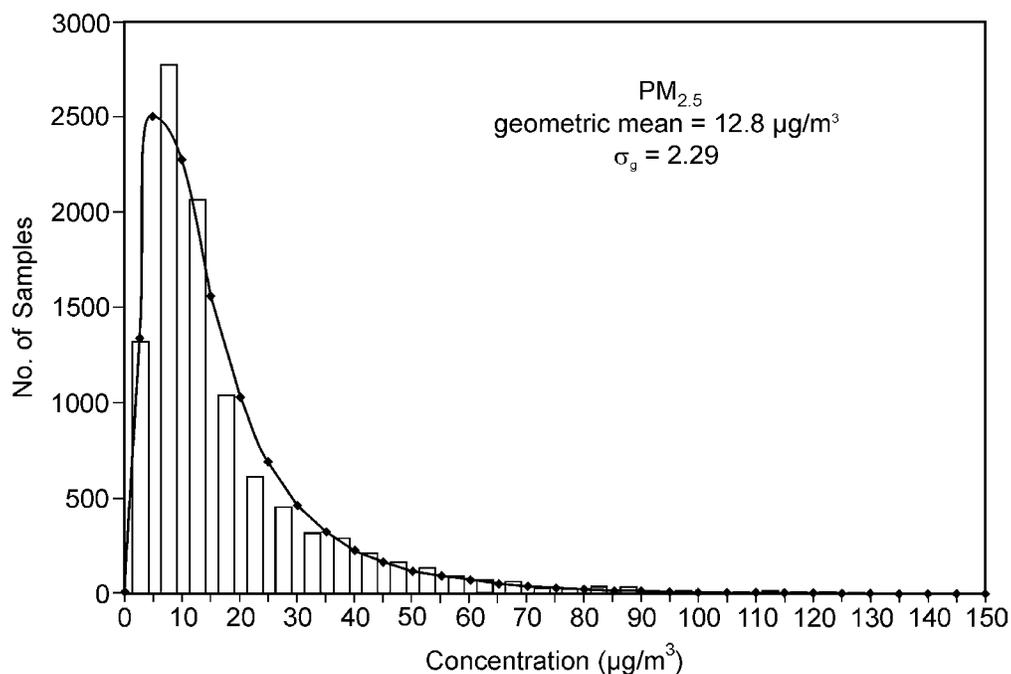

**Figure 3-11. Concentrations of 24-h average PM<sub>2.5</sub> measured at the EPA site in Phoenix, AZ from 1995 to 1997. The data show the lowest, lowest tenth percentile, lowest quartile, median (black circles), highest quartile, highest tenth percentile, and highest PM<sub>2.5</sub> values.**

1 dust suspension at Riverside. In addition, the seasonal variability of  $PM_{2.5}$  concentrations  
2 observed in Phoenix and Riverside appears to be different from that observed in the MAACS  
3 cities. These considerations demonstrate the hazards in extrapolating conclusions about the  
4 nature of variability in aerosol characteristics inferred at one location to another.  
5

### 6 **3.2.2 Diurnal (Circadian) Variability in PM Concentrations**

7 The variability of PM concentrations on time scales shorter than a day can, in principle, be  
8 characterized by measurements made by continuous samplers (e.g, TEOMs and  $\beta$ -gauge  
9 monitors that are currently used to provide Air Quality Index [AQI] information to the public).  
10 A description of these methods was provided in Section 2.2.9. However, as shown in Chapter 2,  
11 continuous methods are subject to artifacts in large part because of the heating of their inlets to  
12 remove water, which results in the loss of components such as ammonium nitrate and  
13 semivolatile organic compounds (Sections 2.2.2.1 and 2.2.3 for further details concerning the  
14 chemistry of volatilizable components). Consequently, caution should be used in interpreting  
15 results obtained by these techniques. It should be remembered that the Federal Reference  
16 Methods (FRMs) are also subject to artifacts; therefore, caution should also be exercised in  
17 interpreting results obtained by them.

18 The composite diurnal variation of  $PM_{2.5}$  concentrations obtained throughout the  
19 continental United States by 31 TEOM and  $\beta$ -gauge monitors reporting to AIRS in 1999 is  
20 shown in Figure 3-17. As can be seen, there is a distinct pattern with maxima occurring during  
21 the morning and evening. Notable exceptions to this pattern occur in California where broad  
22 nighttime maxima and daytime minima occur which may be related to the use of  $\beta$ -gauges with  
23 unheated inlets there. It should be noted in examining the diurnal variations shown in  
24 Figure 3-17 that there is substantial day-to-day variability in the diurnal profile of  $PM_{2.5}$   
25 measured at the same location that is smoothed out after a suitably long averaging period is  
26 chosen. The large ratio of the interquartile range to the median values supports the view that  
27 there is substantial variability in the diurnal profiles.

28 The diurnal variability of PM components is determined by interactions between variations  
29 in emissions, the rates of photochemical transformations, and the vertical extent and intensity of  
30 turbulent mixing near the surface. Wilson and Stockburger (1990) characterized the diurnal  
31 variability of sulfate and lead in Philadelphia. At that time, Pb was emitted mainly by motor

**Figure 3-17. Intraday variability of hourly average PM<sub>2.5</sub> concentrations across the United States. Interquartile ranges, median and mean (+) values are shown. Values above the box plots refer to the number of observations during 1999.**

Source: Fitz-Simons et al. (2000).

1 vehicles. Pollutants emitted mainly by motor vehicles, such as carbon monoxide, show two  
 2 distinct peaks occurring during the morning and evening rush hours (see Chapter 3, U.S.  
 3 Environmental Protection Agency, 2000b). Pollutants, such as sulfate, which are transported  
 4 long distances in the free troposphere (i.e., above the planetary boundary layer), tend to be mixed  
 5 downward and have their highest concentrations during the afternoon when the intensity and  
 6 vertical extent of turbulent mixing (and chemical oxidation) are greatest. Secondary aerosol  
 7 components (such as secondary organic compounds) that are produced by photochemical  
 8 reactions may have a daily maximum in the afternoon, similar to ozone. PM produced by  
 9 residential heating (e.g., from wood burning), on the other hand, reach maximum levels during  
 10 the night when mixing heights are much lower than during the day.

11 Although the interquartile ranges for hour-to-hour changes in PM<sub>2.5</sub> concentrations shown  
 12 in Figure 3-17 encompass several µg/m<sup>3</sup>, extreme values for the hour-to-hour variations can be  
 13 much larger (Fitz-Simons et al., 2000). The 98<sup>th</sup> percentile values for positive and negative

1 excursions in concentration are all less than  $20 \mu\text{g}/\text{m}^3$ . Maximum positive excursions were much  
2 larger, ranging from  $27 \mu\text{g}/\text{m}^3$  in the Northeast up to  $220 \mu\text{g}/\text{m}^3$  in the Southwest and with  
3 maximum excursions in other regions all less than  $125 \mu\text{g}/\text{m}^3$ . It should be borne in mind that  
4 the hour-to-hour changes that are reported reflect the effects of a number of processes occurring  
5 during passage through the sampler inlets and on the TEOM measurement elements. These  
6 factors add uncertainty to the interpretation of the hour-to-hour changes that are observed, as  
7 discussed in Chapter 2. However, because of the tendency of these monitoring instruments to  
8 lose material by evaporation, the concentrations reported during excursions probably represent  
9 lower limits to the true values that were present.

### 11 **3.2.3 Relations Among Particulate Matter in Different Size Fractions**

#### 12 *Relations Among $PM_{2.5}$ , $PM_{10-2.5}$ , and $PM_{10}$*

13 Data obtained in 1999 by collocated  $PM_{2.5}$  and  $PM_{10}$  FRM monitors have been used to  
14 calculate the ratio of  $PM_{2.5}$  to  $PM_{10}$  concentrations and correlations among  $PM_{2.5}$ ,  $PM_{10-2.5}$ , and  
15  $PM_{10}$  concentrations. Results are shown in Table 3-1 for each of the seven aerosol characteristic  
16 regions identified in Chapter 6 of the 1996 PM AQCD. As can be seen from the table, the ratio  
17 of  $PM_{2.5}$  to  $PM_{10}$  concentrations tends to be higher in the eastern United States than in the  
18 western United States. This general pattern and the values are consistent with that found for the  
19 studies included in Appendix 6A of 1996 PM AQCD. In that compilation based on the results of  
20 studies using dichotomous samplers, the mean ratio of  $PM_{2.5}$  to  $PM_{10}$  was 0.75 in the East,  
21 0.52 in the central United States, and 0.53 in the western United States. Although a large  
22 number of paired entries have been included in Table 3-1, seasonal variations and annual  
23 averages in a number of regions could not be determined from the data set because of data  
24 sparseness mainly during the early part of 1999. It also can be seen in Table 3-1 that the ratio of  
25  $PM_{2.5}$  to  $PM_{10}$  was greater than one for a few hundred measurements. There are a number of  
26 reasons for these results, as mentioned in Section 3.2.1 in the discussion on  $PM_{10-2.5}$   
27 concentrations.

#### 29 *Ultrafine Particle Concentrations*

30 Data for characterizing the concentrations of ultrafine particles ( $< 0.10 \mu\text{m } D_a$ ) and the  
31 relations between ultrafine particles and larger particles are sparse. Although ultrafine particles

**TABLE 3-1. DISTRIBUTION OF RATIOS OF PM<sub>2.5</sub> TO PM<sub>10</sub> AND CORRELATIONS BETWEEN PM<sub>2.5</sub> AND PM<sub>10</sub>, PM<sub>2.5</sub> AND PM<sub>10-2.5</sub>, AND PM<sub>10-2.5</sub> AND PM<sub>10</sub> FOUND AT COLLOCATED MONITORING SITES IN SEVEN AEROSOL CHARACTERISTIC (EPA/HEI) REGIONS IN 1999**

1 dominate particle number concentrations, they make very minor contributions to  $PM_{2.5}$  mass.  
2 For example, Cass et al. (2000) found that particles between 0.056 and 0.1  $\mu m D_a$  contributed  
3 only 0.55 - 1.16  $\mu g/m^3$  at several sites in southern California. Perhaps the most extensive data  
4 set for ultrafine particle properties is that described by Woo et al. (2001) for a site located 10 km  
5 to the northwest of downtown Atlanta, GA. Size distributions from 3 to 2000 nm were measured  
6 every 12 minutes for 24 months beginning in August 1998. Approximately 89% of the total  
7 number of particles were found to be smaller than 100 nm; whereas 26% were found to be  
8 smaller than 10 nm. Concentrations tend to be lower during the summer than during the winter.  
9 No correlation was found between number concentration and either volume or surface area for  
10 particle sizes up to 2  $\mu m$ . Because the total number of particles is concentrated in the smallest  
11 size ranges, these results also indicate that fine particle mass does not correlate with the number  
12 of ultrafine particles. The high time resolution of the measurements allows some inferences to  
13 be made about the possible sources of the ultrafine particles. The number of particles larger than  
14 10 nm tends to peak during the morning rush hour (around 8 am) and then to decrease through  
15 the day and to increase again after 6 pm, consistent with a traffic-related source. Particles  
16 smaller than 10 nm tend to peak during the mid-afternoon, consistent with nucleation involving  
17 products of active photochemistry (McMurry et al., 2000). More direct relations between  
18 particle mass observed in different size ranges can be obtained using multi-stage impactors.  
19 Keywood et al. (1999) found a correlation between  $PM_{2.5}$  and  $PM_{0.15}$  of about 0.7; whereas they  
20 found correlations of about 0.96 between  $PM_1$  and  $PM_{2.5}$  and between  $PM_{2.5}$  and  $PM_{10}$  based on  
21 samples collected by MOUDIs (Multiple Orifice Uniform Deposit Impactors) in six Australian  
22 cities.

### 23 24 **3.2.4 Relations Between Mass and Chemical Component Concentrations**

25 Time series of elemental composition data for  $PM_{2.5}$  based on X-ray fluorescence (XRF)  
26 analyses have been obtained at a number of locations across the United States. Time series of  
27 components of the organic carbon fraction of the aerosol have not yet been obtained. The results  
28 of XRF analyses for the composition of the inorganic fraction of  $PM_{2.5}$  and  $PM_{10-2.5}$  are presented  
29 in Table 3-2 for Philadelphia, PA, and in Table 3-3 for Phoenix, AZ. Frequency distribution for  
30  $PM_{2.5}$  concentration data collected at these sites were shown in Figures 3-10 and 3-11. All XRF  
31 analyses were performed at the same X-ray spectrometry facility operated by the U.S.

Source: Calculations based on data obtained by Zweidinger et al. (1998).

1 Environmental Protection Agency in Research Triangle Park, NC. Data shown in the first  
 2 column of Table 3-2 are based on analyses of filters collected over three years (April 1992 to  
 3 April 1995, labeled a) at the PBY site in southwestern Philadelphia. These data and data for

1 PM<sub>10</sub> were collected using Harvard impactors. Data for PM<sub>2.5</sub> and PM<sub>10-2.5</sub> shown in the second  
2 and third columns were collected at the Castor Avenue Laboratory operated by the City of  
3 Philadelphia from July 25 to August 14, 1994, using a modified dichotomous sampler (VAPS).  
4 The samples at the Phoenix site were collected in 1996 and 1997 using the same type of  
5 dichotomous sampler used in the shorter term study in Philadelphia. These data are shown to  
6 give an idea of the range of concentrations found in studies conducted more recently than those  
7 shown in Appendix 6A of the 1996 PM AQCD. The speciation network will at least provide  
8 more thorough coverage of the composition of particles in the PM<sub>2.5</sub> size range across the  
9 United States. Results from the pilot study for the speciation network are given in Appendix 3B.

10 As can be seen from inspection of Tables 3-2 and 3-3, the analytical uncertainty (given in  
11 parentheses next to concentrations) as a fraction of the absolute concentration is highly variable.  
12 It exceeds the concentration for a number of trace metals whose absolute concentrations are low;  
13 whereas it is very small for abundant elements such as sulfur.

14 Sulfur is the major element analyzed in the PM<sub>2.5</sub> size fraction in the two Philadelphia  
15 studies and is highly correlated with PM<sub>2.5</sub>; however its abundance is roughly two orders of  
16 magnitude lower in the PM<sub>10-2.5</sub> size range and is negatively correlated with PM<sub>10-2.5</sub>.  
17 Concentrations of the crustal elements Al, Si, K, Ca, and Fe are much higher in the PM<sub>10-2.5</sub> size  
18 range than in the PM<sub>2.5</sub> size range and are well correlated with PM<sub>10-2.5</sub>. A number of trace  
19 elements (e.g., Cr, Co, Ni, Cu, Zn, As, Se and Pb) are detectable in the two PM<sub>2.5</sub> data sets, and  
20 the concentrations of many of these elements are much greater than the uncertainty in their  
21 determination. Except for Co, As, and Se which are not detected in the PM<sub>10-2.5</sub> samples, the  
22 concentrations of many elements (Cr, Zn, and Pb) are comparable in the PM<sub>2.5</sub> and PM<sub>10-2.5</sub> size  
23 ranges. The concentration of Cu is significantly higher in the PM<sub>10-2.5</sub> size range, whereas the  
24 concentration of Ni is smaller in the PM<sub>10-2.5</sub> size range than in the PM<sub>2.5</sub> size range.

25 There are a number of distinct differences between the PM<sub>2.5</sub> sets for Philadelphia and  
26 Phoenix. For instance, sulfate and associated cations and water that would be expected to  
27 correspond to the measurement of S appear to constitute a major fraction of the composition of  
28 the PM in the Philadelphia data set; whereas they appear to constitute a much smaller fraction of  
29 the PM in the Phoenix data set. The highest PM<sub>2.5</sub> values were observed in Philadelphia during  
30 episodes driven by high sulfate abundances; whereas those in Phoenix were driven by raised soil  
31 dust. The concentration of S in Phoenix is much lower in the Phoenix PM<sub>2.5</sub> data set than in

1 either Philadelphia  $PM_{2.5}$  data set, even though it represents the most abundant element and it is  
2 only weakly correlated with  $PM_{2.5}$ . This is in marked contrast to the data shown for Philadelphia  
3 and also to data found at other eastern sites. It is not clear what the reasons are for this finding.  
4 As in Philadelphia, the concentration of S in Phoenix is higher in the  $PM_{2.5}$  size range than in the  
5  $PM_{10-2.5}$  size range. Trace metals (e.g., Cr, Co, Ni, Cu, Zn, As, and Pb) are not well correlated  
6 ( $0.04 < r < 0.25$ ) with  $PM_{2.5}$  in the Philadelphia data set; whereas they are more variably  
7 correlated ( $0.01 < r < 0.69$ ) with  $PM_{2.5}$  in the Phoenix data set. The uncertainty in the  
8 concentration measurement most probably plays a role in determining a species' correlation with  
9  $PM_{2.5}$  especially when the analytical uncertainty is high relative to concentration as it is for a  
10 number of elements in the data shown in Tables 3-2 and 3-3. Concentrations of Al, Si, K, Ca,  
11 and Fe are again much higher in the  $PM_{10-2.5}$  size range than in the  $PM_{2.5}$  size range and are  
12 strongly correlated with  $PM_{10-2.5}$  in both data sets.

13 There are also similarities in the  $PM_{2.5}$  data sets for Philadelphia and Phoenix. Crustal  
14 elements are not as well correlated with  $PM_{2.5}$  as they are with  $PM_{10-2.5}$  in both data sets. The  
15 concentrations of trace metals (Cr, Ni, Cu, and Zn) in  $PM_{2.5}$  are similar in Philadelphia and  
16 Phoenix. It can also be seen that their concentrations are of the same order of magnitude in both  
17  $PM_{2.5}$  and  $PM_{10-2.5}$ . Concentrations of Cu are noticeably higher in  $PM_{10-2.5}$  than in  $PM_{2.5}$  in both  
18 Philadelphia and Phoenix. These results are consistent with those of many monitoring studies  
19 shown in Appendix 6A of the 1996 PM AQCD, which also show that concentrations of these  
20 metals are of the same order of magnitude in both size fractions and that concentrations of Cu  
21 tend to be higher in  $PM_{10-2.5}$  than in  $PM_{2.5}$ .

22 One study suggests that the partitioning of trace metals between the fine and coarse  
23 fractions varies with PM concentration. Salma et al. (2002) determined the size distribution of a  
24 number of trace elements at four sites characterizing environments ranging from the urban  
25 background to an urban traffic tunnel in Budapest, Hungary. S, K, V, Ni, Cu, Zn, As, and Pb  
26 were found mainly in the fine fraction at the urban background site; but their mass median  
27 aerodynamic diameters increased with increasing PM concentrations until they were all found  
28 mainly in the coarse fraction in the traffic tunnel. They also found that Na, Mg, Al, Si, P, Ca, Ti,  
29 Fe, Ga, Sr, Zr, Mo, and Ba were concentrated mainly in the coarse fraction at all four sites and  
30 that their mass median aerodynamic diameters increased with increasing PM concentrations.

1           The mean concentration of Pb observed in the methods evaluation study for the speciation  
2 network was only about 5 ng/m<sup>3</sup> in Philadelphia during the first half of 2000 (Appendix 3B);  
3 whereas its concentration was about three times higher during the studies conducted during the  
4 early 1990s (Table 3-3). In a study conducted in the greater Philadelphia area during the  
5 summer of 1982, Dzubay et al. (1988) found concentrations of Pb of about 250 ng/m<sup>3</sup>, or about  
6 fifty times higher than observed in 2000. The mean Pb concentration was about 3 ng/m<sup>3</sup> at the  
7 Phoenix site included as part of the same methods evaluation study for the speciation network;  
8 however, the mean Pb concentration was 39 ng/m<sup>3</sup> during an earlier study conducted during  
9 1989 and 1990 in Phoenix (Chow et al., 1991). These changes in Pb concentrations are  
10 consistent with those in many other urban areas for which monitoring studies have been  
11 conducted during the late 1970s and 1980s (cf., Appendix 6A of the 1996 PM AQCD) and for  
12 which there are data given in Appendix 3B. It should be remembered that the older studies were  
13 conducted while Pb was still used as a gasoline additive. The ratio of Pb in PM<sub>2.5</sub> to Pb in  
14 PM<sub>10-2.5</sub> was also much higher in the older studies than in the more recent ones, reflecting the  
15 importance of combustion as its source. Smaller decreases are apparent in the concentrations of  
16 other trace metals such as Cu, Ni, and Zn between studies conducted in the early 1980s and in  
17 the methods evaluation study for the speciation network conducted in 2000.

18           Some indication of the sources of metals such as Pb, Cu, Cd, and Zn in current, ambient  
19 PM<sub>2.5</sub> and PM<sub>10-2.5</sub> samples can be obtained by examining their sources in urban runoff. The  
20 sources of these elements in urban runoff were found to be the weathering of building surfaces,  
21 motor vehicle brake and tire wear, engine oil and lubricant leakage and combustion, and wet and  
22 dry atmospheric deposition (Davis et al., 2001). Once deposited on the ground, these elements  
23 can be resuspended with other material as PM<sub>2.5</sub> and PM<sub>10-2.5</sub> although research is needed into the  
24 mechanisms of how this is accomplished. Wind-abrasion on building siding and roofs (coatings  
25 such as Pb paint and building material such as brick, metal, and wood siding); brake wear (brake  
26 pads contain significant quantities of Cu and Zn); tire wear (Zn is used as a filler in tire  
27 production); and burning engine oil could all produce particles containing these metals,  
28 especially Zn.

29           Data for the chemical composition of ambient ultrafine particles are sparse. In a study  
30 conducted at several urban sites in Southern California, Cass et al. (2000) found that the  
31 composition of ultrafine particles ranged from 32 to 67% organic compounds, 3.5 to 17.5%

1 elemental carbon, 1 to 18% sulfate, 0 to 19% nitrate, 0 to 9% ammonium, 1 to 26% metal oxides,  
2 0 to 2% sodium, and 0 to 2% chloride. Thus carbon, in various forms, was found to be the major  
3 contributor to the mass of ultrafine particles. However, ammonium was found to contribute 33%  
4 of the mass of ultrafine particles at one site in Riverside. Iron was the most abundant metal  
5 found in the ultrafine particles. Chung et al. (2001) found that carbon was the major component  
6 of the mass of ultrafine particles in a study conducted during January of 1999 in Bakersfield,  
7 CA. However, in the study of Chung et al., the contribution of carbonaceous species (OC and  
8 EC; typically 20 to 30%) was much lower than that found in the cities in Southern California.  
9 They found that calcium was the dominant cation, accounting for about 20% of the mass of  
10 ultrafine particles in their samples. Sizable contributions from silicon (0 to 4%) and aluminum  
11 (6 to 14%) were also found. Further studies, including scanning electron microscopy, may be  
12 needed to quantify the role of coarse particle bounce from the upper stages of their MOUDI  
13 impactor.

14         Gone et al. (2000) measured the size distribution of trace elements from 0.056  $\mu\text{m}$  to  
15 1.8  $\mu\text{m}$   $D_a$  in Pasadena, CA, and in the Great Smoky Mountains National Park, TN. They found  
16 that elements identified as being of anthropogenic origin had mass median diameters below  
17 1  $\mu\text{m}$  PM; whereas elements of crustal origin generally had a mass median diameter greater than  
18 1  $\mu\text{m}$ . Concentrations of trace metals were much higher in the accumulation mode than in the  
19 ultrafine mode in both study areas. In  $\text{PM}_{10}$ , 76% of Cr, 95% of Fe, 94% of Zn, 89% of As, and  
20 79% of Cd at the Tennessee site were found in the accumulation mode; and 70% of Fe, 85% of  
21 Zn, 92% of As, and 84% of Cd were found in the accumulation mode in Pasadena. Fe was the  
22 most abundant metal found in the ultrafine particles. The abundance of crustal elements, such as  
23 Al, declined rapidly with decreasing particle size at both locations; and Al in  $\text{PM}_{10}$  probably  
24 represented the lower tail of the coarse PM mode. However, on two days at Pasadena there were  
25 increases in the concentration of Al in ultrafine particles that were associated with increases in  
26 Sc and Sm. The latter two elements originate exclusively from crustal material (Gone et al.,  
27 2000).

### 3.2.5 Spatial Variability in Particulate Matter and its Components

#### *PM<sub>2.5</sub>*

Aspects of the spatial variability of  $PM_{2.5}$  concentrations on the urban scale are examined in this section. Intersite correlation coefficients for  $PM_{2.5}$  can be calculated based on the results of FRM monitors placed at multiple sites within Metropolitan Statistical Areas (MSAs) across the United States. Pearson correlation coefficients ( $r$ ) calculated for pairs of monitoring sites in the Philadelphia, PA; Cleveland, OH; Dallas, TX; and Los Angeles, CA MSAs are shown in Table 3-4. The 90<sup>th</sup> percentile value,  $P_{90}$ , of the absolute differences (in  $\mu\text{g}/\text{m}^3$ ) between the two sites is shown in parentheses below  $r$  along with the coefficient of divergence (COD), and the number of observations used in the calculation of  $r$ ,  $P_{90}$  and COD is given on the third line. The COD was used by Wongphatarakul et al. (1998) as a measure of the degree of similarity between aerosol data sets<sup>1</sup>. The annual mean concentrations, the number of observations used to calculate the annual average, and the standard deviation are shown directly beneath the correlation tables for each site. These analyses and those for another 23 MSAs are given along with maps in Appendix 3A. As the concentrations of  $PM_{2.5}$  at two sampling sites become more alike, the COD approaches zero; as the concentrations diverge, the COD approaches one.

The four MSAs shown in Table 3-4 were chosen to illustrate different patterns of spatial variability across the United States. In addition, air-pollution health-outcome studies have been performed in a few of these MSAs. It can be seen from inspection of Table 3-4 that correlation coefficients vary over a wide range in the MSAs shown. Correlations between sites in the Philadelphia, PA; Cleveland OH; and Dallas, TX MSAs are all high and span a relatively narrow range (0.82 to 0.97). However, correlations between sites in the Los Angeles-Long Beach MSA are lower than in the three other MSAs and span a wider range of values (0.60 to 0.95). If the monitoring site in Lancaster, CA, were included, correlations would be even lower. This site was omitted because it did not meet completeness criteria for 2001. The extension of these

---

<sup>1</sup>The COD for this purpose is defined as follows:

$$COD_{jk} = \sqrt{\frac{1}{P} \sum_{i=1}^p \left( \frac{x_{ij} - x_{ik}}{x_{ij} + x_{ik}} \right)^2} \quad (3-1)$$

where  $x_{ij}$  and  $x_{ik}$  represent the 24-h average  $PM_{2.5}$  concentration for day  $i$  at site  $j$  and site  $k$  and  $p$  is the number of observations.

1 analyses to include the relevant CMSAs (consolidated MSA) would also produce a number of  
2 sites that are even less well correlated with each other in part because sites are located outside of  
3 urban airsheds.

4 Correlation coefficients between pairs of sites in the other 23 MSAs given in Appendix 3A  
5 for the most part fall within the range of values given in Table 3-4. In four MSAs (Columbia,  
6 SC; Norfolk, VA; Grand Rapids, MI; and Baton Rouge, LA), intersite correlations are all greater  
7 than 0.9. In nine others (Cleveland, OH; Louisville, KY; Chicago, IL; Milwaukee, WI;  
8 Philadelphia, PA; Detroit, MI; Kansas City, KS-MO; Dallas, TX; and Salt Lake City, UT), they  
9 are all greater than 0.8. Correlations between sites in the other MSAs examined tend to be lower  
10 and span a broader range than for the MSAs mentioned above.

11 Seven pairs of collocated monitors in seven MSAs (Columbia, SC; Dallas, TX; Detroit,  
12 MI; Grand Rapids, MI; Louisville, KY; Steubenville, OH; Washington, DC) provide an  
13 indication of the performance of collocated monitors (see Table 3A-1). Mean values of r, P90,  
14 and COD for these seven pairs of monitors are 0.986, 1.63  $\mu\text{g}/\text{m}^3$ , and 0.060 suggesting that  
15 most of the intersite variability seen is not due to sampler imprecision.

16 There are no strong regional patterns evident in the data given in Appendix 3A except that  
17 correlations tend to be higher between monitoring sites in MSAs in the southeastern United  
18 States than between monitoring sites in other regions.

19 A number of factors affect intersite correlations within MSAs. These include field  
20 measurement and laboratory analysis errors, placement of monitors close to active sources,  
21 placement of monitors in outlying areas, placement of monitors in locations that are isolated  
22 topographically from other monitors, placement of monitors in areas outside of local  
23 atmospheric circulation regimes (e.g., land-sea breezes), and transient local events  
24 (thunderstorms, sporadic emissions). In several MSAs such as Atlanta, GA; Seattle, WA; and  
25 Los Angeles-Long Beach, CA, there is at least one site that is remote from the others (by at least  
26 100 km), is physically separated from them by mountains, and is really not part of the urban area  
27 nor the urban airshed. Correlations between concentrations at these sites and others tend to be  
28 lower than among the other sites, and concentration differences tend to be larger. It should be  
29 noted that outlying sites such as these are included in many epidemiologic time-series studies  
30 without any weighting (e.g., with respect to the exposed population, spatial differences in  
31 susceptibility) or regard to compositional differences. Although it is frequently the case that

1 distance between sites in urban areas is largely responsible for the spatial variability that is  
2 observed, there are a few instances for which correlations are higher and differences in  
3 concentrations lower for sites that are located farthest apart. This situation may arise because  
4 these sites are influenced more by the regional background of secondary PM rather than by local  
5 sources, nor is there any set distance below which correlations and differences in concentrations  
6 tend towards some limiting values. However, it is generally the case that outlying sites are  
7 characterized by lower annual mean concentrations.

8 Indications of land use (commercial, industrial, residential, agricultural, forest) and  
9 location of sites (urban/city center, suburban, rural) are given in the AIRS data base. Categories  
10 such as urban/city center can refer to very different conditions in Columbia, SC, and Chicago,  
11 IL. Also, it should not be automatically assumed that concentrations measured at sites  
12 categorized as industrial are dominated by local emissions. The PM<sub>2.5</sub> monitoring sites are  
13 generally deployed to capture potential population exposures in a variety of environments as  
14 opposed to monitoring for compliance as it exists around local sources. It should be  
15 remembered that much of PM<sub>2.5</sub> is secondary in origin. The widespread formation of secondary  
16 PM coupled with the long lifetime of PM<sub>2.5</sub> ensures some measure of uniformity in the  
17 correlations of PM<sub>2.5</sub> across urban areas. Correlations between many site pairs classified as  
18 industrial can be high even though they are separated by large distances, as in the Seattle MSA.

19 Some indication of the variability of primary PM<sub>2.5</sub> produced by local sources can be  
20 obtained by examining the variability of carbon monoxide (CO), which is produced mainly by  
21 mobile sources (U.S. Environmental Protection Agency, 2000b), and by the variability in  
22 elemental carbon (EC) concentrations (Kinney et al., 2000). CO is relatively inert on the urban  
23 scale, and its distribution is governed by the spatial pattern of its emissions and the subsequent  
24 dispersion of these emissions not by photochemistry. Carbon monoxide concentrations are at  
25 least a factor of three higher near urban centers than in surrounding rural areas within the four  
26 consolidated metropolitan statistical areas examined in the EPA document, Air Quality Criteria  
27 for Carbon Monoxide (CO AQCD; U.S. Environmental Protection Agency, 2000b).  
28 The correlations of CO within the urban areas examined in that document were all low to  
29 moderate. Therefore, it might be expected that primary PM<sub>2.5</sub> produced by local traffic should be  
30 at least as heterogeneous as CO in a given urban area. EC is a significant component of diesel  
31 exhaust (cf., Appendix 3D). Kinney et al. (2000) measured EC and PM<sub>2.5</sub> concentrations at four

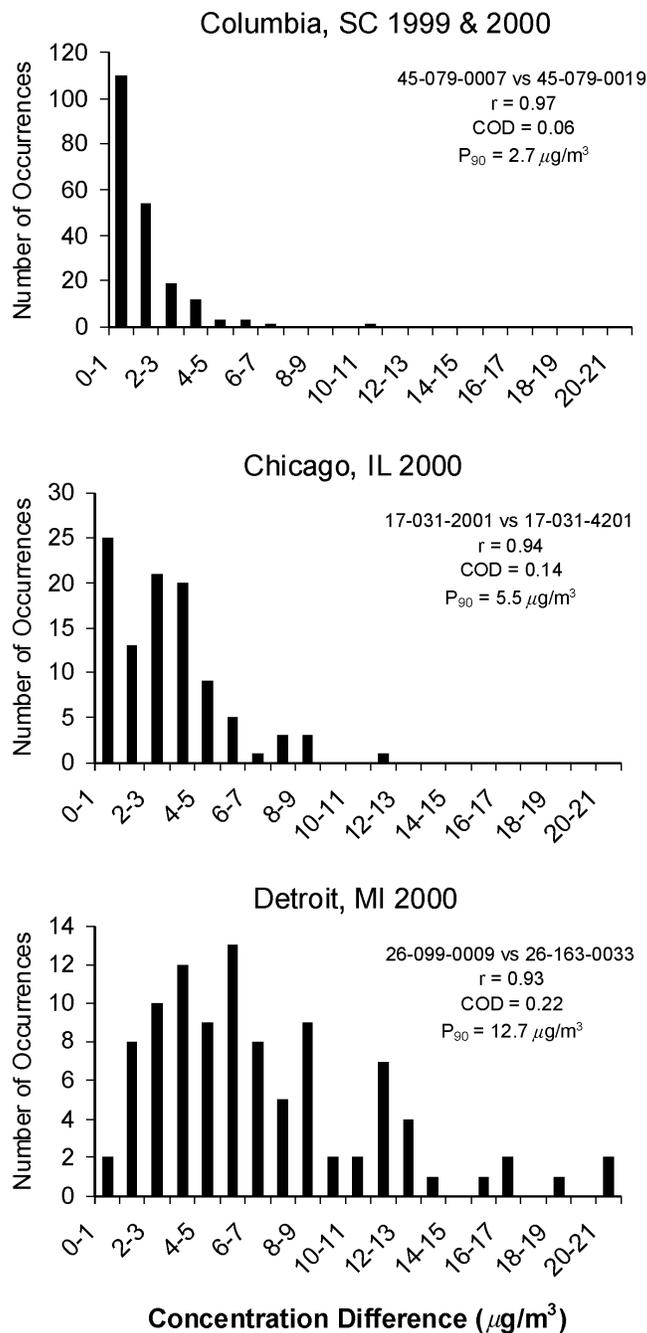

1 sites located on sidewalks of streets characterized by varying exposures to diesel emissions in  
2 upper Manhattan (Harlem, NY). Whereas the mean  $PM_{2.5}$  concentrations varied by about one-  
3 third from 37 to 47  $\mu\text{g}/\text{m}^3$  at the four sites, mean EC concentrations varied by a factor of four  
4 from 1.5 to 6.2  $\mu\text{g}/\text{m}^3$ . The corresponding ratios of EC to  $PM_{2.5}$  ranged from 0.039 to 0.14.  
5 Although EC constituted a relatively small fraction of  $PM_{2.5}$  in this study, spatial variability in its  
6 sources (diesel and gasoline fueled vehicles, resuspended road dust, and cooking) contributed, on  
7 average, about one-third of the spatial variability observed in  $PM_{2.5}$  concentrations. Further  
8 analyses are needed to determine whether the remaining variability could be attributed to other  
9 local and city-wide sources. Because the effects of emissions from local point sources on  
10 receptor sites depend strongly on wind direction, correlations involving contributions from local  
11 sources can be much lower than from area sources (much as motor vehicle traffic) or from  
12 regionally dispersed sources (such as the photochemical production of secondary organic PM  
13 and sulfate).

14 The difference in mean  $PM_{2.5}$  concentrations between the site with the lowest and the site  
15 with the highest mean concentration range in all MSAs included in Appendix 3A ranges from  
16 0.4  $\mu\text{g}/\text{m}^3$  (Baton Rouge) to about 8  $\mu\text{g}/\text{m}^3$  (Pittsburgh). Six MSAs (Chicago, Seattle, Cleveland,  
17 St. Louis, Detroit, and Pittsburgh) show maximum intersite differences in the annual mean larger  
18 than 6  $\mu\text{g}/\text{m}^3$ . In the Seattle MSA, there is one monitoring site (Figure 3A-23a) that is separated  
19 from the remaining sites by topography and has much lower mean  $PM_{2.5}$  concentrations, much  
20 smaller seasonal variability in concentrations, and much lower maximum concentrations than  
21 these other sites. However, the annual mean concentrations at all the other sites within the  
22 Seattle MSA are within 3  $\mu\text{g}/\text{m}^3$  of each other. Differences in annual mean concentrations are  
23 also larger between sites located in different MSAs but within the same CMSA. For example,  
24 in the consolidated MSA of Los Angeles-Riverside the range of annual mean  $PM_{2.5}$   
25 concentrations is extended from about 20  $\mu\text{g}/\text{m}^3$  in the urban area of Los Angeles county to  
26 about 29  $\mu\text{g}/\text{m}^3$  in Riverside County. Large differences in annual mean concentrations within a  
27 given area reflect differences in source or meteorological or unique topographic characteristics  
28 affecting sites; whereas very small differences found in some areas may only be the result of  
29 measurement imprecision.

30 Whereas high correlations of  $PM_{2.5}$  provide an indication of the spatial uniformity in  
31 temporal variability (directions of changes) in  $PM_{2.5}$  concentrations across urban areas, they do

1 not imply uniformity in the  $PM_{2.5}$  concentrations themselves. The 90<sup>th</sup> percentile difference in  
2 concentrations ( $P_{90}$ ) and the coefficient of divergence (COD) are used here to give a more  
3 quantitative indication of the degree of spatial uniformity in  $PM_{2.5}$  concentrations across urban  
4 areas. A COD of zero implies that both data sets are identical, and a COD of one indicates that  
5 two data sets are completely different. The calculation of the Pearson correlation coefficient,  
6  $P_{90}$ , and COD allows for distinctions between pairs of sites to be made based on various  
7 combinations of these parameters. Figure 3-18 shows examples of the varying degree of  
8 heterogeneity in concentrations between pairs of sites that are highly correlated ( $r > 0.9$  for all  
9 three site pairs). The increase in the spread of concentrations between the chosen site-pairs is  
10 reflected in increases in both  $P_{90}$  and COD. Pairs of sites showing high correlations and  
11 CODs  $< 0.1$  and  $P_{90}$ 's  $< 4 \mu\text{g}/\text{m}^3$  (as in Columbia, SC, Figure 3-7a) indicate homogeneity in both  
12  $PM_{2.5}$  concentrations and in their temporal variations. Presumably, sites such as these are more  
13 strongly affected by regional than local sources. Pairs of sites showing low correlations, values  
14 of  $P_{90} > 10 \mu\text{g}/\text{m}^3$  and CODs  $> 0.2$ , as in Los Angeles, CA (Table 3-5), indicate heterogeneity in  
15 both  $PM_{2.5}$  concentrations and in their temporal variations. Note that the extended urban area or  
16 the CMSA includes Riverside County, as well as Los Angeles County. Even lower correlations  
17 and a greater degree of heterogeneity in  $PM_{2.5}$  concentrations were found in the extended CMSA.  
18 Pairs of sites showing high correlations ( $r > 0.9$ ) and CODs  $> 0.2$  and  $P_{90}$ 's  $> 10 \mu\text{g}/\text{m}^3$  indicate  
19 heterogeneity in concentrations but homogeneity in their day to day changes. Selected pairs of  
20 sites in the Cleveland MSA show moderate to high correlations coupled with CODs  $> 0.2$  and  
21  $P_{90}$ 's  $\geq 10 \mu\text{g}/\text{m}^3$  (Table 3-4), suggesting moderate homogeneity in day to day changes, but  
22 significant spatial heterogeneity in concentrations.

23 The effect of local point sources on intersite variability can be seen at several sites among  
24 those listed in Table 3-4 and Appendix 3A. Sites 39-035-0038 (Cleveland, OH; Table 3-4 and  
25 Figure 3A-8), 18-089-0022 (Gary, IN; Figure 3A-15), 55-079-0043 (Milwaukee, WI;  
26 Figure 3A-13), and 17-119-0023 (St. Louis, MO; Figure 3A-17) are designated as “source  
27 oriented” in the AIRS data base in contrast to the “population exposure” objective associated  
28 with most of the MSA sites.  $PM_{2.5}$  concentrations at these sites are weakly correlated with other  
29 sites within the MSA as evidenced by low correlation coefficients and large  $P_{90}$ s and CODs even  
30 though some of the neighboring sites may be located short distances away. Other sites  
31 designated as “source oriented” in Chicago, Milwaukee, and St. Louis do not show clear

**Figure 3-18. Occurrence of differences between pairs of sites in three MSAs. The absolute differences in daily average  $\text{PM}_{2.5}$  concentrations between sites are shown on the x-axis and the number of occurrences on the y-axis. The MSA, years of observations, AIRS site I.D. numbers for the site pairs, Pearson correlation coefficients ( $r$ ), coefficients of divergence (COD), 90<sup>th</sup> percentile ( $P_{90}$ ) difference in concentration between concurrent measurements are also shown.**

1 evidence that local sources are contributing to intersite variability. Conversely, in the Tampa,  
2 FL MSA pairs of sites are only moderately correlated ( $0.7 < r < 0.87$ ), but the distribution of  
3 concentrations is rather homogeneous ( $COD < 0.14$  and  $P_{90} < 5 \mu\text{g}/\text{m}^3$ ; Figure 3A-7). Thus, a  
4 number of different combinations of spatial uniformity in  $\text{PM}_{2.5}$  concentrations and correlations  
5 of these concentrations are found.

6 Values of  $P_{90}$  for absolute differences in concentrations between sites span a wide range in  
7 the data set given in Appendix 3A. In many instances they can be quite low, only about a few  
8  $\mu\text{g}/\text{m}^3$ ; these cases are found mainly in the eastern United States. The largest  $P_{90}$  values were  
9 associated with a single site in Pittsburgh and reached as high as  $21 \mu\text{g}/\text{m}^3$  (Figure 3A-9).  
10 Excluding this site, large  $P_{90}$  values are found mainly in the western United States. Values of  $P_{90}$   
11  $> 18 \mu\text{g}/\text{m}^3$  are found in the Riverside and Los-Angeles-Long Beach MSAs. Maximum  
12 differences in concentrations between sites can be much larger than shown in Figure 3-18 and  
13 have been larger than  $100 \mu\text{g}/\text{m}^3$  on several occasions in the Atlanta, GA and Los Angeles-Long  
14 Beach, CA MSAs. Rizzo and Pinto (2001) and Fitz-Simons et al. (2000) examined correlations  
15 between sites located even farther apart than those examined here based on the 1999 AIRS data  
16 set for  $\text{PM}_{2.5}$ . They found that in a number of MSAs,  $\text{PM}_{2.5}$  concentrations are still well  
17 correlated ( $r > 0.7$ ) up to distances of 100 km or more. Leaderer et al. (1999) found  $r = 0.49$   
18 between sites outside of homes and a regional background monitor located from 1 to 175 km  
19 away in southwestern Virginia.  $\text{PM}_{2.5}$  tends to be correlated over much larger areas in the East  
20 than in the West, mainly because the terrain tends to be flatter over wider areas in the East  
21 (Rizzo and Pinto, 2001). As a result, there is a greater opportunity for mixing of emissions  
22 among dispersed source regions. Many large urban areas in the West are surrounded by  
23 mountains. The presence of more rugged terrain in the West leads to greater confinement of  
24 emissions from large urban areas. Other factors such as differences in the composition and  
25 amount of emissions of precursors and in the rates of photochemical oxidation of these  
26 emissions in the atmosphere also play a role.

27 There is also evidence for inter-annual variability in the spatial variability in  $\text{PM}_{2.5}$   
28 concentrations. The median year-to-year changes in inter-site  $r$  (0.03),  $P_{90}$  ( $-0.75 \mu\text{g}/\text{m}^3$ ), and  
29  $COD$  ( $-0.015$ ) from 1999 to 2000 do not differ significantly from zero for all the site pairs  
30 considered in Appendix 3A. The year-to-year changes in the spatial variability of  $\text{PM}_{2.5}$   
31 concentrations in a number of MSAs such as the Columbia, SC; Grand Rapids, MI; Milwaukee,

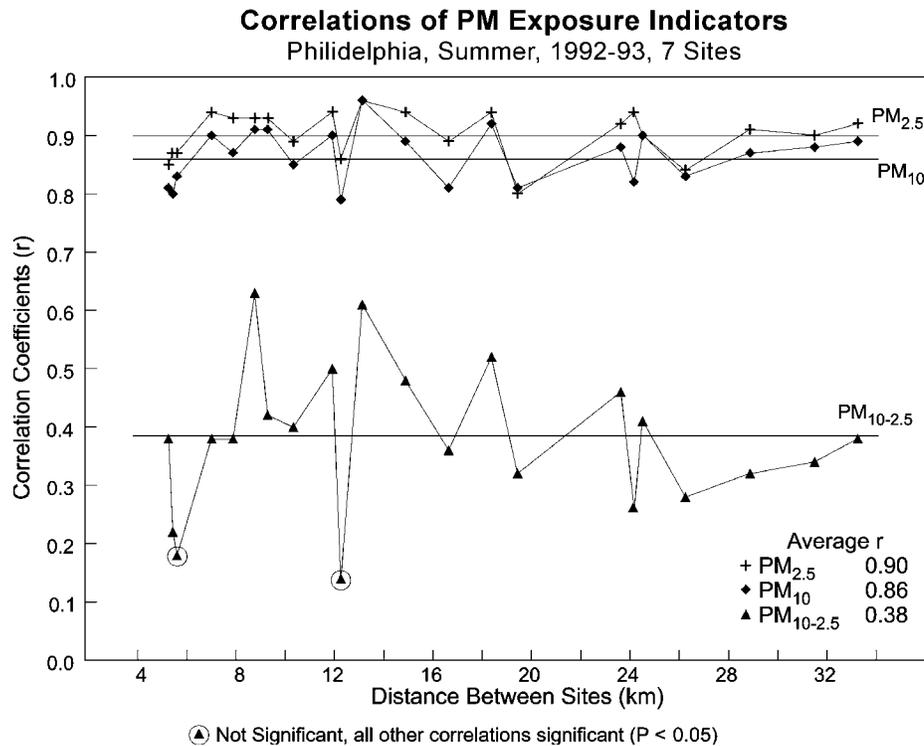

1 WI; Baton Rouge, LA; Kansas City, KS-MO; Boise, ID; and Portland, OR MSAs are similar and  
2 are smaller than those found in the Cleveland, OH; Salt Lake City, UT; and San Diego, CA  
3 MSAs. The ranges in these parameters are largest for a number of individual site-pairs,  
4 especially those involving sites that are remote from the others in their MSAs. In these MSAs  
5 (such as the Atlanta, GA; Los Angeles, CA; and Seattle, WA MSAs) there are sites that may be  
6 located in different airsheds from the remaining sites. Year-to-year changes in parameters  
7 describing spatial variability in  $PM_{2.5}$  concentrations tend to be larger when sites in different  
8 counties within a given MSA are considered rather than when sites in the same county are  
9 considered. There are a number of factors that can account for inter-annual variability in these  
10 parameters, such as changes in patterns in the emissions of primary  $PM_{2.5}$ ; in the transport and  
11 rates of transformation of secondary  $PM_{2.5}$  precursors in field measurement; and analysis  
12 procedures.

13 Some additional data for indicating the stability with respect to year-to-year changes in  
14 spatial variability are available from earlier studies. For example, a comparison between data  
15 obtained during the summers of 1992 and 1993 (Wilson and Suh, 1997), shown in Figure 3-19,  
16 and data obtained during the summer of 1994 (Pinto et al., 1995) (cf., Table 3-8) in Philadelphia,  
17 PA, suggests that inter-site correlations of  $PM_{2.5}$  have remained high and have changed very little  
18 between the two study periods.

### 19 $PM_{10-2.5}$

20 Intersite correlations of  $PM_{10-2.5}$  concentrations obtained during the summers of 1992 and  
21 1993 in Philadelphia, PA, (Wilson and Suh, 1997) are shown in Figure 3-19. As can be seen,  
22 correlations of  $PM_{10-2.5}$  are substantially lower than those for  $PM_{2.5}$ .  
23

24 Intersite correlation coefficients can also be calculated for  $PM_{10-2.5}$  based on the AIRS data  
25 set as shown in Table 3-5 for the Cleveland, OH; Dallas, TX; and Los Angeles, CA MSAs.  
26 However, data for analyzing the spatial variability of  $PM_{10-2.5}$  are more limited than for  $PM_{2.5}$ ;  
27 therefore, fewer urban areas could be characterized in Appendix 3A (Figures 3A-28 to 3A-44).  
28 Whereas  $PM_{2.5}$  concentrations were found to be highly correlated between sites in the Detroit,  
29 MI MSA (Table 3-4), estimated  $PM_{10-2.5}$  concentrations are noticeably less well correlated.  
30 Likewise, correlations of  $PM_{10-2.5}$  in the Chicago, IL MSA are also lower than those for  $PM_{2.5}$ .

**Figure 3-19. Intersite correlation coefficients for PM<sub>2.5</sub>, PM<sub>10</sub>, and PM<sub>10-2.5</sub>.**

Source: Wilson and Suh (1997).

1 In contrast, correlations of PM<sub>10-2.5</sub> concentrations between several pairs of sites in the  
 2 Los Angeles-Long Beach partial MSA are higher than those for PM<sub>2.5</sub>.

3 The interpretation of these results is not straightforward, as concentrations of PM<sub>10-2.5</sub> are  
 4 generated by taking the difference between collocated PM<sub>2.5</sub> and PM<sub>10</sub> monitors. Consequently,  
 5 caution must be exercised when viewing them. Errors in the measurement of PM<sub>2.5</sub> and PM<sub>10</sub>  
 6 may play a large role in reducing apparent correlations of PM<sub>10-2.5</sub> such that collocated PM<sub>10-2.5</sub>  
 7 “measurements” may be expected to be poorly correlated (White, 1998). Indeed, several  
 8 estimates of concentrations are negative. Negative PM<sub>10-2.5</sub> concentrations also lead to artifacts  
 9 in the calculation of CODs. In cases where these artifacts cause a division by zero or a very  
 10 small number in the calculation of CODs, dashes are used in Table 3-5 and Figures 3A-28  
 11 through 3A-44. These results imply that negative concentrations can be almost or identically  
 12 equal in absolute magnitude to positive concentrations in the same MSA. The possible causes of  
 13 these errors are essentially the same as those discussed in Section 3.2.1 with regard to the

1 occurrence of PM<sub>2.5</sub> to PM<sub>10</sub> ratios greater than one. There are also physical bases for expecting  
2 that PM<sub>10-2.5</sub> concentrations may be more variable than those for PM<sub>2.5</sub>. PM<sub>10-2.5</sub> is mainly  
3 primary in origin, and its emissions are spatially and temporally heterogenous. Similar  
4 considerations apply to primary PM<sub>2.5</sub>, but much of PM<sub>2.5</sub> is secondary, and sources of secondary  
5 PM are much less spatially and temporally variable. Dry deposition rates of particles depend  
6 strongly on particle size. Whereas all particles may be brought to the surface by turbulent  
7 motions in the atmosphere; gravitational settling becomes more important with increasing  
8 particle size. Gravitational settling can effectively limit the horizontal distance a particle can  
9 travel. For example, 10 μm D<sub>a</sub> particles suspended in a hypothetical 1 km deep planetary  
10 boundary layer can be removed within a few hours, but 1 μm D<sub>a</sub> particles can remain suspended  
11 in the atmosphere for up to 100 to 1,000 times longer before being dry deposited. (Estimated  
12 atmospheric lifetimes were based on deposition velocities given in Lin et al. [1994] for typical  
13 wind speeds.) The findings of larger correlations of PM<sub>10-2.5</sub> between several site pairs in the  
14 Los Angeles basin (cf., Figures 3A-25/26 and Figures 3A-42/43) and one other site pair in the  
15 St. Louis, MO-IL MSA (cf., Figures 3A-17 and 3A-37) are anomalous in light of the discussion  
16 above. However, these findings could have resulted from differences between the spatial and  
17 temporal behavior of sources of PM<sub>2.5</sub> and PM<sub>10-2.5</sub> in these locations. Because of negative  
18 values, CODs were not calculated.

### 20 ***PM Components***

21 Three methods for comparing the chemical composition of aerosol databases obtained at  
22 different locations and times were discussed by Wongphatarakul et al. (1998). Log-log plots of  
23 chemical concentrations obtained at pairs of sampling sites accompanied by the coefficient of  
24 divergence (COD) were examined as a way to provide an easily visualized means of comparing  
25 two data sets<sup>2</sup>. Examples comparing downtown Los Angeles with Burbank and with

---

<sup>2</sup>The COD for two sampling sites is defined as follows:

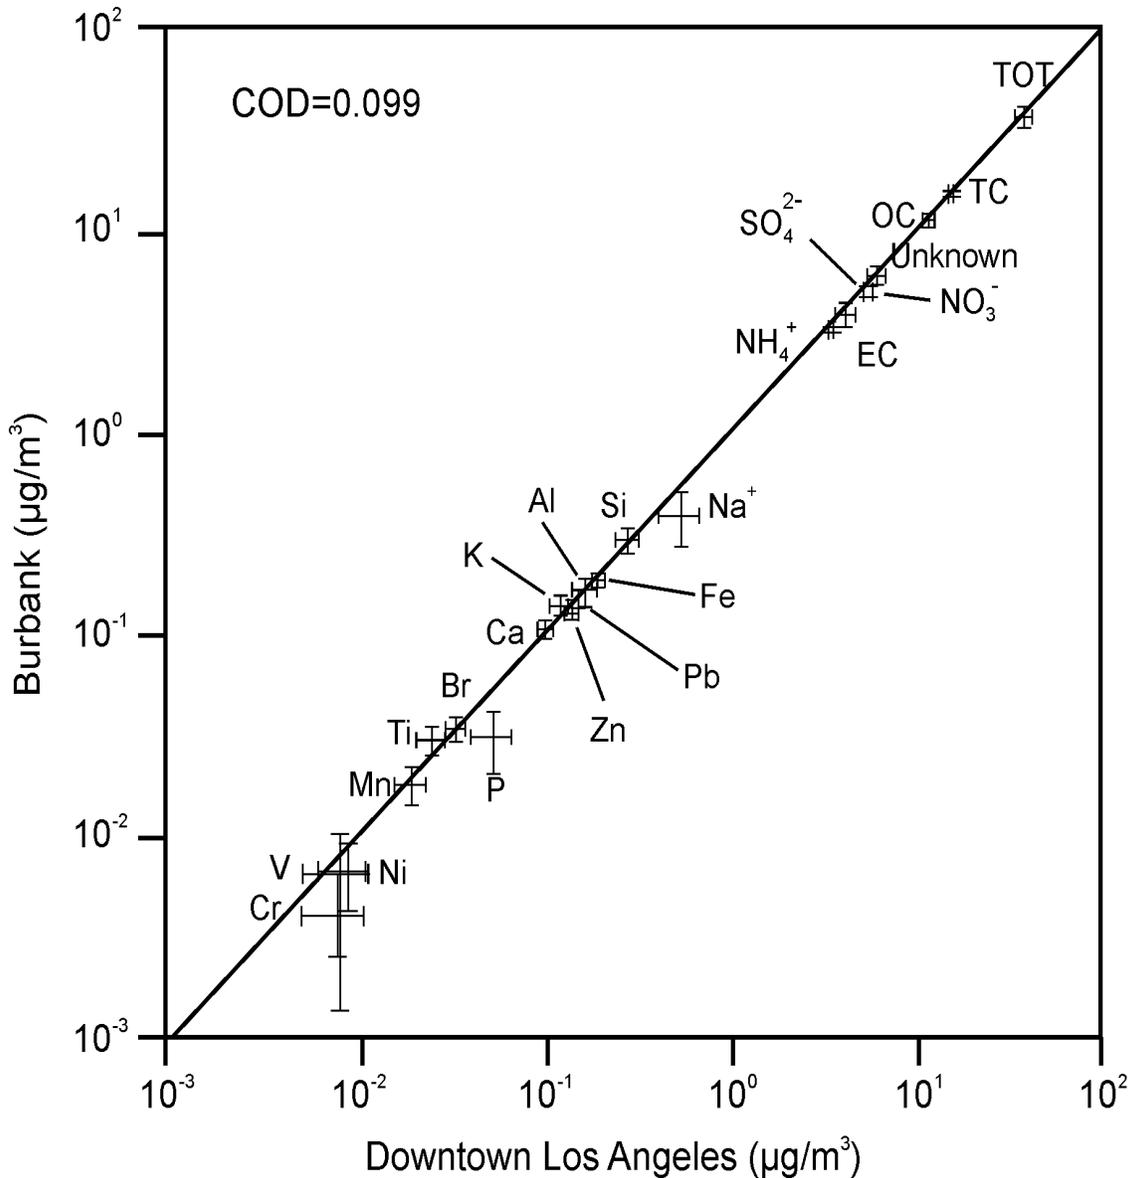

$$COD_{jk} = \sqrt{\frac{1}{p} \sum_{i=1}^p \left( \frac{x_{ij} - x_{ik}}{x_{ij} + x_{ik}} \right)^2} \quad (3-2)$$

where  $x_{ij}$  represents the average concentration for a chemical component  $i$  at site  $j$ ,  $j$  and  $k$  represent two sampling sites, and  $p$  is the number of chemical components.

1 Riverside-Rubidoux are shown in Figures 3-20 and 3-21. As the composition of two sampling  
2 sites become more similar, the COD approaches zero; as their compositions diverge, the COD  
3 approaches one. Correlation coefficients calculated between components can be used to show  
4 the degree of similarity between pairs of sampling sites.

5 In addition to calculating correlation coefficients for total mass or for individual  
6 components, correlation coefficients for characterizing the spatial variation of the contributions  
7 from given source types can also be calculated by averaging the correlation coefficients of the  
8 set of chemical components that represent the source type. Correlation coefficients showing the  
9 spatial relationships among PM<sub>2.5</sub> (total) and contributions from different source categories  
10 obtained at various sites in the South Coast Air Basin (SoCAB) Study are shown in Table 3-6.  
11 In Wongphatarakul et al. (1998), crustal material (crustal), motor vehicle exhaust (mv), residual  
12 oil emissions (residual oil), and secondary PM (sec) were considered as source categories.  
13 Al, Si, Fe, and Ca were used as markers for crustal material (crustal); V and Ni were used as  
14 markers for fuel oil combustion (residual oil); and Pb, Br, and Mn were used as markers for  
15 motor vehicle exhaust (mv), based on the lack of other, perhaps more suitable, tracers. NO<sub>3</sub><sup>-</sup>,  
16 NH<sub>4</sub><sup>+</sup>, and SO<sub>4</sub><sup>-2</sup> represent secondary PM components. The average of the correlation  
17 coefficients of marker elements within each source category are shown in Table 3-6. Values of  
18 r<sub>sec</sub> and r<sub>mv</sub> are much higher than those for r<sub>crustal</sub> and r<sub>residual oil</sub> throughout the SoCAB, suggesting a  
19 more uniform distribution of the contributions from secondary PM formation and automobiles  
20 than from crustal material and localized stationary sources.

21 Correlation coefficients in Philadelphia air based on data obtained at four sites for PM<sub>2.5</sub>  
22 (total), crustal components (Al, Si, Ca, and Fe), the major secondary component (sulfate),  
23 organic carbon (OC), and elemental carbon (EC) are shown in Table 3-7. Because these data  
24 were obtained after Pb had been phased out of gasoline, a motor vehicle contribution could not  
25 be estimated from the data. Pb also is emitted by discrete point sources, such as the Franklin  
26 smelter. Concentrations of V and Ni were often beneath detection limits; so, the spatial  
27 variability in PM due to residual oil combustion were not estimated. Sulfate in aerosol samples  
28 collected in Philadelphia arises mainly from long-range transport from regionally dispersed  
29 sources (Dzubay et al., 1988). This conclusion is strengthened by the high correlations in sulfate  
30 between different monitoring sites and the uniformity in sulfate concentrations observed among  
31 the sites. Widespread area sources (e.g., motor vehicle traffic) also may emit pollutants that are

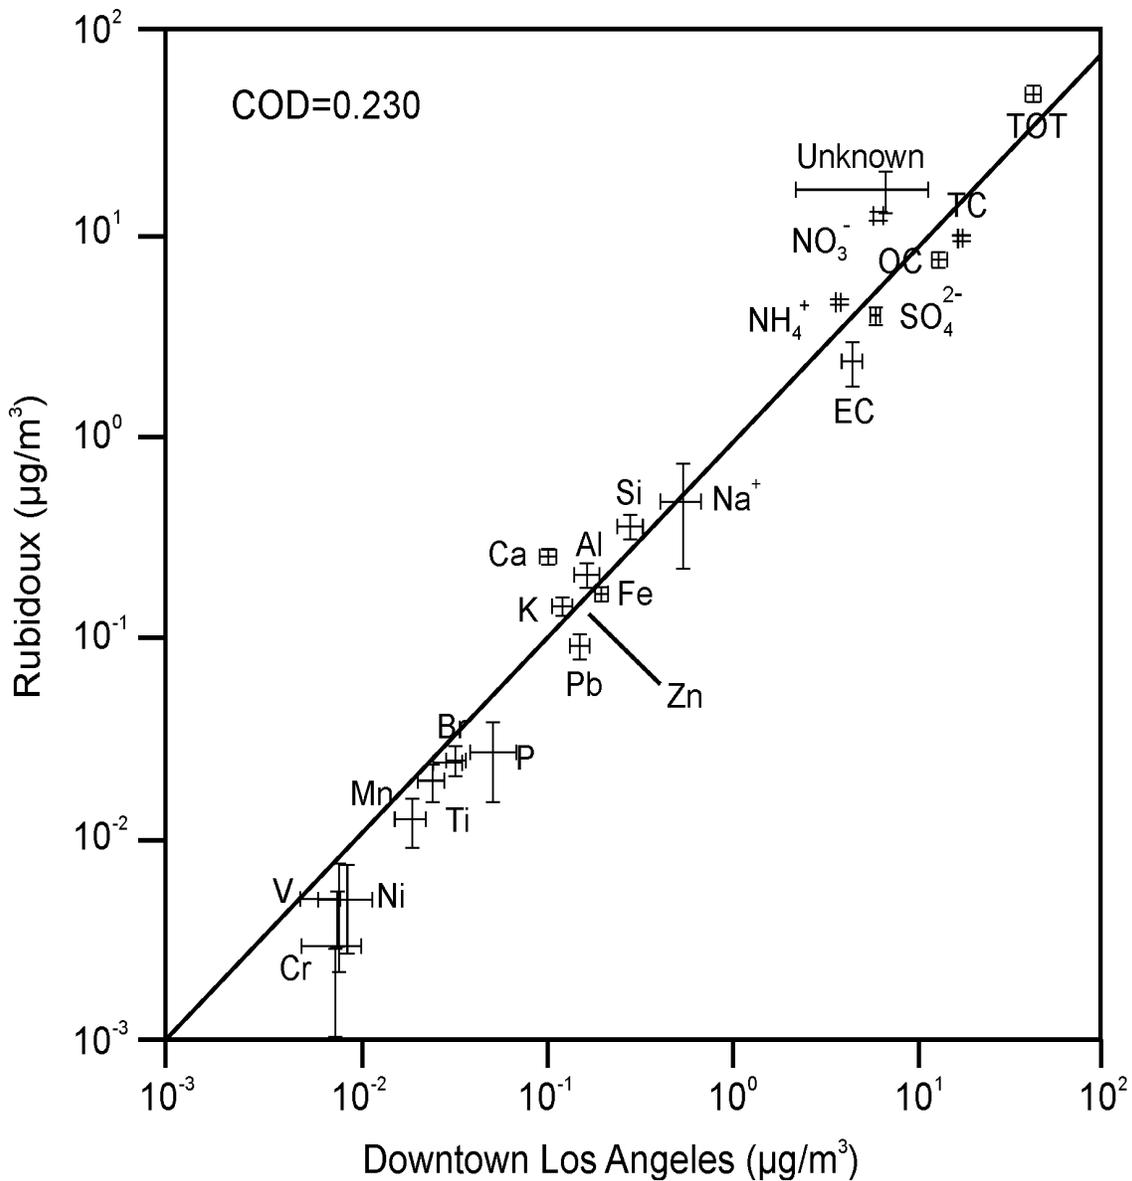

**Figure 3-20. PM<sub>2.5</sub> chemical components in downtown Los Angeles and Burbank (1986) have similar characteristics. The spread in the data is shown by the bars.**

Source: Wongphatarakul et al. (1998).

1 correlated between sites provided that traffic patterns and emissions are similar throughout the  
 2 area under consideration.

3 Landis et al. (2001) found relatively high correlations between PM<sub>2.5</sub> (r = 0.97), sulfate  
 4 (r = 0.99), OC (r = 0.97), EC (r = 0.83), NaCl (r = 0.83), and nitrate (r = 0.83) measured at two

- 1 sites located several km apart in the Baltimore, MD area. Concentrations of crustal material
- 2 ( $r = 0.63$ ) and the sum of total metal oxides ( $r = 0.76$ ) were not as well correlated. These results
- 3 are consistent with those for another eastern city, Philadelphia, PA, given in Table 3-7.

Source: Pinto et al. (1995).

1 The results presented above for Philadelphia, PA; Baltimore, MD; and Los Angeles, CA,  
2 indicate that secondary PM components are more highly correlated than primary components  
3 and may be more highly correlated than total PM<sub>2.5</sub>. These results suggest that the correlation of  
4 PM concentrations across an urban area may depend on the relative proportions of primary and  
5 secondary components of PM at individual sites. Sampling artifacts affecting the measurement  
6 of nitrate and organic carbon can obscure these relations and may depress correlations between  
7 sites.

8 Kao and Friedlander (1995) examined the statistical properties of a number of PM  
9 components in the South Coast Air Basin (Los Angeles area). They found that, regardless of  
10 source type and location within their study area, the concentrations of nonreactive, primary  
11 components of PM<sub>10</sub> had approximately log-normal frequency distributions with constant values  
12 of the geometric standard deviations (GSDs). However, aerosol constituents of secondary origin  
13 (e.g., SO<sub>4</sub><sup>-2</sup>, NH<sub>4</sub><sup>+</sup>, and NO<sub>3</sub><sup>-</sup>) were found to have much higher GSDs. Surprisingly, the GSDs of  
14 organic (1.87) and elemental (1.74) carbon were both found to be within 1 SD (0.14) of the mean  
15 GSD (1.85) for nonreactive primary species, compared to GSD's of 2.1 for sulfate, 3.5 for  
16 nitrate, and 2.6 for ammonium. These results suggest that most of the organic carbon seen in  
17 ambient samples in the South Coast Air Basin was of primary origin. Pinto et al. (1995) found  
18 similar results for data obtained during the summer of 1994 in Philadelphia. Further studies are  
19 needed to determine if these relations are valid at other locations and to what extent the results  
20 might be influenced by sampling artifacts such as the evaporation of volatile constituents during  
21 or after sampling.

22 The use of correlations between OC and EC and OC to EC ratios based on a comparison  
23 between values measured in source emissions and ambient observations has also been suggested  
24 as a means to distinguish between secondary; and primary sources of OC (Turpin and  
25 Huntzicker, 1995; Strader et al., 1999). Ratios of OC to EC from combustion sources are  
26 typically three or less and may even be less than one in diesel emissions (cf., Appendix 3D).  
27 Cabada et al. (2002) concluded that secondary organic PM can contribute from 10 to 35% of  
28 total organic PM on an annual basis, with values > 50% during the summer and 0% during the  
29 winter months in Pittsburgh, PA, based on chemistry-transport model results and comparison  
30 with emissions inventory values of OC to EC ratios. All of these inferences are subject to  
31 considerable uncertainty in the methods for measuring OC (as discussed in Section 2).

1     Ambiguity also arises in the ratio method as the ratios may change due to chemical reactions  
2     occurring during aging of the particles. However, not much work has been done on this issue.  
3     The ratio can be greater than nine in emissions from wildfires, and transport from distant fires  
4     can skew results unless this transport is taken into account (cf., Appendix 3D). Modeling studies  
5     that rely on OC to EC ratios in emissions inventories to predict the amount of secondary OC may  
6     be biased towards higher ratios of secondary OC because emissions of primary biologic particles  
7     are not included in the inventories. Additional concerns arise from uncertainties in the  
8     mechanism of formation of secondary OC from gaseous biogenic and anthropogenic precursor  
9     emissions and the uncertainty in those emissions (Section 3.3.1). It is clear, however, that  
10    secondary organic PM is being formed in the atmosphere (Blando et al., 1998 and Appendix 3C).

11         Few studies have compared aerosol composition in urban areas to that in nearby rural  
12    areas. One exception is Tanner and Parkhurst (2000), which indicates that sulfate constituted a  
13    larger fraction of fine particle mass at rural sites in the Tennessee Valley PM<sub>2.5</sub> monitoring  
14    network than did organic carbon. For urban sites, the situation was largely reversed: organic  
15    carbon constituted a larger fraction of aerosol mass than sulfate. Future systematic comparisons  
16    of urban-rural differences in aerosol properties should be facilitated with implementation of the  
17    national speciation network and continued operation of the IMPROVE network.

### 18 19 20    **3.3    SOURCES OF PRIMARY AND SECONDARY PARTICULATE** 21    **MATTER**

22         Information about the nature and relative importance of sources of ambient PM is  
23    presented in this section. Table 3-8 summarizes anthropogenic and natural sources for the major  
24    primary and secondary aerosol constituents of fine and coarse particles. Anthropogenic sources  
25    can be further divided into stationary and mobile sources. Stationary sources include those such  
26    as: fuel combustion for electrical utilities, residential space heating, and industrial processes;  
27    construction and demolition; metals, minerals, and petrochemicals; wood products processing;  
28    mills and elevators used in agriculture; erosion from tilled lands; waste disposal and recycling;  
29    and fugitive dust from paved and unpaved roads. Mobile or transportation-related sources  
30    include direct emissions of primary PM and secondary PM precursors from highway and off-  
31    highway vehicles and non-road sources. In addition to fossil fuel combustion, biomass in the  
32    form of wood is burned for fuel. Vegetation is burned to clear new land for agriculture and for

**TABLE 3-8. CONSTITUENTS OF ATMOSPHERIC PARTICLES AND THEIR MAJOR SOURCES<sup>1</sup>**

Aerosol species	Sources					
	Primary (PM < 2.5 µm)		Primary (PM > 2.5 µm)		Secondary PM Precursors (PM < 2.5 µm)

<sup>1</sup>Dash (—) indicates either very minor source or no known source of component.

1 building construction, to dispose of agricultural and domestic waste, to control the growth of  
2 animal or plant pests, and to manage forest resources (prescribed burning). Also shown are  
3 sources for precursor gases whose oxidation forms secondary particulate matter. The  
4 atmospheric chemical processes producing secondary PM are described in Section 3.3.1.

5 In general, the sources of fine PM are very different from those for coarse PM. Some of  
6 the mass in the fine size fraction forms during combustion from material that has volatilized in  
7 combustion chambers and then recondensed before emission into the atmosphere. Some ambient  
8  $PM_{2.5}$  forms in the atmosphere from photochemical reactions involving precursor gases. PM  
9 formed by the first mechanism is referred to as primary, and PM formed by the second  
10 mechanism is referred to as secondary.  $PM_{10-2.5}$  is mainly primary in origin as it is produced by  
11 the abrasion of surfaces or by the suspension of biological material. Because precursor gases  
12 undergo mixing during transport from their sources, it is difficult to identify individual sources  
13 of secondary constituents of PM. Transport and transformations of precursors can occur over  
14 distances of hundreds of kilometers. The coarse PM constituents have shorter lifetimes in the  
15 atmosphere, so their effects tend to be more localized. Only major sources for each constituent  
16 within each broad category shown at the top of Table 3-8 are listed. Not all sources are equal in  
17 magnitude. Chemical characterizations of primary particulate emissions for a wide variety of  
18 natural and anthropogenic sources (as shown in Table 3-8) were given in Chapter 5 of the 1996  
19 PM AQCD. Summary tables of the composition of source emissions presented in the 1996 PM  
20 AQCD and updates to that information are provided in Appendix 3D. The profiles of source  
21 composition were based in large measure on the results of various studies that collected  
22 signatures for use in source apportionment studies.

23 Natural sources of primary PM include windblown dust from undisturbed land, sea spray,  
24 and plant and insect debris. The oxidation of a fraction of terpenes emitted by vegetation and  
25 reduced sulfur species from anaerobic environments leads to secondary PM formation.

26 Ammonium ( $NH_4^+$ ) ions, which play a major role in regulating the pH of particles, are derived  
27 from emissions of ammonia ( $NH_3$ ) gas. Source categories for  $NH_3$  have been divided into  
28 emissions from undisturbed soils (natural) and emissions that are related to human activities  
29 (e.g., fertilized lands, domestic and farm animal waste). There is ongoing debate about  
30 characterizing emissions from wildfires (i.e., unwanted fire) as either natural or anthropogenic.  
31 Wildfires have been listed in Table 3-8 as natural in origin, but land management practices and

1 other human actions affect the occurrence and scope of wildfires. For example, fire suppression  
2 practices allow the buildup of fire fuels and increase the susceptibility of forests to more severe  
3 and infrequent fires from whatever cause, including lightning strikes. Similarly, prescribed  
4 burning is listed as anthropogenic, but can be viewed as a substitute for wildfires that would  
5 otherwise occur eventually on the same land.

6 The transformations that gaseous precursors to secondary PM undergo after being emitted  
7 from the sources shown in Table 3-8 are described in Section 3.3.1. Aspects of the transport of  
8 primary PM and secondary PM, including the transport of material from outside the United  
9 States, are described in Section 3.3.2. A brief introduction to the deposition of particles is also  
10 given in Section 3.3.2, and a more detailed discussion of deposition processes is presented in  
11 Chapter 4. Methods to infer contributions from different source categories to ambient PM using  
12 receptor models and the results of these modeling efforts are given in Section 3.3.3. Estimates of  
13 emissions of primary PM and precursors to secondary PM from major sources are presented in  
14 Section 3.3.4. A discussion of the uncertainties associated with these emissions is given in  
15 Section 3.3.5.

### 17 **3.3.1 Chemistry of Secondary PM Formation**

18 Precursors to secondary PM have natural and anthropogenic sources, just as primary PM  
19 has natural and anthropogenic sources. The major atmospheric chemical transformations leading  
20 to the formation of particulate nitrate and sulfate are relatively well understood; whereas those  
21 involving the formation of secondary aerosol organic carbon are less so and are still subject to  
22 much current investigation. A large number of organic precursors are involved; many of the  
23 kinetic details still need to be determined; and many of the actual products of the oxidation of  
24 hydrocarbons have yet to be identified.

#### 26 ***Formation of Sulfates and Nitrates***

27 A substantial fraction of the fine particle mass, especially during the warmer months of the  
28 year, is secondary sulfate and nitrate formed as the result of atmospheric reactions. Such  
29 reactions involve the gas phase conversion of  $\text{SO}_2$  to  $\text{H}_2\text{SO}_4$  (which forms liquid particles)  
30 initiated by reaction with OH radicals and aqueous-phase reactions of  $\text{SO}_2$  with  $\text{H}_2\text{O}_2$ ,  $\text{O}_3$ , or  $\text{O}_2$   
31 (catalyzed by Fe and Mn). These heterogeneous reactions may occur in cloud and fog droplets

1 or in films on atmospheric particles.  $\text{NO}_2$  can be converted to gaseous  $\text{HNO}_3$  by reaction with  
2 OH radicals during the day. At night,  $\text{NO}_2$  also is oxidized to nitric acid by a sequence of  
3 reactions initiated by  $\text{O}_3$  that produce nitrate radicals ( $\text{NO}_3$ ) and dinitrogenpentoxide ( $\text{N}_2\text{O}_5$ ) as  
4 intermediates. Both  $\text{H}_2\text{SO}_4$  and  $\text{HNO}_3$  react with atmospheric ammonia ( $\text{NH}_3$ ). Gaseous  $\text{NH}_3$   
5 reacts with gaseous  $\text{HNO}_3$  to form particulate  $\text{NH}_4\text{NO}_3$ . Gaseous  $\text{NH}_3$  reacts with  $\text{H}_2\text{SO}_4$  to form  
6 acidic  $\text{HSO}_4^-$  (in  $\text{NH}_4\text{HSO}_4$ ) as well as  $\text{SO}_4^{2-}$  in  $(\text{NH}_4)_2\text{SO}_4$ . In addition, acid gases such as  $\text{SO}_2$   
7 and  $\text{HNO}_3$  may react with coarse alkaline particles to form coarse secondary PM containing  
8 sulfate and nitrate. Examples include reactions with basic compounds resulting in neutralization  
9 (e.g.,  $\text{CaCO}_3 + 2 \text{HNO}_3 \rightarrow \text{Ca}(\text{NO}_3)_2 + \text{H}_2\text{CO}_3 \uparrow$ ) or with salts of volatile acids resulting in release  
10 of the volatile acid (e.g.,  $\text{SO}_2 + 2\text{NaCl} + \text{H}_2\text{O} \rightarrow \text{Na}_2\text{SO}_3 + 2\text{HCl} \uparrow$ ).

11 If particulate  $\text{NH}_4\text{NO}_3$  coagulates with an acidic sulfate particle ( $\text{H}_2\text{SO}_4$  or  $\text{HSO}_4^-$ ), gaseous  
12  $\text{HNO}_3$  will be released, and the  $\text{NH}_3$  will increase the neutralization of the acidic sulfate. Thus,  
13 in the eastern United States, where PM tends to be acidic, sulfate usually constitutes a larger  
14 fraction of PM mass than nitrate. However, in the western United States, where higher  $\text{NH}_3$  and  
15 lower  $\text{SO}_2$  emissions permit complete neutralization of  $\text{H}_2\text{SO}_4$ , the concentration of nitrate could  
16 be higher than that of sulfate as it is in areas such as the Los Angeles Basin and the San Joaquin  
17 Valley. As  $\text{SO}_2$  concentrations in the atmosphere in the eastern United States are reduced, the  
18  $\text{NH}_3$  left in the atmosphere after neutralization of  $\text{H}_2\text{SO}_4$  will be able to react with  $\text{HNO}_3$  to form  
19  $\text{NH}_4\text{NO}_3$ . Therefore, a reduction in  $\text{SO}_2$  emissions, especially without a reduction in  $\text{NO}_x$   
20 emissions, could lead to an increase in  $\text{NH}_4\text{NO}_3$  concentrations (West et al., 1999; Ansari and  
21 Pandis, 1998). Thus, possible environmental effects of  $\text{NH}_4\text{NO}_3$  are of interest for both the  
22 western and eastern United States.

23 Chemical reactions of  $\text{SO}_2$  and  $\text{NO}_x$  within plumes are an important source of  $\text{H}^+$ ,  $\text{SO}_4^{2-}$ ,  
24 and  $\text{NO}_3^-$ . These conversions can occur by gas-phase and aqueous-phase mechanisms.  
25 In power-plant or smelter plumes containing  $\text{SO}_2$  and  $\text{NO}_x$ , the gas-phase chemistry depends on  
26 plume dilution, sunlight, and volatile organic compounds either in the plume or in the ambient  
27 air mixing into and diluting the plume. For the conversion of  $\text{SO}_2$  to  $\text{H}_2\text{SO}_4$  in the gas-phase in  
28 such plumes during summer midday conditions in the eastern United States, the rate typically  
29 varies between 1 and 3%  $\text{h}^{-1}$  but in the cleaner western United States rarely exceeds 1%  $\text{h}^{-1}$ .  
30 For the conversion of  $\text{NO}_x$  to  $\text{HNO}_3$ , the gas-phase rates appear to be approximately three times

1 faster than the SO<sub>2</sub> conversion rates. Winter rates for SO<sub>2</sub> conversion are approximately an order  
2 of magnitude lower than summer rates.

3 The contribution of aqueous-phase chemistry to particle formation in point-source plumes  
4 is highly variable, depending on the availability of the aqueous phase (wetted aerosols, clouds,  
5 fog, and light rain) and the photochemically generated gas-phase oxidizing agents, especially  
6 H<sub>2</sub>O<sub>2</sub> for SO<sub>2</sub> chemistry. The in-cloud conversion rates of SO<sub>2</sub> to SO<sub>4</sub><sup>-2</sup> can be several times  
7 larger than the gas-phase rates given above. Overall, it appears that SO<sub>2</sub> oxidation rates to SO<sub>4</sub><sup>-2</sup>  
8 by gas-phase and aqueous-phase mechanisms may be comparable in summer, but aqueous-phase  
9 chemistry may dominate in winter. Further details concerning the chemistry of SO<sub>2</sub> and NO<sub>x</sub> in  
10 power plant plumes can be found in Hewitt (2001).

11 In the western United States, markedly higher SO<sub>2</sub> conversion rates have been reported in  
12 smelter plumes than in power plant plumes. The conversion occurs predominantly by a gas-  
13 phase mechanism. This result is attributed to the lower NO<sub>x</sub> in smelter plumes. In power plant  
14 plumes, NO<sub>2</sub> depletes OH radicals and competes with SO<sub>2</sub> for OH radicals.

15 In urban plumes, the upper limit for the gas-phase SO<sub>2</sub> conversion rate appears to be about  
16 5% h<sup>-1</sup> under the more polluted conditions. For NO<sub>2</sub>, the rates appear to be approximately three  
17 times faster than the SO<sub>2</sub> conversion rates. Conversion rates of SO<sub>2</sub> and NO<sub>x</sub> in background air  
18 are comparable to the peak rates in diluted plumes. Neutralization of H<sub>2</sub>SO<sub>4</sub> formed by SO<sub>2</sub>  
19 conversion increases with plume age and background NH<sub>3</sub> concentration. If the NH<sub>3</sub>  
20 concentrations are more than sufficient to neutralize H<sub>2</sub>SO<sub>4</sub> to (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, the HNO<sub>3</sub> formed  
21 from NO<sub>x</sub> conversions may be converted to NH<sub>4</sub>NO<sub>3</sub>.

### 22 23 ***Formation of Secondary Organic Particulate Matter (SOPM)***

24 Atmospheric reactions involving volatile organic compounds such as alkanes, alkenes,  
25 aromatics, cyclic olefins, and terpenes (or any reactive organic gas that contains at least seven  
26 carbon atoms) yield organic compounds with low saturation vapor pressures at ambient  
27 temperature. Such reactions may occur in the gas phase, in fog or cloud droplets (Graedel and  
28 Goldberg, 1983; Faust, 1994), or possibly in aqueous aerosols (Aumont et al., 2000). Reaction  
29 products from the oxidation of reactive organic gases also may nucleate to form new particles or  
30 condense on existing particles to form secondary organic PM (SOPM). Organic compounds  
31 with two double bonds or cyclic olefins may react to form dicarboxylic acids, which, with four

1 or more carbon atoms, also may condense. Both biogenic and anthropogenic sources contribute  
2 to primary and secondary organic particulate matter (Grosjean, 1992; Hildemann et al., 1996;  
3 Mazurek et al., 1997; Schauer et al., 1996). Oxalic acid was the most abundant organic acid  
4 found in PM<sub>2.5</sub> in California (Poore, 2000).

5 Although the mechanisms and pathways for forming inorganic secondary particulate  
6 matter are fairly well known, those for forming SOPM are not as well understood. Ozone and  
7 the OH radicals are thought to be the major initiating reactants. However, HO<sub>2</sub> and NO<sub>3</sub> radicals  
8 also may initiate reactions; and organic radicals may be nitrated by HNO<sub>2</sub>, HNO<sub>3</sub>, or NO<sub>2</sub>. Pun  
9 et al. (2000) discuss formation mechanisms for highly oxidized, multifunctional organic  
10 compounds. The production of such species has been included in a photochemical model by  
11 Aumont et al. (2000), for example. Understanding the mechanisms of formation of secondary  
12 organic PM is important because SOPM can contribute in a significant way to ambient PM  
13 levels, especially during photochemical smog episodes. Experimental studies of the production  
14 of secondary organic PM in ambient air have focused on the Los Angeles Basin. Turpin and  
15 Huntzicker (1991, 1995) and Turpin et al. (1991) provided strong evidence that secondary PM  
16 formation occurs during periods of photochemical ozone formation in Los Angeles and that as  
17 much as 70% of the organic carbon in ambient PM was secondary in origin during a smog  
18 episode in 1987. Schauer et al. (1996) estimated that 20 to 30% of the total organic carbon  
19 PM in the < 2.1 μm size range in the Los Angeles airshed is secondary in origin on an annually  
20 averaged basis.

21 Pandis et al. (1992) identified three mechanisms for formation of SOPM: (1) condensation  
22 of oxidized end-products of photochemical reactions (e.g., ketones, aldehydes, organic acids, and  
23 hydroperoxides), (2) adsorption of semivolatile organic compounds (SVOC) onto existing solid  
24 particles (e.g., polycyclic aromatic hydrocarbons), and (3) dissolution of soluble gases that can  
25 undergo reactions in particles (e.g., aldehydes). The first and third mechanisms are expected to  
26 be of major importance during the summer when photochemistry is at its peak. The second  
27 pathway can be driven by diurnal and seasonal temperature and humidity variations at any time  
28 of the year. With regard to the first mechanism, Odum et al. (1996) suggested that the products  
29 of the photochemical oxidation of reactive organic gases are semivolatile and can partition  
30 themselves onto existing organic carbon at concentrations below their saturation concentrations.

1 Thus, the yield of SOPM depends not only on the identity of the precursor organic gas but also  
2 on the ambient levels of organic carbon capable of absorbing the oxidation products.

3 Haagen-Smit (1952) first demonstrated that hydrocarbons irradiated in the presence of  $\text{NO}_x$   
4 produce light scattering aerosols. The aerosol-forming potentials of a wide variety of individual  
5 anthropogenic and biogenic hydrocarbons were compiled by Pandis et al. (1992) based mainly  
6 on estimates made by Grosjean and Seinfeld (1989) and on data from Pandis et al. (1991) for  
7  $\beta$ -pinene and from Izumi and Fukuyama (1990) for aromatic hydrocarbons. Zhang et al. (1992)  
8 examined the oxidation of  $\alpha$ -pinene. Pandis et al. (1991) found no aerosol products formed in  
9 the photochemical oxidation of isoprene, although they and Zhang et al. (1992) found that the  
10 addition of isoprene to reaction mixtures increased the reactivity of the systems studied. Further  
11 details about the oxidation mechanisms and secondary organic PM yields from various reactive  
12 organic gases are given in the above studies. Estimates of the production rate of secondary  
13 organic PM in the Los Angeles airshed are provided in the 1996 PM AQCD (U.S.  
14 Environmental Protection Agency, 1996).

15 More recently, Odum et al. (1997a,b) have found that the aerosol-formation potential of  
16 whole gasoline vapor can be accounted for solely by summing the contributions of the individual  
17 aromatic compounds in the fuel. In general, data for yields for secondary organic PM formation  
18 can be broken into two distinct categories. The oxidation of toluene and aromatic compounds  
19 containing ethyl or propyl groups (i.e., ethylbenzene, ethyltoluene, n-propylbenzene) produced  
20 higher yields of secondary organic PM than did the oxidation of aromatic compounds containing  
21 two or more methyl groups (i.e., xylenes, di-, tri-, tetra-methylbenzenes). Yields in the first  
22 group ranged from about 7 to 10%; and in the second group, they ranged from 3 to 4% for  
23 organic carbon concentrations between 13 and 100  $\mu\text{g}/\text{m}^3$ . Reasons for the differences in  
24 secondary organic PM yields found between the two classes of compounds are not clear.

25 There have been a few recent studies that have examined the composition of secondary  
26 organic PM. Edney et al. (2001) carried out a smog chamber study to investigate the formation  
27 of multi-functional oxygenates from photooxidation of toluene. The experiments were carried  
28 out by irradiating toluene/propylene/ $\text{NO}_x$ /air mixtures in a smog chamber operated in the  
29 dynamic mode and analyzing the collected aerosol by positive chemical ionization GC-MS after  
30 derivatization of the carbonyl oxidation products. The results of the GC-MS analyses were  
31 consistent with the formation of semivolatile multi-functional oxygenates, including hydroxy

1 diones as well as triones, tetraones, and pentaones. The authors also suggested that some of  
2 these compounds could be present in SOPM in the form of polymers.

3 Jang and Kamens (2001a) employed a number of analytical approaches, including GC-MS  
4 detection of volatile derivatives of carbonyl, hydroxy, and acid compounds in SOPM formed in  
5 the irradiation of toluene/NO<sub>x</sub> mixtures. A wide range of substituted aromatics, nonaromatic  
6 ring-retaining and ring-opening products were detected. Newly identified ring-opening  
7 oxycarboxylic acids detected included glyoxylic acid; methylglyoxylic acid; 4-oxo-2-butenic  
8 acid; oxo-C<sub>5</sub>-alkenoic acids; dioxopentenoic acids; oxo-C<sub>7</sub>-alkadienoic acids; dioxo-C<sub>6</sub>-alkenoic  
9 acids; hydroxydioxo-C<sub>7</sub>-alkenoic acids; and hydroxytrioxo-C<sub>6</sub>-alkanoic acids. Other newly  
10 identified compounds included methylcyclohexenetriones; hydroxymethylcyclohexenetriones;  
11 2-hydroxy-3-penten-1,5-dial, hydroxyoxo-C<sub>6</sub>-alkenals; hydroxy-C<sub>5</sub>-triones, hydroxydioxo-C<sub>7</sub>-  
12 alkenals; and hydroxy-C<sub>6</sub>-tetranones. Included among these compounds were a number of the  
13 hydroxy polyketones detected by Edney et al., (2001).

14 Recent laboratory and field studies support the concept that nonvolatile and semivolatile  
15 oxidation products from the photooxidation of biogenic hydrocarbons contribute significantly to  
16 ambient PM concentrations in both urban and rural environments. The oxidation of a variety of  
17 biogenic hydrocarbons emitted by trees and plants, such as terpenes ( $\alpha$ -pinene,  $\beta$ -pinene,  
18  $\Delta^3$ -carene, sabinene,  $\alpha$ -terpinene,  $\gamma$ -terpinene, terpinolene, myrcene, and ocimene) and  
19 sesquiterpenes ( $\beta$ -caryophyllene and  $\alpha$ -humulene) could form SOPM. Vegetation also emits  
20 oxygenated organic compounds such as alcohols, acetates, aldehyde, ketones, ethers, and esters  
21 (Winer et al., 1992). However, their contribution to SOPM remains uncertain. Hoffmann et al.  
22 (1997) found SOPM yields of  $\approx$ 5% for open-chain biogenic hydrocarbons such as ocimene and  
23 linalool; 5 to 25% for monounsaturated cyclic monoterpenes such as  $\alpha$ -pinene,  $\Delta$ -3 carene and  
24 terpinene-4-ol; and  $\approx$ 40% for a cyclic monoterpene with an endocyclic and an exocyclic double  
25 bond such as d-limonene. Secondary organic PM yields of close to 100% were observed during  
26 the photochemical oxidation of one sesquiterpene, trans-caryophyllene. These results were all  
27 obtained for initial hydrocarbon mixing ratios of 100 ppb, which are much higher than found in  
28 the atmosphere.

29 Kamens et al. (1999) observed SOPM yields of 20 to 40% for  $\alpha$ -pinene. Using information  
30 on the composition of secondary PM formed from  $\alpha$ -pinene (Jang and Kamens, 1999), they were

1 able to calculate formation rates with a kinetic model including formation mechanisms for  
2  $O_3 + \alpha$ -pinene reaction products.

3 Griffin et al. (1999) introduced the concept of incremental aerosol reactivity, the change in  
4 the secondary organic aerosol mass produced (in  $\mu\text{g}/\text{m}^3$ ) per unit change of parent organic  
5 reacted (in ppb), as a measure of the aerosol-forming capability of a given parent organic  
6 compound in a prescribed mixture of other organic compounds. They measured the incremental  
7 aerosol reactivity for a number of aromatic and biogenic compounds for four initial mixtures.  
8 Incremental aerosol reactivity ranged from 0.133 to 10.352  $\mu\text{g m}^{-3} \text{ppb}^{-1}$  and varied by almost a  
9 factor of two depending on the initial mixture.

10 A number of multifunctional oxidation products produced by the oxidation of biogenic  
11 hydrocarbons have been identified in laboratory studies (Yu et al., 1998; Glasius et al., 2000;  
12 Christoffersen et al., 1998; Koch et al., 2000; and Leach et al., 1999). Many of these compounds  
13 have subsequently been identified in field investigations (Yu et al., 1999; Kavouras et al., 1998,  
14 1999a,b; Pio et al., 2001; and Castro et al., 1999). Most studies of the formation of secondary  
15 organic aerosol formation from terpenes have focused on their reactions with ozone. There have  
16 been many fewer studies dealing with the oxidation of terpenes initiated by OH radicals. Larsen  
17 et al. (2001) found that the major aerosol products produced ultimately from the reaction of OH  
18 radicals with monoterpenes with endocyclic double bonds ( $\alpha$ -pinene, 3-carene) were  $C_{10}$   
19 keto-carboxylic acids (such as pinonic and caronic acids); whereas the major products from the  
20 oxidation of monoterpenes with exocyclic double bonds ( $\beta$ -pinene) were  $C_9$ -dicarboxylic acids  
21 (such as pinic acid), and the major product from the oxidation of limonene (which has both  
22 endo- and exocyclic double bonds) was 3-acetyl-6-oxo-heptanal (keto-limonaldehyde). A large  
23 number of related aldehydes, ketones and acids were also found in their experiments. However,  
24 the total yields of condensable products are much lower than for the corresponding reactions  
25 with ozone. For example, yields of  $C_9$ -dicarboxylic acids,  $C_{10}$ -hydroxy-keto-carboxylic acids,  
26 and  $C_{10}$ -hydroxy-keto-aldehydes from the reaction of ozone with mono-terpenes with endocyclic  
27 double bonds ranged from 3% to 9%; whereas they ranged only from 0.4 to 0.6% in the reaction  
28 with OH radicals. Likewise, the reaction of monoterpenes with exocyclic double bonds with  
29 ozone produced much higher yields (1% to 4%) of  $C_8$ - and  $C_9$ -dicarboxylic acids than did their  
30 reaction with OH radicals (0.2% to 0.3%). Apart from the complex products noted above, it  
31 should be remembered that much simpler products, such as formaldehyde and formic acid, are

1 also formed in much larger yields from the same reactants (e.g., Winterhalter et al., 2000).  
2 Compounds such as these also contribute to the formation of secondary organic aerosol  
3 according to the mechanisms given in Pandis et al. (1992) and mentioned earlier in this section.

4 It is worth noting that the dicarboxylic acids and hydroxy-keto-carboxylic acids have very  
5 low vapor pressures and may act as nucleating species in OH- and O<sub>3</sub>-terpene reactions (Larsen  
6 et al., 2001). The rate coefficient for reaction of  $\alpha$ -pinene with OH radicals is approximately a  
7 factor of 10<sup>6</sup> greater than for its reaction with O<sub>3</sub>, based on data given in Atkinson (1994). The  
8 daytime average concentration of O<sub>3</sub> is typically a factor of 10<sup>6</sup> greater than that for OH radicals  
9 in polluted boundary layers; whereas the above mentioned yields of aerosol products are roughly  
10 a factor of ten greater in the O<sub>3</sub>-initiated reaction than in the corresponding OH radical reaction.  
11 The foregoing analysis suggests that the O<sub>3</sub>-initiated reaction may be more important than the  
12 OH-initiated reaction for the formation of aerosol products. During the day, new particles may  
13 be generated indoors through the infiltration of ambient ozone; and, because ambient ozone is  
14 also present at night in lower concentrations, new particles may be generated under these  
15 conditions at lower rates. For example, Wainman et al. (2000) found that ozone can react with  
16 limonene released by air fresheners in indoor environments to produce substantial quantities of  
17 submicron particles. The corresponding reaction involving OH radicals outdoors at night is  
18 expected to be negligible by comparison because of the very low OH concentrations present.  
19 Sarwar et al. (2002) estimated indoor OH radical concentrations and suggested that OH in indoor  
20 environments is produced mainly by reactions of ozone transported from outdoors and terpenes  
21 emitted from indoor sources. They reported that indoor OH levels ( $1-5 \times 10^5$  OH/cm<sup>3</sup>) are  
22 usually lower than typical urban outdoor daytime OH levels ( $1-5 \times 10^6$  OH/cm<sup>3</sup>). However, they  
23 can be greater than typical urban outdoor night time OH levels ( $1-5 \times 10^4$  OH/cm<sup>3</sup>). Although  
24 much progress has been made in determining the importance of anthropogenic and biogenic  
25 hydrocarbons for the formation of secondary organic PM, further investigations are needed to  
26 accurately assess their overall contributions to PM<sub>2.5</sub> concentrations.

27 Reactions of organic compounds either in particles or on the surface of particles have only  
28 come under study during the past 20 years. Tobias and Ziemann (2000) reported evidence for  
29 the formation of relatively stable low volatility peroxy hemiacetals from reactions of  
30 hydroperoxides with aldehydes and ketones on the surface of secondary organic particles.  
31 Not long after the publication of these results, Jang and Kamens (2001a) suggested, based on

1 results of their outdoor Teflon chamber studies of SOPM formation from irradiation of  
2 toluene/propylene/NO<sub>x</sub>/air mixtures, that carbonyls and hydroxy compounds (either within or on  
3 the surface of aromatic SOPM) could react together to form larger and less volatile hemiacetals  
4 and acetals. They also proposed that dissolved carbonyls could undergo further reactions  
5 leading to the formation of a polymer, a mechanism that has also been suggested by Edney et al.  
6 (2001). Jang and Kamens (2001b) carried out a series of screening experiments to assess  
7 whether volatile carbonyl compounds absorbed into particles could undergo heterogeneous  
8 reactions forming low vapor pressure compounds. Experiments were carried out in which  
9 aldehydes were introduced in Teflon bags in the dark in the presence of a seed aerosol containing  
10 either ammonium sulfate or a mixture of ammonium sulfate and sulfuric acid. The increase in  
11 the aerosol volume was then measured using a scanning mobility particle sizer. The aldehydes  
12 employed for the study included glyoxal, butanal, hexanal, octanal, and decanal. Increased  
13 organic aerosol yields were found in the presence of the ammonium sulfate seed aerosol for each  
14 of the carbonyls; the highest yield was found for hexanal followed in decreasing order by  
15 glyoxal and then octanal. The presence of the acidified sulfate salt significantly increased the  
16 yields even further. In a number of other experiments, 1-decanol was added to the carbonyl-  
17 aerosol system to investigate the possible formation of hemiacetals and/or acetals. Again, the  
18 volume of aerosol increased in both the presence of ammonium sulfate aerosol and the acidified  
19 salt with a significantly larger yield found in the presence of acidity.

20 To explain their findings for acid-catalyzed carbonyl reactions, Jang and Kamens (2001a,b)  
21 proposed a chemical mechanism in which the dissolved carbonyl first undergoes a protonization  
22 reaction forming an adduct that can react with water to form its hydrate (1,1-dihydroxy gem-  
23 diol). The adducts can then react with OH groups of the gem-diol forming higher molecular  
24 weight and less volatile dimers that are subject to further reactions. In principal, this process,  
25 which the authors refer to as a “zipping reaction” can lead to the formation of polymers.  
26 However, because the individual reactions are reversible, the process can be reversed by an  
27 unzipping reaction. The zipping process could serve as an important mechanism for SOPM  
28 formation by converting volatile oxidation products including glyoxal and methyl glyoxal into  
29 low volatility compounds. On the other hand, the unzipping process that could take place during  
30 the workup of the aerosol samples could be responsible for the detection of highly volatile  
31 oxidation products in SOPM, including glyoxal and methyl glyoxal, that has been reported by

1 Edney et al. (2001), Cocker et al. (2001), and Jang and Kamens (2001a). While these processes  
2 may take place in the absence of significant acidity, the experimental results suggest that the  
3 processes are likely enhanced by acid-catalyzed reactions. Further research is needed to  
4 determine the importance of the mechanisms proposed above for the ambient atmosphere.

5 Sampling and characterizing PM in the ambient atmosphere and in important  
6 microenvironments is required to address important issues in exposure, toxicology, and  
7 compliance. Currently, it is not possible to fully quantify the concentration, composition, or  
8 sources of the organic components. Many of the secondary organic aerosol components are  
9 highly oxidized, difficult to measure, multifunctional compounds. Additional laboratory studies  
10 are needed to identify such compounds; strategies need to be developed to sample and measure  
11 such compounds in the atmosphere; and models of secondary organic aerosol formation need to  
12 be improved and added to air quality models in order to address issues related to human  
13 exposure.

14 A high degree of uncertainty is associated with all aspects of the calculation of secondary  
15 organic PM concentrations. This is compounded by the volatilization of organic carbon from  
16 filter substrates during and after sampling as well as potential positive artifact formation from  
17 the absorption of gaseous hydrocarbon on quartz filters. Significant uncertainties always arise in  
18 the interpretation of smog chamber data because of wall reactions, sampling artifacts, and the  
19 use of unrealistically high concentrations of reactants. Limitations also exist in extrapolating the  
20 results of smog chamber studies to ambient conditions found in urban airsheds and forest  
21 canopies. Concentrations of terpenes and  $\text{NO}_x$  are much lower in forest canopies (Altshuller,  
22 1983) than the levels commonly used in smog chamber studies. The identification of aerosol  
23 products of terpene oxidation has seldom been a specific aim of field studies, making it difficult  
24 to judge the results of model calculations of secondary organic PM formation.

25 Uncertainties also arise because of the methods used to measure biogenic hydrocarbon  
26 emissions. Khalil and Rasmussen (1992) found much lower ratios of terpenes to other  
27 hydrocarbons (e.g., isoprene) in forest air than were expected based on their relative emissions  
28 strengths and rate coefficients for reaction with OH radicals and  $\text{O}_3$ . In many cases, reactions  
29 with these species are capable of reducing the concentrations of monoterpenes to beneath  
30 minimum detection levels as has been found by others in a wide range of North American forest  
31 ecosystems (Guenther et al., 1996, Helmig et al., 1998, Geron et al., 2000). Thus, making

1 judgments about the importance of additional loss processes can be a highly problematic  
2 exercise given uncertainties in obtaining relevant OH radical and O<sub>3</sub> concentrations and in the  
3 reaction rate coefficients. The ocimenes and sesquiterpenes are estimated to have half lives of  
4 seconds to minutes in the presence of ambient ozone levels while the pinenes and isoprene have  
5 lifetimes ranging from several hours to days. Reaction with hydroxyl radicals is the major sink  
6 for isoprene. Khalil and Rasmussen offered two explanations for their findings: (1) either the  
7 terpenes were being removed rapidly by some heterogeneous process or (2) emissions were  
8 enhanced artificially by feedbacks caused by the bag enclosures they used. The isoprene  
9 emission rates observed by Khalil and Rasmussen (1992) are reasonably consistent with those  
10 found by Geron et al. (2000a and 2001) given inevitable self-shading of much of the foliage  
11 within the bag enclosures and also the lower position of the foliage within the accessible portion  
12 of the sampled tree crowns. Temperatures were sufficiently warm ( $\geq 30$  °C) and sunny to induce  
13 high isoprene emission although cloudiness from a passing thunderstorm could have reduced  
14 these emissions from some of the species considerably. Disturbance or elevated temperatures  
15 may also have induced elevated monoterpene emissions from several of the species sampled by  
16 Khalil and Rasmussen because emissions rates they reported are in many cases 2-20 times higher  
17 than those reported by other investigators, including those who performed enclosure studies  
18 which did not cause elevated temperatures as well as micrometeorological flux studies which did  
19 not disturb the forest canopy. Thus the somewhat reduced isoprene emissions, combined with  
20 elevated monoterpene emissions, can indeed affect the comparison of ambient isoprene versus  
21 monoterpene emissions. However, monoterpene compounds recently have been found to  
22 undergo heterogenous reactions on the surface of acid aerosol particles. Further work is needed  
23 to assess the importance of these reactions on ambient monoterpene concentrations and in the  
24 rate of production of secondary organic PM in forest ecosystems.

### 26 **3.3.2 Source Contributions to Ambient PM Determined by Receptor Models**

27 Receptor models are perhaps the primary means used to estimate the contributions of  
28 different source categories to PM concentrations at individual monitoring sites. Dispersion  
29 models (i.e., three-dimensional chemistry and transport models) are formulated in a prognostic  
30 manner (i.e., they attempt to predict species concentrations using a tendency equation that  
31 includes terms based on emissions inventories, atmospheric transport, chemical transformations,

1 and deposition). Receptor models are diagnostic in their approach (i.e., they attempt to derive  
2 source contributions based either on ambient data alone or in combination with data from the  
3 chemical composition of sources). These methods have the advantage that they do not invoke all  
4 of the uncertainties inherent in emissions inventories or in parameterizing atmospheric transport  
5 processes in grid point models.

6       There are two main approaches to receptor modeling. Receptor models such as the  
7 chemical mass balance (CMB) model (Watson et al., 1990a) relate source category contributions  
8 to ambient concentrations based on analyses of the composition of ambient particulate matter  
9 and source emissions samples. This technique has been developed for apportioning source  
10 categories of primary particulate matter and was not formulated to include the processes of  
11 secondary particulate matter formation. In the second approach, various forms of factor analysis  
12 are used that rely on the analysis of time series of compositional data from ambient samples to  
13 derive both the composition of sources and the source contributions. Standard approaches such  
14 as factor analysis or Principal Component Analysis (PCA) can apportion only the variance and  
15 not the mass in an aerosol composition data set. The other techniques described below, PMF and  
16 UNMIX, do apportion mass, however. Positive matrix factorization (PMF) is a recently  
17 developed multivariate technique (Paatero and Tapper, 1993; 1994) that overcomes many of the  
18 limitations of standard techniques, such as PCA, by allowing for the treatment of missing data  
19 and data near or below detection limits. This is accomplished by weighting elements inversely  
20 according to their uncertainties. Standard methods such as PCA weight elements equally  
21 regardless of their uncertainty. Solutions also are constrained to yield non-negative factors.  
22 Both the CMB and the PMF approaches find a solution based on least squares fitting and  
23 minimize an object function. Both methods provide error estimates for the solutions based on  
24 estimates of the errors in the input parameters. It should be remembered that the error estimates  
25 often contain subjective judgments. For a complete apportionment of mass, all of the major  
26 sources affecting a monitoring site must be sampled for analysis by CMB; whereas there is no  
27 such restriction in the use of PMF.

28       Among other approaches, the UNMIX model takes a geometric approach that exploits the  
29 covariance of the ambient data to determine the number of sources, the composition and  
30 contributions of the sources, and the uncertainties (Henry, 1997). A simple example may help  
31 illustrate the approach taken by UNMIX. In a two-element scatter plot of ambient Al and Si, a

1 straight line and a high correlation for Al versus Si can indicate a single source for both species  
2 (soil) while the slope of the line gives information on the composition of the soil source. In the  
3 same data set, iron may not plot on a straight line against Si, indicating other sources of Fe in  
4 addition to soil. More importantly, the Fe-Si scatter plot may reveal a lower edge. The points  
5 defining this edge represent ambient samples collected on days when the only significant source  
6 of Fe was soil. Success of the UNMIX model hinges on the ability to find these “edges” in the  
7 ambient data from which the number of source types and the source compositions are extracted.  
8 UNMIX uses principal component analysis to find edges in m-dimensional space, where m is the  
9 number of ambient species. The problem of finding edges is more properly described as finding  
10 hyperplanes that define a simplex. The vertices at which the hyperplanes intersect represent pure  
11 sources from which source compositions can be determined. However, there are measurement  
12 errors in the ambient data that “fuzz” the edges making them difficult to find. UNMIX employs  
13 an “edge-finding” algorithm to find the best edges in the presence of error. UNMIX does not  
14 make explicit use of errors or uncertainties in the ambient concentrations, unlike the methods  
15 outlined above. This is not to imply that the UNMIX approach regards data uncertainty as  
16 unimportant, but rather that the UNMIX model results implicitly incorporate error in the ambient  
17 data. The underlying philosophy is that the uncertainties are often unquantifiable, and hence it is  
18 best to make no *a priori* assumptions about what they are.

19 In addition to chemical speciation data, Norris et al. (1999) showed that meteorological  
20 indices could prove useful in identifying sources of particulate matter that are responsible for  
21 observed health effects (specifically asthma) associated with exposure to particulate matter.  
22 They examined meteorology associated with elevated pollution events in Spokane and Seattle,  
23 WA, and identified a “stagnation index” that was associated with low wind speeds and increases  
24 in concentrations of combustion-related pollutants. Their factor analysis also identified a  
25 meteorological index (low relative humidity and high temperatures) that was associated with  
26 increases in soil-derived particulate matter as well as a third factor (low temperatures and high  
27 relative humidity) that was associated with increases in concentrations of particulate sulfate and  
28 nitrate species (Norris, 1998).

29 Ondov (1996) examined the feasibility of using sensitive isotopic and elemental tracer  
30 materials to determine the contributions of petroleum-fueled sources of PM<sub>10</sub> in the San Joaquin  
31 Valley, CA. Costs of these experiments are affected not only by the tracer materials cost, but

1 also by the sensitivities of the analytical methods for each, as well as the background levels of  
2 the tracers. Suarez et al. (1996) used iridium as a tracer to tag emissions from diesel-burning  
3 sanitation trucks in Baltimore and determined the size distribution of soot from the trucks.

4 A number of specialty conference proceedings, review articles, and books have been  
5 published that provide greater detail about source category apportionment receptor models than  
6 described in the 1996 PM AQCD. A review of the various methods used to apportion PM in  
7 ambient samples among its source categories was given in Section 5.5.2 of the 1996 PM AQCD.  
8 The collection of the source category characterization profiles shown in Appendix 3D has been  
9 motivated in many cases by the need to use them in receptor modeling applications.

10 The results of several source apportionment studies are discussed in this section to provide  
11 an indication of the relative importance of different sources of particulate matter across the  
12 United States. First, results obtained mainly by using the chemical mass balance (CMB)  
13 approach for estimating contributions to  $PM_{2.5}$  from different source categories at monitoring  
14 sites in the United States are discussed and presented in Table 3-9. More recent results using the  
15 PMF approach are included for Phoenix, AZ. Results obtained at a number of monitoring sites  
16 in the central and western United States by using the CMB model for  $PM_{10}$  are shown in  
17 Table 3-10. The sampling sites represent a variety of different source characteristics within  
18 different regions of Arizona, California, Colorado, Idaho, Illinois, Nevada, and Ohio.  
19 Definitions of source categories also vary from study to study. The results of the  $PM_{10}$  source  
20 apportionment studies were given in the 1996 PM AQCD and are presented here to allow easy  
21 comparison with results of  $PM_{2.5}$  source apportionment studies. Chow and Watson (2002)  
22 present a detailed comparison of numerous studies using the CMB model performed mainly after  
23 1995.

24 There are several differences between the broadly defined source categories shown at the  
25 tops of Tables 3-9 and 3-10. These differences reflect the nature of sources that are important  
26 for producing fine and coarse particulate matter shown in Table 3-8. They also are related to  
27 improvements in the ability to distinguish between sources of similar nature (e.g., diesel and  
28 gasoline vehicles, meat cooking, and vegetation burning). The use of organic tracers allows  
29 motor vehicle emissions to be broken down into contributions from diesel and gasoline vehicles.  
30 In studies where this distinction cannot be made, the source type is listed as ‘total motor  
31 vehicles’ in the tables. The studies that were reported to be able to distinguish gasoline- from

<sup>w</sup>Incineration<sup>x</sup>Unexplained mass

1 diesel-fueled vehicles found that gasoline vehicles make significant, and sometimes the  
2 dominant, contributions to ambient  $PM_{2.5}$  concentrations. Meat cooking is also distinguished  
3 from vegetation burning in more recent studies although both are considered to be part of  
4 biomass burning. Vegetation burning consists of contributions from residential fuel wood  
5 burning, wildfires, prescribed burning, and burning of agricultural and other biomass waste.  
6 Miscellaneous sources of fine particles include contributions from combustion sources; whereas  
7 miscellaneous sources of coarse particles consist of contributions from soil and sea spray and  
8 industrial processing of geological material (e.g., cement manufacturing). Although a large  
9 number of elements and chemical components are used to differentiate among source categories  
10 and although there can be a large number of source types affecting a given site, only a few  
11 broadly defined source types are needed to account for most of the mass of  $PM_{2.5}$  and  $PM_{10}$ .  
12 At any given site,  $\leq 5$  source types account for  $> 65\%$  of the mass of  $PM_{2.5}$  (Table 3-9); and  
13  $\leq 5$  source types account for  $> 65\%$  of the mass of  $PM_{10}$  (Table 3-10).

14 Secondary sulfate is the dominant component of  $PM_{2.5}$  samples collected in the studies of  
15 Dzubay et al. (1988) and Glover et al. (1991). Both studies found that sulfate at their monitoring  
16 site arose from regionally dispersed sources. Sulfate also represents the major component of  
17  $PM_{2.5}$  found in monitoring studies in the eastern United States shown in Appendix 6A of the  
18 1996 PM AQCD. Primary and secondary organic components also make major contributions to  
19  $PM_{2.5}$ . Contributions from road dust and soils are relatively minor, typically constituting less  
20 than 10% of  $PM_{2.5}$  in the studies shown in Table 3-9. Studies in the western United States shown  
21 in Table 3-9 have found larger contributions from motor vehicles, fugitive dust, and ammonium  
22 nitrate. The most notable difference in the relative importance of major source categories of  
23  $PM_{2.5}$  shown in Table 3-9 and  $PM_{10}$  shown in Table 3-10 involves crustal material, (e.g., soil,  
24 road dust), which represents about 40% on average of the total mass of  $PM_{10}$  in the studies  
25 shown in Table 3-10. The fraction is higher at sites located away from specific sources such as  
26 sea spray or smelters. Emissions of crustal material are concentrated mainly in the  $PM_{10-2.5}$  size  
27 range.

28 In Table 3-10, primary motor vehicle exhaust contributions are highly variable and can  
29 account for over 40% of average  $PM_{10}$  at a few of the sampling sites. Vehicle exhaust  
30 contributions are also variable at different sites within the same study area. The mean value and  
31 the variability of motor vehicle exhaust contributions reflects the proximity of sampling sites to

1 roadways and traffic conditions during the time of sampling. Many studies were conducted  
2 during the late 1980s when a portion of the vehicle fleet still used leaded gasoline. Pb and Br in  
3 motor vehicle emissions facilitated the distinction of motor vehicle contributions from other  
4 sources. Vehicles using leaded fuels have higher emission rates than vehicles using unleaded  
5 fuels. Pb also poisons automobile exhaust catalysts and produces adverse human health effects.  
6 As a result, Pb has been eliminated from vehicle fuels. Organic species such as n-pentacosane  
7 through n-nonacosene, cholestanes, ergostanes, sitostanes, and hopanes have replaced Pb as a  
8 source marker for motor vehicle emissions (e.g., Schauer and Cass, 2000). In their  
9 comprehensive review of CMB modeling studies undertaken since 1995, Chow and Watson  
10 (2002) note that in twenty-two studies fossil fuel combustion was found to be a large contributor  
11 to PM<sub>2.5</sub> and PM<sub>10</sub> concentrations, with most of the contributions to primary PM originating from  
12 the exhaust of diesel and gasoline vehicles.

13 Marine aerosol is found, as expected, at coastal sites such as Long Beach (average 3.8% of  
14 total mass) and San Nicolas Island (25%). These contributions to PM<sub>10</sub> are relatively variable  
15 and are larger at the more remote sites. Individual values reflect proximity to local sources.  
16 Of great importance are the contributions from secondary ammonium sulfate in the eastern  
17 United States and ammonium nitrate in the western United States. Secondary ammonium sulfate  
18 is especially noticeable at sites in California's San Joaquin Valley (Bakersfield, Crows Landing,  
19 Fellows, Fresno, and Stockton) and in the Los Angeles area.

20 Because many source apportionment studies address problems in compliance with the  
21 National Ambient Air Quality Standards and other air quality standards, samples selected for  
22 chemical analysis are often biased toward the highest PM<sub>10</sub> mass concentrations in the studies  
23 shown in Table 3-10. Thus, the average source contribution estimates shown in Table 3-10 are  
24 probably not representative of annual averages and may not be representative of a large spatial  
25 area for some source-dominated studies. For example, the study by Motallebi (1999) considered  
26 only days when the PM<sub>10</sub> concentration was greater than 40 µg/m<sup>3</sup>. Quoted uncertainties in the  
27 estimated contributions of the individual sources shown in Tables 3-9 and 3-10 range from 10 to  
28 50%. Errors can be much higher when the chemical source profiles for different sources are  
29 highly uncertain or are too similar to distinguish one source from another.

30 Very few source apportionment studies using the CMB modeling technique have examined  
31 the spatial variability of source contributions at different sites within an urban area. As can be

1 seen from Table 3-9, Dzubay et al. (1988) found a uniform distribution of sulfate at the NE  
2 Airport in Philadelphia, PA; downtown Camden, NJ; and Clarksboro, NJ, during the summer of  
3 1982. The farthest distance between two monitoring sites (NE Airport and Clarksboro) was  
4 approximately 40 km. Magliano et al. (1998) examined the spatial variability of PM<sub>10</sub> source  
5 contributions at a number of sites in Fresno and Bakersfield, CA, during the winter of 1995-1996  
6 and reported values for 1 day, December 27, 1995. During that day, mobile sources contributed  
7 from 13.0 to 15.8 µg/m<sup>3</sup>, vegetation burning contributed from 5.1 to 11.1 µg/m<sup>3</sup>, ammonium  
8 sulfate contributed 2.4 to 3.4 µg/m<sup>3</sup>, and ammonium nitrate contributed 19.3 to 24.6 µg/m<sup>3</sup> to  
9 PM<sub>10</sub> at the sites in Bakersfield. Mobile sources contributed 13.9 to 22.5 µg/m<sup>3</sup>, vegetation  
10 burning contributed 8.2 to 15.7 µg/m<sup>3</sup>, ammonium sulfate contributed 1.8 to 2.3 µg/m<sup>3</sup>, and  
11 ammonium nitrate contributed 14.5 to 18.9 µg/m<sup>3</sup> at the sites in Fresno. All of these components  
12 are expected to be found mainly in the PM<sub>2.5</sub> size fraction. As can be seen, source contributions  
13 at different sites varied by factors of 1.2 to 2.2 in Bakersfield and by factors of 1.3 to 1.9 in  
14 Fresno on that day.

15 The receptor modeling methods outlined above do not explicitly include consideration of  
16 the distances between PM sources and the receptor site. Information about the relative  
17 importance of sources as a function of distance may be available from examination of data  
18 obtained by continuous monitoring methods. For example, concentration spikes are expected to  
19 be the result of transport from nearby sources because turbulent mixing in the atmosphere would  
20 not allow them to persist for very long. Short duration spikes in the time series of concentrations  
21 are assumed to result from emissions from local sources (0.1 to 1 km away) in this method.  
22 Contributions from sources located further away are determined by comparisons between  
23 baselines measured at different sites. Details such as these are also lost in integrated 24-h  
24 samples. Watson and Chow (2001) used time series of black carbon (BC) obtained by  
25 aetholometers over five minute intervals to estimate the contributions from sources located  
26 < 1 km away, 1 to 5 km away, and > 5 km away from a monitoring site in downtown Mexico  
27 City. They found that most of the BC was produced by sources scattered throughout the city and  
28 that sources located less than 1 km away from the site contributed only about 10% to BC  
29 concentrations even in the presence of local sources such as buses and trucks.

### 3.3.3 Background Concentrations of PM in the United States

This section contains information about the concentrations of “background” PM that are relevant for policy setting. For the purposes of this document (and consistent with the 1996 PM AQCD), background concentrations are those that would result in the United States from emissions from natural sources worldwide plus anthropogenic sources outside of North America. In other words, they are the concentrations that would exist if anthropogenic emissions in North America were zero. Concentrations defined this way will be referred to here as policy relevant background (PRB) concentrations. It is impossible to obtain estimates of PRB concentrations solely by examining measurements of PM<sub>2.5</sub>, PM<sub>10-2.5</sub>, or PM<sub>10</sub> concentrations because of long-range transport from anthropogenic source regions within North America. Other additional information must be used.

Annual average natural background concentrations of PM<sub>10</sub> have been estimated to range from 4 to 8 µg/m<sup>3</sup> in the western United States and 5 to 11 µg/m<sup>3</sup> in the eastern United States. Corresponding PM<sub>2.5</sub> levels have been estimated to range from 1 to 4 µg/m<sup>3</sup> in the western United States and from 2 to 5 µg/m<sup>3</sup> in the eastern United States; PM<sub>10-2.5</sub> levels have been very roughly estimated at 3 µg/m<sup>3</sup> in both the East and the West, with a range of 0 to 9 µg/m<sup>3</sup> in the East and 0 to 7 µg/m<sup>3</sup> in the West (U.S. Environmental Protection Agency, 1996). The estimated natural background concentrations given above do not include contributions from long-range transport from sources outside North America. Values in the lowest 5<sup>th</sup> percentile annual mean PM<sub>2.5</sub> concentrations for specific sites in the AIRS data base range from 2.8 µg/m<sup>3</sup> to 6.9 µg/m<sup>3</sup>. This range is consistent with the range of annual mean PM<sub>2.5</sub> concentrations at IMPROVE network sites in the western United States (cf., Appendix E). However, PM<sub>2.5</sub> concentrations are much higher at sites in the eastern United States than at sites in the western United States. At most IMPROVE sites in the western United States, the annual mean concentration of PM<sub>10-2.5</sub> is higher than that of PM<sub>2.5</sub>, and daily average PM<sub>2.5</sub> concentrations are moderately correlated ( $r = 0.72$ ) with PM<sub>10-2.5</sub> concentrations. In contrast, PM<sub>2.5</sub> concentrations are higher than those of PM<sub>10-2.5</sub> at IMPROVE sites in the eastern United States, and PM<sub>2.5</sub> concentrations are only weakly correlated ( $r = 0.26$ ) with those of PM<sub>10-2.5</sub>. Peak 24-h average natural background concentrations may be substantially higher than the annual or seasonal average natural background concentrations, especially within areas affected by wildfires and dust storms.

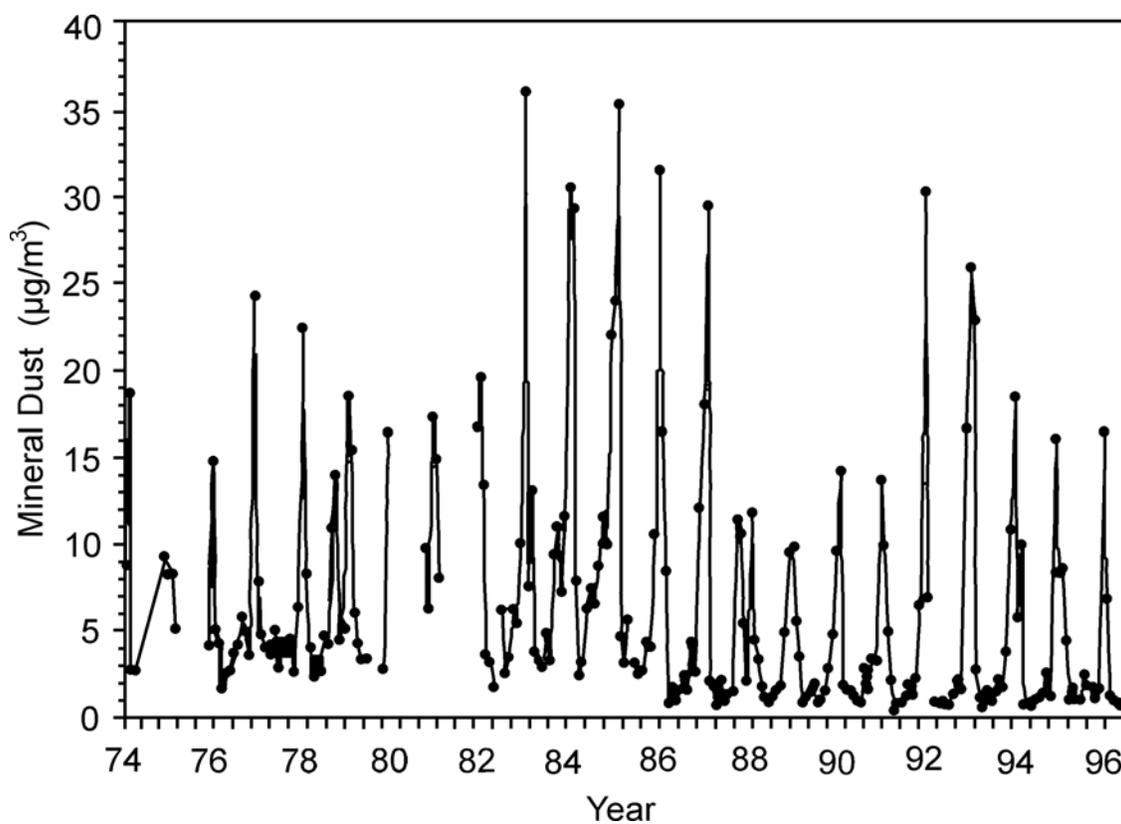

1 Sources of PM that fit under the definition of PRB are located either within or outside of North  
2 America.

### 4 *Long-Range Transport from Outside North America*

5 Windblown dust from dust storms in the Sahara desert has been observed in satellite  
6 images as plumes crossing the Atlantic Ocean and reaching the southeast coast of the United  
7 States (e.g., Ott et al., 1991). Dust transport from the deserts of Asia across the Pacific Ocean  
8 also occurs (Prospero, 1996). Most dust storms in the deserts of China occur in the spring  
9 following the passage of strong cold fronts after the snow has melted and before a surface  
10 vegetation cover has been established. Strong winds and unstable conditions result in the rapid  
11 transport of dust to altitudes of several kilometers where it is transported by strong westerly  
12 winds out over the Pacific Ocean (Duce, 1995). Satellite images were used to track the progress  
13 of a dust cloud from the Gobi desert to the northwestern United States during the spring of 1998  
14 (Husar et al., 2000).

15 Satellite images obtained at visible wavelengths cannot track mineral dust across the  
16 continents because of a lack of contrast between the plume and the underlying surface. Other  
17 means must be used to track the spread of North African dust through the eastern United States.  
18 Perry et al. (1997) used two criteria ( $PM_{2.5}$  soil concentration  $> 3 \mu\text{g m}^{-3}$  and  $Al/Ca > 3.8$ ) to  
19 distinguish between soil of local origin from soil originating in North Africa in characterizing  
20 the sources of PM in aerosol samples collected in the IMPROVE network. North African dust  
21 has been tracked as far north as Illinois (Gatz and Prospero, 1996) and Maine (Perry et al.,  
22 1997). The analysis of Perry et al. (1997) indicates that incursions of Saharan dust into the  
23 continental United States have occurred, on average, about three times per year from 1992 to  
24 1995. These events persist for about 10 days on average, principally during the summer. Large  
25 scale dust events typically cover from 15 to 30% of the area of the continental United States and  
26 result in increases of  $PM_{2.5}$  levels of  $8.7 \pm 2.3 \mu\text{g m}^{-3}$  throughout the affected areas during these  
27 events, with mean maximum dust contributions of  $19.7 \pm 8.4 \mu\text{g m}^{-3}$  and a peak contribution of  
28  $32 \mu\text{g m}^{-3}$  to 24-h average  $PM_{2.5}$  levels.

29 As can be expected, the frequency of dust events is highest in the southeastern United  
30 States. About half of these events are observed only within the state of Florida and are  
31 associated with dense hazes in Miami (Figure 3-22) during the summer (Prospero et al., 1987).

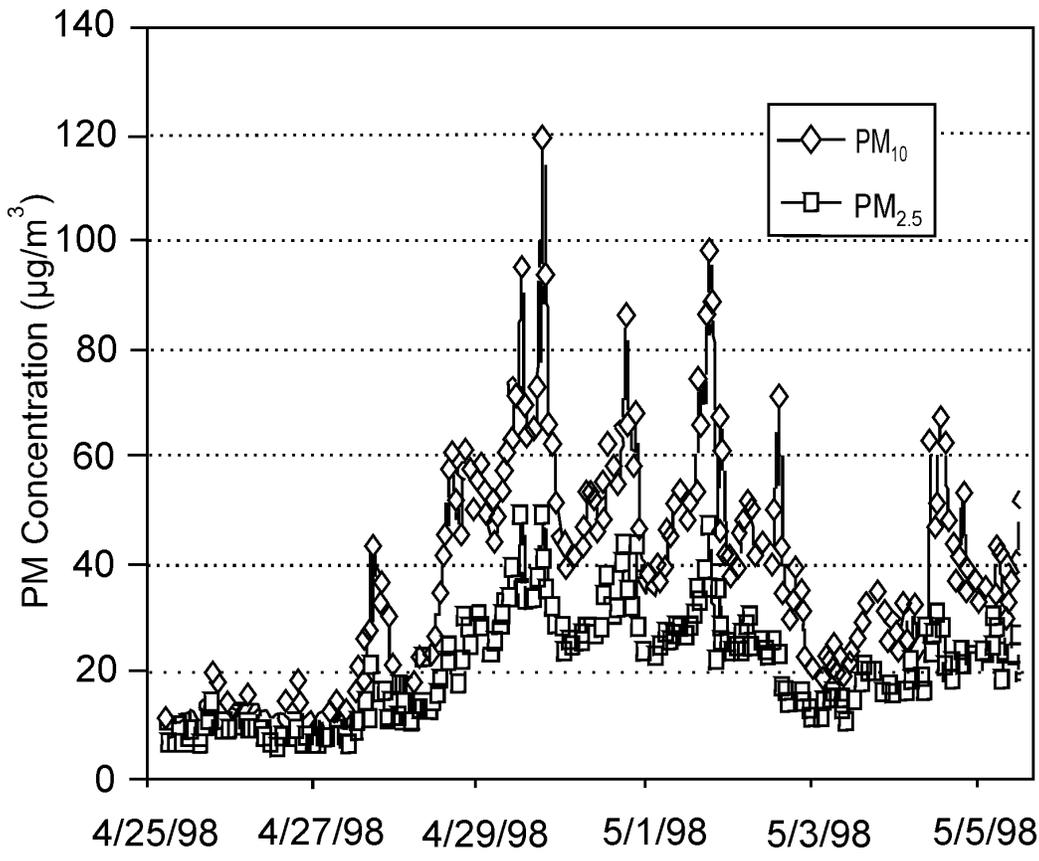

**Figure 3-22. Monthly average Saharan dust components of the aerosol sampled in Miami, FL, from 1974 to 1996. Approximately one-third to one-half of Saharan dust is in the PM<sub>2.5</sub> size range.**

Source: Prospero (1999).

1 North African dust is the dominant aerosol constituent in southern Florida during the summer;  
 2 whereas soil dust constitutes only a minor fraction of PM during the remainder of the year  
 3 (Prospero, 1999). Approximately one-third to one-half of the mass of the particles reaching  
 4 southern Florida have aerodynamic diameters less than 2.5 micrometers (Prospero et al., 2001).  
 5 During episodes when daily total dust concentrations ranged up to 100 µg/m<sup>3</sup>, it can be seen that  
 6 daily PM<sub>2.5</sub> concentrations of up to 50 µg/m<sup>3</sup> could have resulted in Miami, FL.

7 Husar et al. (2000) documented the transport of dust from the Gobi and Taklimakan deserts  
 8 to North America during April 1998. The PM<sub>10</sub> concentration averaged over 150 stations in  
 9 Washington, Oregon, California, Nevada, and Idaho reporting data to AIRS was 65 µg/m<sup>3</sup>

1 between April 26 and May 1, compared to about 20  $\mu\text{g}/\text{m}^3$  during the rest of April and May.  
2 Data from several networks indicated that  $\text{PM}_{10}$  concentrations were over 100  $\mu\text{g}/\text{m}^3$  in central  
3 British Columbia, Washington State, and Oregon. The highest PM concentrations observed  
4 were 120  $\mu\text{g}/\text{m}^3$  for  $\text{PM}_{10}$  and 50  $\mu\text{g}/\text{m}^3$  for  $\text{PM}_{2.5}$  at Chilliwack Airport in northwestern  
5 Washington State (Figure 3-23). Aircraft measurements made over the northwestern United  
6 States were consistent with a mass median diameter of the dust being between 2 and 3  $\mu\text{m}$ .  
7

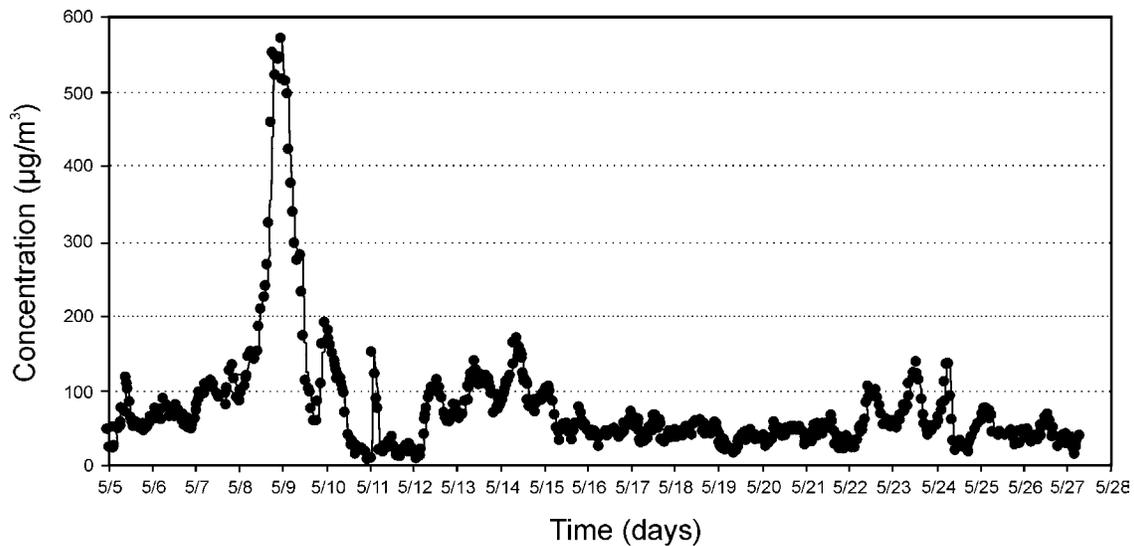

**Figure 3-23.  $\text{PM}_{2.5}$  and  $\text{PM}_{10}$  concentrations measured at Chilliwack Airport, located in northwestern Washington State, just before and during the Asian desert dust episode of April and May 1998.**

Source: Aerometric Information Retrieval System (AIRS; U.S. Environmental Protection Agency, 2002b).

1 Desert dust deposited over oceans provides nutrients to marine ecosystems (Savoie and  
2 Prospero, 1980). Desert dust deposited on nutrient depleted soils also provides nutrients, as in  
3 Hawaiian rain forests (Chadwick et al., 1999). Microorganisms, including fungi and bacteria,  
4 have been found attached to African dust particles in the U.S. Virgin Islands (Griffin et al.,  
5 2001). The fungus, *Aspergillus sydowii*, which has been connected to the death of coral reefs,  
6 has been identified in air samples collected in the Caribbean during African dust transport events  
7 (Smith et al., 1996; Shinn et al., 2000). Measurements of the composition of Saharan dust in  
8 Miami indicate enhancements of nitrate, non-sea-salt sulfate, ammonium, and trace metals over  
9 concentrations expected for clean marine air, suggesting pollution emitted in Europe and North  
10 Africa as sources (Prospero, 1999). It is likely that many other constituents will be found  
11 associated with dust from outside North America as more measurements are made. It should be  
12 noted that, as North African dust and associated material are transported northward through the  
13 United States during the summer, they are added to the mixture of primary and secondary PM  
14 generated domestically.

15 The transport of PM from uncontrolled biomass burning in Central America and southern  
16 Mexico resulted in anomalously high PM levels observed in southern Texas and generally  
17 elevated PM concentrations throughout the entire central and southeastern United States during  
18 the spring and early summer of 1998. Biomass burning for agricultural purposes occurs  
19 normally during the spring of each year in Central America and southern Mexico. During the  
20 spring of 1998, fires burned uncontrollably because of abnormally hot and dry conditions  
21 associated with the intense El Niño of 1997 to 1998. PM<sub>10</sub> concentrations observed in the  
22 southern Rio Grande Valley were elevated substantially during the passage northward of the  
23 biomass burning plume produced by these fires as shown in Figure 3-24. Elevated PM<sub>10</sub>  
24 concentrations also were found as far north as St. Louis, MO (Figure 3-25). As can be seen from  
25 Figure 3-24 and Figure 3-25, the elevations in PM concentrations were limited in duration.  
26 Uncontrolled wildfires occur in the United States every year, but their effects on air quality  
27 throughout the United States still need to be evaluated systematically. These fires can be  
28 widespread, and the frequency of their occurrence can vary markedly from year to year.  
29 For example, approximately 26,000 km<sup>2</sup> of forested land were consumed during 2000, but only a  
30 small fraction of this area was burnt during 2001 in the western United States. Wildfires also  
31 occur throughout the boreal forests of Canada. Wotawa and Trainer (2000) suggested that the

**Figure 3-24. Time series of 24-h average PM<sub>10</sub> concentrations observed in the Rio Grande Valley during May 1998.**

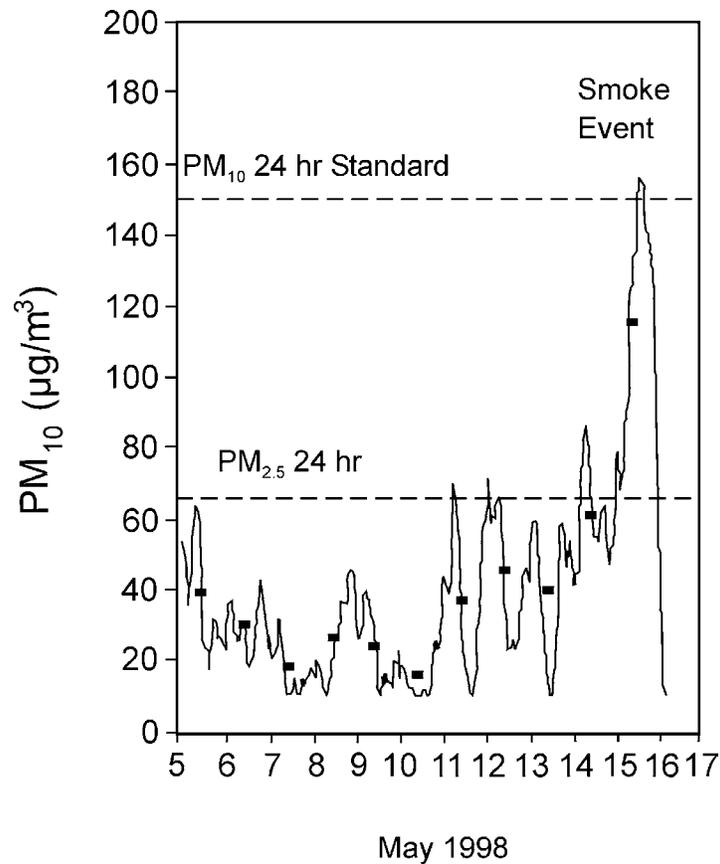

Source: Aerometric Information Retrieval System (AIRS; U.S. Environmental Protection Agency, 2002b).

1 plume from fires occurring in the Northwest Territories of Canada in early July 1995 may have  
 2 extended throughout most of the eastern United States, resulting in elevated levels of CO and  
 3 ozone. Simple scaling of their calculated excess CO concentrations because of the fires, by the  
 4 ratio of emission factors of PM<sub>2.5</sub> to CO, indicates that the excess PM<sub>2.5</sub> concentrations in the  
 5 plume may have ranged from about 5 µg/m<sup>3</sup> in the Southeast and to close to 100 µg/m<sup>3</sup> in the  
 6 northern Plains States.

7

8 ***Sources Within North America***

9 It is much more difficult to determine 24-h PRB concentrations in the absence of specific  
 10 events such as those given above because contributions from anthropogenic sources located  
 11 either nearby or elsewhere within North America can contribute substantially to observed values  
 12 and perhaps overwhelm the contributions from PRB sources. Source-apportionment modeling  
 13 techniques (described in Section 5.5 of the 1996 PM AQCD and updated in Section 3.3.2 of this  
 14 document) can be helpful for this purpose. Western sites are most useful because contributions  
 15 from pollution sources can overwhelm those from background sources in the East, and

**Figure 3-25. PM<sub>10</sub> concentrations observed in St. Louis, MO, during May 1998.**

Source: Aerometric Information Retrieval System (AIRS; U.S. Environmental Protection Agency, 2002b).

1 background source contributions can be lost within the errors of their source contributions.  
 2 However, it should be noted that source apportionment techniques such as PMF are not able to  
 3 distinguish between bioaerosol and organic PM from whatever source, mainly because of  
 4 analytical limitations. In addition, background PM source contributions are contaminated by  
 5 contributions from pollution sources during transport from source to receptor monitoring site.  
 6 Thus, background source contributions derived by these methods should be regarded as upper  
 7 limits on the true values; however, the daily time series can provide more stringent limits about  
 8 what the day to day variability in these contributions might be than by examining ambient PM<sub>2.5</sub>  
 9 data alone.

10 Song et al. (2001) derived source contributions to PM<sub>2.5</sub> concentrations measured at  
 11 Washington, DC, Brigantine, NJ, and Underhill, VT, using PMF. They found that wildfires

1 could contribute  $0.93 \pm 0.97 \mu\text{g}/\text{m}^3$ ; soil could contribute  $0.11 \pm 0.22 \mu\text{g}/\text{m}^3$ ; and sea spray could  
2 contribute  $0.90 \pm 1.0 \mu\text{g}/\text{m}^3$  on an annual basis at Brigantine, NJ throughout the sampling period  
3 from 1989 to 1999. They also derived contributions of  $1.2 \pm 0.9 \mu\text{g}/\text{m}^3$  from wildfires;  $0.32 \pm$   
4  $0.61 \mu\text{g}/\text{m}^3$  from soil; and  $0.05 \pm 0.05 \mu\text{g}/\text{m}^3$  from sea spray at Underhill, VT from 1989 through  
5 1999. The “background” sources contribute about 7% to annual average  $\text{PM}_{2.5}$  concentrations at  
6 Brigantine and about 12% at Underhill. The daily time series at the NJ and VT sites show  
7 striking variability in background components, characterized by spikes. Maximum daily values  
8 during these spikes are in the range of several  $\mu\text{g}/\text{m}^3$ . Song et al. concluded these spikes in  
9 concentrations are likely caused by transient meteorological events such as storms or transport of  
10 dust from remote regions such as northern Africa and by events such as wild fires. Contributions  
11 from all of these sources should be regarded as upper limits because of entrainment of pollutant  
12 emissions during transport from source to receptor of the background source emissions.

13 Pun et al. (2002) used a regional scale chemistry-transport model (CMAQ) to simulate  $\text{O}_3$   
14 and  $\text{PM}_{2.5}$  concentrations arising from natural sources alone in model domains centered over  
15 Tennessee and over the mid-Atlantic region for several days in July 1995. These calculations  
16 were performed for meteorological conditions that resulted in high ambient ozone concentrations  
17 in the eastern United States. They found that natural sources contributed about  $1.7 \mu\text{g}/\text{m}^3$  to  
18 Washington, DC, ( ranging from about  $0.6$  to  $3.1 \mu\text{g}/\text{m}^3$  in the mid-Atlantic domain) and about  
19  $1.2 \mu\text{g}/\text{m}^3$  to Nashville, TN, on a 24 h average basis. The formation of secondary organic PM  
20 from biogenic precursors may be expected to be maximized for these conditions; however, their  
21 contribution was estimated to be at most 15% of natural  $\text{PM}_{2.5}$  or less than  $1 \mu\text{g}/\text{m}^3$ . The largest  
22 contributions in both cases came from natural  $\text{PM}_{2.5}$  that was advected in from other regions of  
23 the United States. In addition to the sources considered above, contributions to both primary and  
24 secondary PM from events such as volcanic eruptions or geothermal activity are highly sporadic.  
25 The spatial and temporal distributions of secondary PM produced by background sources shown  
26 in Table 3-8 still remain to be investigated.

27 It can be concluded from the above that 24-h policy relevant background concentrations  
28 are highly variable both spatially and temporally. Contributions to PRB concentrations from  
29 external sources (e.g., Asian and North African dust storms and Central American wildfires) can  
30 be significant on an episodic, but probably not on an annual basis. More local sources of  
31 primary PRB PM are also likely to be episodic, reflecting the occurrence of volcanic eruptions,

1 wildfires, and storms that raise dust and sea spray. The influence from events such as these can  
2 be felt over thousands of square kilometers. Very little work has been done to quantify the  
3 magnitude and variability of contributions from the production of secondary PM. However, the  
4 one modeling study cited above found values  $< 1 \mu\text{g}/\text{m}^3$  as secondary PM. Perhaps the greatest  
5 possibility for estimating these concentrations comes from the application of source  
6 apportionment techniques such as PMF (positive matrix factorization) to time series of species  
7 compositional data obtained at relatively remote monitoring sites (RRMS) to minimize  
8 interference from anthropogenic sources. In the absence of such results, some useful estimates  
9 may be obtained by examining the time series of PM concentrations at RRMS with screening to  
10 eliminate days when concentrations are influenced by anthropogenic sources.

11 It is instructive in this regard to examine the variability observed at RRMS. Data from  
12 eighteen IMPROVE sites are examined in Appendix 3E and analyzed in greater detail in Lefohn  
13 et al. (2004). The ranges of annual average  $\text{PM}_{2.5}$ ,  $\text{PM}_{10-2.5}$ , and  $\text{PM}_{10}$  concentrations are shown  
14 in Table 3-E1 and the corresponding ranges for the 90<sup>th</sup> percentile concentrations are  
15 summarized in Table 3-E2. Information about the range of 24-h average  $\text{PM}_{2.5}$  and  $\text{PM}_{10-2.5}$   
16 concentrations observed at selected sites in the IMPROVE network on a calendar quarter basis  
17 are shown in Figures 3-E2a-d and Figures 3-E3a-d.

18 As mentioned earlier, it is impossible to obtain estimates of PRB concentrations solely on  
19 the basis of measurements of  $\text{PM}_{2.5}$ ,  $\text{PM}_{10-2.5}$ , or  $\text{PM}_{10}$ . It is preferable to quantify contributions  
20 from both background and non-background sources by using compositional data in techniques  
21 such as source apportionment modeling. However, of those measured throughout the United  
22 States, the concentrations observed at several RRMS in the western United States probably come  
23 closest to what PRB concentrations might be in the West. It must be recognized at the outset  
24 that these concentrations will only provide upper limits. However, at some sites in the western  
25 United States (e.g., Bridger, WY, and Yellowstone Park, WY) annual mean concentrations are  
26 within the range of PRB values estimated in 1996 PM AQCD and given earlier in this section.  
27 At other RRMS in the western United States, they are consistent with, although slightly above,  
28 the annual average values defined earlier in the 1996 PM AQCD. Some screening should be  
29 performed to rule out transport from urban areas or other sources of anthropogenic PM on a day  
30 by day basis. Such a procedure is impractical in the eastern United States as concentrations there  
31 are heavily affected by anthropogenic emissions. Mean concentrations observed there are often

1 several times those defined in the 1996 PM AQCD. It is important to note that there is much  
2 smaller relative variability in PM<sub>2.5</sub> concentrations (from the minimum to the P<sub>90</sub> level) on a  
3 year-to-year basis at the western IMPROVE sites than at the eastern IMPROVE sites (cf., Figure  
4 3E-4a-d). This may be related to a lack of discrete transport events affecting most samples at the  
5 western sites compared to the eastern sites and does not rule out the possibility that the western  
6 sites are receiving highly diluted contributions from many distant urban sources. Further inquiry  
7 is needed to address these issues. Likewise, data for PM<sub>10-2.5</sub> concentrations at RRMS can be  
8 used for similar purposes.

9 The above discussions do not explicitly consider the contributions from primary biological  
10 particles (PBP). As mentioned earlier, one extensive study conducted in Mainz, Germany,  
11 (Mathias-Maser, 1998) found that PBP could contribute from about 17 to 20% of total aerosol  
12 volume and from 9 to 30% of total particle number in the size range from 0.35 µm to 50 µm,  
13 depending on season. Pollen can at times represent the dominant contributors to PM in particles  
14 larger than 10 µm. These pollen grains can then fracture and appear as fragments in the smaller  
15 size ranges.

#### 16 17 **3.3.4 Emissions Estimates for Primary Particulate Matter, and Precursors** 18 **to Secondary Particulate Matter (SO<sub>2</sub>, NO<sub>x</sub>, VOCs, and NH<sub>3</sub>) in the** 19 **United States**

20 In principle, source contributions to ambient PM also could be estimated on the basis of  
21 predictions made by chemistry-transport models (CTM) or even on the basis of emissions  
22 inventories alone. Uncertainties in emissions inventories have arguably been regarded as  
23 representing the largest source of uncertainty in CTMs (Calvert et al., 1993). Apart from  
24 uncertainties in emission inventories, a number of other factors limit the ability of an emissions  
25 inventory-driven CTM to determine the effects of various sources on particle samples obtained  
26 at a particular location. CTM predictions represent averages over the area of a grid cell, which  
27 in the case of CMAQ (Community Model for Air Quality) and MAQSIP (Multiscale Air Quality  
28 Simulation Platform), ranges from 16 km<sup>2</sup> (4 km × 4 km) to 1296 km<sup>2</sup> (36 km × 36 km). CMAQ  
29 and MAQSIP constitute the CTMs within the overall Models3 framework, which also includes  
30 emissions processors, the meteorological model, and modules for decision support. The  
31 contributions of sources to pollutant concentrations at a monitoring site are controlled strongly  
32 by local conditions that cannot be resolved by an Eulerian grid-cell model. Examples would be

1 the downward mixing of tall-stack emissions and deviations from the mean flow caused by  
2 buildings. The effect of local sources at a particular point in the model domain may not be  
3 predicted accurately because their emissions would be smeared over the area of a grid cell or if  
4 the local wind fields at the sampling point deviated significantly from the mean wind fields  
5 calculated by the model. CTMs also have problems in predicting pollutant concentrations  
6 because of uncertainties in vertical mixing and in predicting concentrations of pollutants from  
7 stationary combustion sources resulting from uncertainties in estimates of plume rise. CTMs are  
8 an integral part of air quality management programs and are reviewed in the NARSTO Fine  
9 Particle Assessment (NARSTO, 2002).

10 Estimated emissions of primary  $PM_{2.5}$  from different sources in the United States are  
11 summarized in Table 3-11, and estimated emissions of precursors to the formation of secondary  
12  $PM_{2.5}$  ( $SO_2$ ,  $NO_x$ , VOCs, and  $NH_3$ ) are summarized in Table 3-12. These estimates are given to  
13 provide a rough overview of the relative importance of major PM sources in the United States.  
14 The emissions estimates are based on information presented in the EPA National Air Pollutant  
15 Emission Trends Report, 1990-1999 (U.S. Environmental Protection Agency, 2001), to which  
16 the reader is referred for detailed tables showing trends in  $PM_{2.5}$  emissions from a number of  
17 source categories from 1990 to 1999. Detailed descriptions of the methodology for constructing  
18 emissions inventories for criteria pollutants, quality assurance procedures, and examples of  
19 calculations of emissions can be found in U. S. Environmental Protection Agency (1999).  
20 Although uncertainties associated with the estimates in the National Air Pollutant Emission  
21 Trends Report are not given therein, a discussion of uncertainties in emissions estimates is given  
22 in Section 3.3.5.

23 For the sake of completeness, an attempt was made to supplement the information given in  
24 the emissions tables in the Trends Report, which concentrates mainly on anthropogenic  
25 emissions, with information about emissions from natural sources. Details regarding the  
26 composition of the emissions of primary  $PM_{2.5}$  from the source categories shown in Table 3-11  
27 are summarized in Appendix 3D, where available. Fugitive dust emissions are estimated to  
28 constitute over 50 percent of nationwide primary  $PM_{2.5}$  emissions according to Table 3-11.  
29 However, there are a number of issues concerning the methods for obtaining relevant emissions  
30 factor data for fugitive dust in field studies as discussed in Section 3.3.5. An estimate of the  
31 production of  $PM_{2.5}$  from wind erosion on natural surfaces was not included in Table 3-11

**TABLE 3-11. EMISSIONS OF PRIMARY PM<sub>2.5</sub> BY VARIOUS SOURCES IN 1999**

Source	Emissions (10 <sup>9</sup> kg/y)	Major PM Components	Notes
On-road vehicle exhaust	0.21	Organic compounds, elemental carbon	Exhaust emissions from diesel (72%) and gasoline vehicles (28%).
Non-road vehicle exhaust	0.37	Organic compounds, elemental carbon	Exhaust emissions from off-road diesel (57%) and gasoline vehicles (20%); ships and boats (10%); aircraft (7%); railroads (6%).
Fossil fuel combustion	0.36	Crustal elements, trace metals	Fuel burning in stationary sources such as power plants (33%); industries (39%); businesses and institutions (25%); residences (3%).
Industrial processes	0.35	Metals, crustal material, organic compounds	Metals processing (29%); mineral products (27%); chemical mfg. (11%); other industries (33%).
Biomass burning	1.2	Organic compounds, elemental carbon	Managed burning (47%); residential wood burning (28%); agricultural burning (7%); wildfires (18%).
Waste disposal	0.48	Organic compounds, trace metals	Open burning (91%); incineration (9%).
Fugitive dust	3.3	Crustal elements	Dust raised by vehicles on paved (19%) and unpaved roads (40%); construction (15%), dust from raising crops (24%) and livestock (2%).
Windblown dust	NA <sup>1</sup>	Crustal elements	Dust raised by wind on bare land.
Other	0.02	Organic compounds, elemental carbon	Structural fires.
Total	6.2		

<sup>1</sup>NA = not available.

Source: Adapted from U. S. Environmental Protection Agency (2001).

1 because this source is highly sporadic, occurs during periods of high winds, thus, the resulting  
2 emissions are too highly uncertain to be included. As can be seen from a comparison of entries  
3 in Tables 3-11 and 3-12, estimates of emissions of potential precursors to secondary PM  
4 formation are considerably larger than those for estimates of primary PM<sub>2.5</sub> emissions in the  
5 United States. The emissions of SO<sub>2</sub>, NO<sub>x</sub>, and NH<sub>3</sub> should be multiplied by factors of 1.5, 1.35,  
6 and 1.07, respectively, to account for their chemical form in the aerosol phase. Estimating a  
7 factor for VOCs is somewhat less straight forward. Turpin and Lim (2001) recommends a factor  
8 of 2 to account for the conversion of VOC precursors to oxygen- and nitrogen-containing  
9 compounds in the aerosol phase. These factors are all greater than 1 and further underscore the  
10 potential importance of secondary PM precursor emissions relative to primary PM emissions.  
11 However, the emissions of precursors cannot be translated directly into rates of PM formation.

**TABLE 3-12. EMISSIONS OF PRECURSORS TO SECONDARY PM<sub>2.5</sub> FORMATION BY VARIOUS SOURCES IN 1999**

Precursor	Emissions (10 <sup>9</sup> kg/y)	Secondary PM Component	Notes
SO <sub>2</sub>	17	Sulfate	Exhaust from on-road (2%) and non-road (5%) engines and vehicles; fossil fuel combustion by electrical utilities, industries, other sources (85%); various industrial processes (7%); and other minor sources (1%).
NO <sub>x</sub> <sup>1,2</sup>	26	Nitrate	Exhaust from on-road (34%) and non-road (22%) engines and vehicles; fossil fuel combustion by electrical utilities, industries, other sources (39%); lightning (4%); soils (4%); and other minor sources (5%).
Anthropogenic VOCs	16	Various mainly unidentified compounds of 'OC'	Evaporative and exhaust emissions from on-road (29%) and non-road (18%) vehicles; evaporation of solvents and surface coatings (27%); biomass burning (9%); storage and transport of petroleum and volatile compounds (7%); chemical and petroleum industrial processes (5%); other sources (5%).
Biogenic VOCs <sup>1</sup>	44	Various mainly unidentified compounds of 'OC'	Approximately 98% emitted by vegetation. Isoprene (35%); monoterpenes (25%); all other reactive and non-reactive compounds (40%).
NH <sub>3</sub>	45	Ammonium	Exhaust from on-road and non-road engines and vehicles (5%); chemical manufacturing (3%); waste disposal, recycling, and other minor sources (5%); livestock (82%); and fertilizer application (18%).

<sup>1</sup>Includes estimates of natural sources from Guenther et al. (2000).

<sup>2</sup>Emissions expressed in terms of NO<sub>2</sub>.

1 Dry deposition and precipitation scavenging of some of these gaseous precursors and their  
 2 intermediate oxidation products occur before they are converted to PM in the atmosphere.  
 3 In addition, some fraction of these gases are transported outside of the domain of the continental  
 4 United States before being oxidized. Likewise, emissions of these gases from areas outside the  
 5 United States can result in the transport of their oxidation products into the United States.

6 As discussed in Section 3.3.1, the photochemical oxidation of sulfur dioxide leads to the  
 7 production of sulfate; whereas that of nitrogen oxide leads ultimately to particulate-phase nitrite  
 8 and nitrate. Due to uncertainties it is difficult to calculate the rates of formation of secondary  
 9 organic particulate matter (SOPM) from the emissions of VOC precursors. Smog chamber and  
 10 laboratory studies discussed in Section 3.3.1 indicate that anthropogenic aromatic compounds

1 and biogenic terpenoid compounds have the highest potential for forming secondary organic  
2 particulate matter; and as can be seen from Table 3C-1, the dominant compounds tend to be  
3 those derived from these categories. Each of the source categories capable of emitting VOCs  
4 shown in Table 3-12 has components capable of forming SOPM, although in small yields  
5 (ranging typically up to several per cent, cf., Section 3.3.1). The oxidation of lighter organic  
6 compounds leads ultimately to the formation of CO and CO<sub>2</sub>. As discussed by Pandis et al.  
7 (1991) and in Section 3.3.1, soluble gas phase compounds, such as formaldehyde (CH<sub>2</sub>O), other  
8 aldehydes, organic acids, etc., formed during the oxidation of a wide variety of hydrocarbons,  
9 can be incorporated into suspended particles. Although isoprene is a major component of  
10 biogenic emissions, its oxidation has not been found to result in the formation of new particles;  
11 whereas the oxidation of monoterpenes has. However, it should be remembered that soluble gas  
12 phase species such as CH<sub>2</sub>O are formed during the oxidation of isoprene.

13 The emissions estimates shown in this section are based on annual totals. However, annual  
14 averages do not reflect the variability of a number of emissions categories on shorter time scales.  
15 Residential wood burning in fireplaces and stoves, for example, is a seasonal practice that  
16 reaches its peak during cold weather. Cold weather also affects motor vehicle exhaust  
17 particulate matter emissions, both in terms of chemical composition and emission rates (e.g.,  
18 Watson et al., 1990b; Huang et al., 1994). Agricultural activities such as planting, fertilizing,  
19 and harvesting are also seasonal. Forest fires occur mainly during the local dry season and  
20 during periods of drought. Maximum dust production by wind erosion in the United States  
21 occurs during the spring; whereas the minimum occurs during the summer (Gillette and Hanson,  
22 1989). Efforts are being made to account for the seasonal variations of emissions in the  
23 nationwide emissions inventories. Techniques for calculating emissions of criteria pollutants on  
24 a seasonal basis are given in U. S. Environmental Protection Agency (1999).

25 Trends in nationwide, annual average concentrations of PM<sub>10</sub>, and precursor gases (SO<sub>2</sub>,  
26 NO<sub>2</sub>, and VOC) over the 10 years from 1992 to 2001 are shown in Table 3-13. As can be seen  
27 from Table 3-13, there have been substantial decreases in the ambient concentrations of PM<sub>10</sub>,  
28 SO<sub>2</sub>, and NO<sub>2</sub>. Not enough data are available to define trends in concentrations of VOCs. There  
29 also have been substantial decreases in the emissions of all the species shown in Table 3-13,  
30 except for NO<sub>2</sub>, although its average ambient concentration has decreased by 11%. These entries  
31 suggest that decreases in the average ambient concentration of PM<sub>10</sub> could have been produced

**TABLE 3-13. NATIONWIDE CHANGES IN AMBIENT CONCENTRATIONS AND EMISSIONS OF PM<sub>10</sub> AND GASEOUS PRECURSORS TO SECONDARY PARTICULATE MATTER FROM 1992 TO 2001**

	% Change 1992-2001	
	Ambient Concentration	Emissions
PM <sub>10</sub>	-14%	-13%*
PM <sub>2.5</sub>	—	-10%*
SO <sub>2</sub>	-35% (SO <sub>2</sub> )	-24% (SO <sub>2</sub> )
NO <sub>x</sub>	-11% (NO <sub>2</sub> )	-3% (NO <sub>x</sub> )
VOC	—	-8%

\*Includes only primary PM.

Source: U.S. Environmental Protection Agency (2002).

1 by both decreases in emissions of primary PM<sub>10</sub> and the formation of secondary PM<sub>10</sub>. The large  
 2 reductions in ambient SO<sub>2</sub> concentrations have resulted in reductions in sulfate formation that  
 3 would have been manifest in PM<sub>2.5</sub> concentrations on the regional scale in the East and Midwest  
 4 where sulfate has constituted a larger fraction of PM<sub>2.5</sub> than in the West. Likewise, reductions in  
 5 NO<sub>2</sub> concentrations would have had a more noticeable effect on PM<sub>2.5</sub> concentrations in the West  
 6 than in the East because nitrate is a larger component of the aerosol in the West.

7 Trends in aerosol components (i.e., nitrate, sulfate, carbon, etc.) are needed for a more  
 8 quantitative assessment of the effects of changes in emissions of precursors. Aerosol nitrate and  
 9 sulfate concentrations obtained at North Long Beach and Riverside, CA, tracked downward  
 10 trends in NO<sub>x</sub> concentrations. SO<sub>2</sub> and sulfate concentrations have both decreased; however, the  
 11 rate of decline of sulfate has been smaller than that of SO<sub>2</sub>, indicating the long range transport of  
 12 sulfate from outside the airshed may be an important source in addition to the oxidation of  
 13 locally generated SO<sub>2</sub>. There are a number of reasons why pollutant concentrations do not track  
 14 estimated reductions in emissions. Some of these reasons are related to atmospheric effects such  
 15 as meteorological variability and secular changes in the rates of photochemical transformations  
 16 and deposition (U.S. Environmental Protection Agency, 2000c). Other reasons are related to  
 17 uncertainties in ambient measurements and in emissions inventories.

18

### 3.3.5 Uncertainties of Emissions Inventories

As described in the 1996 PM AQCD, it is difficult to quantitatively assign uncertainties to entries in emissions inventories. Methods that can be used to verify or place constraints on emissions inventories are sparse. In general, the overall uncertainty in the emissions of a given pollutant includes contributions from all of the terms used to calculate emissions (i.e., activity rates, emissions factors, and control device efficiencies). Additional uncertainties arise during the compilation of an emissions inventory because of missing sources and computational errors. The variability of emissions can cause errors when annual average emissions are applied to applications involving shorter time scales.

Activity rates for well-defined point sources (e.g., power plants) should have the smallest uncertainty associated with their use because emissions are monitored continuously in many cases and accurate production records need to be kept. On the other hand, activity rates for a number of very disperse fugitive sources are difficult to quantify. Emissions factors for easily measured fuel components that are released quantitatively during combustion (e.g., CO<sub>2</sub>, SO<sub>2</sub>) should be the most reliable. Emissions of components formed during combustion are more difficult to characterize, as the emissions rates are dependent on factors specific to individual combustion units and on combustion stage (i.e., smoldering or active). Although the AP-42 emissions factors (U.S. Environmental Protection Agency, 1995) contain extensive information for a large number of source types, these data are very limited in the number of sources sampled. The efficiency of control devices is determined by their design, age, maintenance history, and operating conditions. It is virtually impossible to assign uncertainties in control device performance because of these factors. It should be noted that the largest uncertainties occur for those devices that have the highest efficiencies (> 90%). This occurs because the efficiencies are subtracted from one, and small errors in assigning efficiencies can lead to large errors in emissions.

Ideally, an emissions inventory should include all major sources of a given pollutant. This may be an easy task for major point sources. However, area sources of both primary PM and precursors to secondary PM formation are more difficult to characterize than point sources; and, thus, they require special emphasis when preparing emission inventories. Further research is needed to better characterize the sources of pollutants to reduce this source of uncertainty. Errors also can arise from the misreporting of data, and arithmetic errors can occur in the course

1 of compiling entries from thousands of individual sources. A quality assurance program is  
2 required to check for outliers and arithmetic errors. Because of the variability in emissions rates,  
3 there can be errors in the application of inventories developed on an annually averaged basis (as  
4 are the inventories shown in Tables 3-11 and 3-12) to episodes occurring on much shorter time  
5 scales. As an example, most modeling studies of air pollution episodes are carried out for  
6 periods of a few days.

7         Uncertainties in annual emissions were estimated to range from 4 to 9% for SO<sub>2</sub> and from  
8 6 to 11% for NO<sub>x</sub> in the 1985 NAPAP inventories for the United States (Placet et al., 1991).  
9 Uncertainties in these estimates increase as the emissions are disaggregated both spatially and  
10 temporally. The uncertainties quoted above are minimum estimates and refer only to random  
11 variability about the mean, assuming that the variability in emissions factors was adequately  
12 characterized and that extrapolation of emissions factors to sources other than those for which  
13 they were measured is valid. The estimates do not consider the effects of weather or variations  
14 in operating and maintenance procedures.

15         Fugitive dust sources, as mentioned above, are extremely difficult to quantify; and stated  
16 emission rates may represent only order-of-magnitude estimates. Although crustal dust  
17 emissions constitute about 50% of the total primary PM<sub>2.5</sub> inventory, they constitute less than  
18 about 15% of the source strengths inferred from the receptor modeling studies shown in  
19 Table 3-9. However, it should be remembered that secondary components (sulfate, nitrate, and  
20 some fractions of organic carbon) often account for most of the mass of ambient PM<sub>2.5</sub> samples.

21         Although mineral dust sources represent the major category in Table 3-11, their  
22 contributions are distributed much more widely than are those from combustion sources.  
23 Watson and Chow (2000) reexamined the methodology used to determine emissions of fugitive  
24 dust. The standard methods use data obtained by particle monitors stacked at several elevations  
25 from 1 to 2 m up to 7 to 10 m above the surface. However, small-scale turbulent motions and  
26 variable winds characterize atmospheric flow patterns immediately adjacent to the surface in this  
27 height range (Garratt, 1994). The depth of this turbulent layer is determined by surface  
28 roughness elements, and there is a high probability of particles being entrained in turbulent  
29 eddies and redepositing on the ground within a very short distance. In addition to the source-  
30 sampling problem referred to above, it should be remembered that dust often is raised in remote  
31 areas far removed from population centers. Precipitation or scavenging by cloud droplets and

1 dry deposition removes particles during transport from the source area. In addition, gravitational  
2 settling can be an important loss mechanism for particles larger than a few micrometers in  
3 aerodynamic diameter.

4 As rough estimates, uncertainties in emissions estimates could be as low as 10% for the  
5 best characterized source categories; whereas emissions figures for windblown dust should be  
6 regarded as order-of-magnitude estimates. The application of emissions inventories to the  
7 estimation of source contributions at monitoring sites is also limited by the effects of local  
8 topography and meteorology. For example, Pinto et al. (1998) found that the contribution of  
9 power plants and residential space heating to PM<sub>2.5</sub> concentrations in northwestern Bohemia are  
10 comparable on the basis of CMB receptor modeling. However, according to the emissions  
11 inventories, the contribution from power plants should have been roughly an order of magnitude  
12 larger than that from residential space heating. The difference between the two methods can be  
13 explained by noting that mixing of the emissions from the power plants downward to the surface  
14 is inhibited by strong surface inversions that develop during the winter season in this area.

15 There have been few field studies designed to test emissions inventories observationally.  
16 The most direct approach would be to use aircraft to obtain cross-sections of pollutants upwind  
17 and downwind of major urban areas. The computed mass flux through a cross section of the  
18 urban plume can then be equated to emissions from the city chosen. This approach has been  
19 attempted on a few occasions, but results have been ambiguous because of contributions from  
20 fugitive sources, variable wind flows, and logistic difficulties.

### 21 22 23 **3.4 SUMMARY AND KEY CONCLUSIONS**

24 The recently deployed PM<sub>2.5</sub> FRM network has returned data for a large number of sites  
25 across the United States. Annual mean PM<sub>2.5</sub> concentrations range from about 5 µg/m<sup>3</sup> to about  
26 30 µg/m<sup>3</sup>. In the eastern United States, the data from 1999 to 2001 indicate that highest  
27 quarterly mean concentrations and maximum concentrations most often occur during the  
28 summer. In the western United States, highest quarterly mean values and maximum values  
29 occur mainly during the winter at a number of sites although there were exceptions to these  
30 general patterns. Sites affected strongly by sources of primary PM are expected to show winter  
31 maxima. These findings are generally consistent with those based on longer term data sets such

1 as MAAQS in the eastern United States and the CARB network of dichotomous samplers in  
2 California.  $PM_{2.5}$  and  $PM_{10}$  concentrations in a number of urban areas have generally declined  
3 over the past few decades. However, they appear to have leveled off in the past few years.

4 Differences in annual mean  $PM_{2.5}$  concentrations between monitoring sites in urban areas  
5 examined are typically less than 6 or 7  $\mu\text{g}/\text{m}^3$ . However, on individual days, differences in 24-h  
6 average  $PM_{2.5}$  concentrations can be much larger. Some sites in metropolitan areas are highly  
7 correlated with each other but not to others due to the presence of local sources, topographic  
8 barriers, etc. Although  $PM_{2.5}$  concentrations at sites within an MSA can be highly correlated,  
9 there still can be significant differences in their concentrations on any given day. Consequently,  
10 additional measures should be used to characterize the spatial variability of  $PM_{2.5}$  concentrations.  
11 The degree of spatial uniformity in  $PM_{2.5}$  concentrations in urban areas varies across the country.  
12 These factors should be considered in using data obtained by the  $PM_{2.5}$  FRM network to  
13 approximate community-scale human exposure, and caution should be exercised in extrapolating  
14 conclusions obtained in one urban area to another.  $PM_{2.5}$  to  $PM_{10}$  ratios were generally higher in  
15 the East than in the West, and values for this ratio are consistent with those found in numerous  
16 earlier studies presented in the 1996 PM AQCD.

17 Data for  $PM_{10-2.5}$  are not as abundant as they are for  $PM_{2.5}$ , and their interpretation is  
18 complicated by the difference method used to determine their concentrations. The more  
19 sporadic nature of sources of  $PM_{10-2.5}$  and its shorter atmospheric lifetime tend to result in lower  
20 spatial correlations for  $PM_{10-2.5}$  than for  $PM_{2.5}$  concentrations. Errors in measurement of  $PM_{2.5}$   
21 and  $PM_{10}$  also result in calculations of lower spatial correlations of  $PM_{10-2.5}$ . Calculated  
22 concentrations of  $PM_{10-2.5}$  are occasionally negative as reflected by  $PM_{2.5}$  to  $PM_{10}$  ratios greater  
23 than one. Because analytical errors are generally larger for individual species than for total  
24 mass, similar problems arise in their determination in  $PM_{10-2.5}$  samples by the difference  
25 approach. Some, but not all of these problems could be resolved by the use of dichotomous  
26 samplers that also provide a direct sample of  $PM_{10-2.5}$  for compositional analyses.

27 Estimates of concentrations of individual species in  $PM_{10-2.5}$  samples used in this chapter  
28 were limited to those obtained by dichotomous samplers. Generally, concentrations of most  
29 elements differ for  $PM_{2.5}$  and  $PM_{10-2.5}$ . However, the available data suggest that concentrations of  
30 many metals are of the same order of magnitude in both size fractions. This is in marked  
31 contrast to the situation twenty years ago when uncontrolled combustion sources were prevalent.

1 At that time, concentrations of many metals, especially lead, were much higher than today in  
2 fine-mode particles, and their concentrations were much higher in the fine-mode than in the  
3 coarse-mode. No substantive conclusions about contemporary concentrations and composition  
4 of ultrafine particles ( $0.1 \mu\text{m} < D_a$ ) can be drawn for the nation as a whole because of a lack of  
5 data.

6 Ambient PM contains both primary and secondary components. The results of ambient  
7 monitoring studies and receptor modeling studies indicate that  $\text{PM}_{2.5}$  is dominated by secondary  
8 components in the eastern United States. General statements about the origin of OC in ambient  
9  $\text{PM}_{2.5}$  samples cannot yet be made and so the contribution of secondary components throughout  
10 the rest of the United States is still highly uncertain. Primary constituents represent smaller but  
11 still important component of  $\text{PM}_{2.5}$ . Crustal materials, which are primary constituents, constitute  
12 the largest measured fraction of  $\text{PM}_{10-2.5}$  throughout the United States. Data for the concentration  
13 of bioaerosols in both the  $\text{PM}_{2.5}$  and  $\text{PM}_{10-2.5}$  size ranges are sparse. Data collected in several  
14 airsheds, including the Los Angeles Basin, Bakersfield and Fresno, CA; and Philadelphia, PA,  
15 suggest that secondary PM components are more uniformly distributed than are primary PM  
16 components. Compositional data obtained at multiple sites in other urban areas are sparse.

17 Because of the complexity of the composition of ambient  $\text{PM}_{2.5}$  and  $\text{PM}_{10-2.5}$ , sources are  
18 best discussed in terms of individual constituents of both primary and secondary  $\text{PM}_{2.5}$  and  
19  $\text{PM}_{10-2.5}$ . Each of these constituents can have anthropogenic and natural sources as shown in  
20 Table 3-8. The distinction between natural and anthropogenic sources is not always obvious.  
21 Although windblown dust might seem to be the result of natural processes, highest emission  
22 rates are associated with agricultural activities in areas that are susceptible to periodic drought.  
23 Examples include the dust bowl region of the midwestern United States and the Sahel of Africa.  
24 There is also ongoing debate about characterizing wildfires as either natural or anthropogenic.  
25 Land management practices and other human actions affect the occurrence and scope of  
26 wildfires. Similarly, prescribed burning can be viewed as anthropogenic or as a substitute for  
27 wildfires that would otherwise eventually occur on the same land.

28 Over the past decade, a significant amount of research has been carried out to improve the  
29 understanding of the atmospheric chemistry of secondary organic PM formation. Although  
30 additional sources of SOPM might still be identified, there appears to be a general consensus that  
31 biogenic compounds (monoterpenes, sesquiterpenes) and aromatic compounds (toluene,

1 ethylbenzene) are the most significant SOPM precursors. A large number of compounds have  
2 been detected in biogenic and aromatic SOPM although the chemical composition of these two  
3 categories has not been fully established, especially for aromatic SOPM. Transformations that  
4 occur during the aging of particles are still inadequately understood. There are still large gaps in  
5 the current understanding of a number of key processes related to the partitioning of semivolatile  
6 compounds between the gas phase and ambient particles containing organic compounds, liquid  
7 water, and inorganic salts and acids. In addition, there is a general lack of reliable analytical  
8 methods for measuring multifunctional oxygenated compounds in the gas and aerosol phases.

9 The results of receptor modeling studies throughout the United States indicate that the  
10 combustion of fossil and biomass fuels is the major source of measured ambient  $PM_{2.5}$ . Fugitive  
11 dust, found mainly in the  $PM_{10-2.5}$  range size, represents the largest source of measured ambient  
12  $PM_{10}$  in many locations in the western United States. Quoted uncertainties in the source  
13 apportionment of constituents in ambient aerosol samples typically range from 10 to 50%. It is  
14 apparent that a relatively small number of source categories, compared to the total number of  
15 chemical species that typically are measured in ambient monitoring-source receptor model  
16 studies, are needed to account for the majority of the observed mass of PM in these studies.

17 The application of any of the source apportionment techniques is still limited by the  
18 availability of source profile data. Whereas the CMB approach relies directly on source profile  
19 data, solutions from the PMF technique yield profiles for the factors that contribute to PM.  
20 However, there is some rotational ambiguity present in the solutions. Source profile data  
21 obtained by PMF must still be verified by comparison with data and these data can be used in  
22 techniques such as PMF to improve the solutions. Serious limitations still exist with regard to  
23 source profiles for organic compounds. The complexity of reactions involving organic  
24 compounds in particles adds to the difficulties of finding stable species that could be used as  
25 tracers.

26 As seen in Table 3-8, emissions of mineral dust, organic debris, and sea spray are  
27 concentrated mainly in the coarse fraction of  $PM_{10}$  ( $> 2.5 \mu\text{m}$  aerodynamic diameter). A small  
28 fraction of this material is in the  $PM_{2.5}$  size range ( $< 2.5 \mu\text{m}$  aerodynamic diameter). Still,  $PM_{2.5}$   
29 concentrations of crustal material can be appreciable, especially during dust events. It also  
30 should be remembered that from one-third to one-half of the Saharan dust reaching the United

1 States is in the PM<sub>2.5</sub> size range. Emissions from combustion sources (mobile and stationary  
2 sources and biomass burning) are also predominantly in the PM<sub>2.5</sub> size range.

3 A number of sources contribute to policy relevant background (PRB) concentrations. Data  
4 obtained at relatively remote monitoring sites (RRMS) in the western United States could be  
5 used to place reasonable upper limits on policy relevant background concentrations. More  
6 definitive results for both annual average and daily average concentrations could potentially be  
7 obtained from the application of source-receptor models and/or the application of large-scale  
8 chemistry transport models. Many areas in the East are affected by dust transported from  
9 northern Africa, and it has recently become apparent that many areas, especially, but not limited  
10 to the Northwest, are affected by dust transported from the deserts of Asia. In addition to crustal  
11 material, pollutants and primary biological aerosol particles (PBP) are also transported during  
12 intercontinental transport events. Many areas are also affected by smoke from wildfires either  
13 within the United States or in Canada, Mexico and Central America. Storms, in which the winds  
14 can suspend material from the surface of the land or seas, contribute soil, sea spray and PBP.  
15 Contributions of primary PM from natural sources and sources outside Northern America as  
16 given above are all episodic. Because the concentration of PBP is so poorly quantified, even  
17 though it can constitute a significant fraction of the organic fraction of the atmospheric aerosol,  
18 estimates of policy relevant background concentrations will remain highly uncertain. Estimates  
19 of annually averaged PRB concentrations or their range have not changed from the previous PM  
20 assessment document.

21 Key points derived from the findings summarized above can be highlighted as follows:

- 22
- Spatial Variability in PM<sub>2.5</sub> Concentrations. Although PM<sub>2.5</sub> concentrations within an MSA can be highly correlated between sites, there can still be significant differences in their concentrations. The degree of spatial uniformity in PM<sub>2.5</sub> concentrations and the strength of site to site correlations in urban areas varies across the country. These factors should be considered in using data obtained by the PM<sub>2.5</sub> FRM network to approximate community-scale human exposures, and caution should be exercised in extrapolating conclusions as to spatial uniformity or correlations obtained in one urban area to another. Limited information also suggests that the spatial variability in urban source contributions is likely to be larger than for regional source contributions to PM<sub>2.5</sub> and for PM<sub>2.5</sub>, itself.

- 1
- PM<sub>10-2.5</sub> Concentrations. Data for PM<sub>10-2.5</sub> concentrations are not as abundant as they are for PM<sub>2.5</sub>. The difference method used in their derivation is subject to the effects of uncertainties in both PM<sub>10</sub> and PM<sub>2.5</sub>. As a result, estimates of PM<sub>10-2.5</sub> concentrations, at times, come out as negative values, based on currently available data (e.g., in the EPA AIRS Database).
- 2
- Evaluating Source Contributions. The use of organic compounds in source apportionment studies could potentially result in the attribution of PM to many more source categories than is possible using only trace elements. However, in the relatively few studies of the composition of the organic fraction of ambient particles that have been performed, typically only about 10 to 20 % of organic compounds have been quantified. The separation of contributions from diesel- and gasoline-fueled vehicles using organic marker compounds is still somewhat problematic. Additional efforts to develop protocols for extraction and analysis of organic markers are needed to fully realize their potential.
- 3
- Policy Relevant Background (PRB) Concentrations. Recent but limited information about PRB concentrations have not provided sufficient evidence to warrant any changes in estimates of the annual average background concentrations given in the 1996 PM AQCD. These are: 1 to 4 µg/m<sup>3</sup> in the West and 2 to 5 µg/m<sup>3</sup> in the East for PM<sub>2.5</sub>; and approximately 3 µg/m<sup>3</sup> in both the East and the West for PM<sub>10-2.5</sub>, with a range of 0 to 9 µg/m<sup>3</sup> in the West and 0 to 7 µg/m<sup>3</sup> in the East. PRB concentration are likely to be highly variable both spatially and temporally. Further information regarding the frequency distribution of 24-hour concentrations based on analyses of observations at relatively remote monitoring sites and on source apportionment analyses has become available and can be used for selected sites.

## APPENDIX 3A

### **Spatial and Temporal Variability of the Nationwide AIRS PM<sub>2.5</sub> and PM<sub>10-2.5</sub> Data Sets**

Aspects of the spatial and temporal variability of 24-h average PM<sub>2.5</sub> concentrations for 1999, 2000, and 2001 in a number of metropolitan statistical areas (MSAs) across the United States are presented in this Appendix. PM<sub>2.5</sub> data for multiple sites in 27 urban areas have been obtained from the AIRS data base and analyzed for their seasonal variations, for their spatial correlations, and for their spatial uniformity. A number of aspects of the spatial and temporal variability of the PM<sub>2.5</sub> data set from 1999 were presented in Rizzo and Pinto (2001) based in part on analyses given in Fitz-Simons et al. (2000). An analysis of the data obtained during the first two years of operation of the Federal Reference Method PM<sub>2.5</sub> network can be found in Pinto et al. (2003).

Information about seasonal and spatial variability in PM<sub>2.5</sub> concentrations within 27 MSAs across the United States are provided in the accompanying figures (Figures 3A-1 to 3A-27). Underneath the value for *r*, the 90<sup>th</sup> percentile values of the absolute difference in PM<sub>2.5</sub> concentrations (in µg/m<sup>3</sup>) and the coefficient of divergence (COD) are given in parentheses. Beneath these two measures of spatial variability, the number of observations used in the calculations of the statistics in part *c* of each figure is given.

Quality assured measurements for at least fifteen days during each calendar quarter for 1999, 2000, and 2001 (preferably) or for 2000 and 2001 at a minimum of four monitoring sites in a given MSA were required for their inclusion in the analyses given in this appendix. The Columbia, SC and Baton Rouge, LA MSAs, which had only three sites meeting this criterion, are exceptions. Typically, at least 200 measurements were available for each monitoring site chosen. Monitoring sites were chosen without consideration of the land use type used to characterize their locations.

Because of changes in monitoring strategies, funding levels etc., there were year to year changes in monitoring sites meeting the above criteria in a number of MSAs. Data for the Philadelphia, PA; Norfolk, VA; Pittsburgh, PA; Detroit, MI; Chicago, IL; Louisville, KY;

1 St. Louis, MO; and the Dallas, TX MSAs have been analyzed only for 2000 and 2001 because of  
2 a lack of consistent coverage in 1999.

3 Information about seasonal and spatial variability in  $PM_{10-2.5}$  concentrations within  
4 17 MSAs across the United States are provided in the accompanying figures (Figures 3A-28 to  
5 3A-44). Underneath the value for  $r$ , the 90<sup>th</sup> percentile values of the absolute difference in  $PM_{2.5}$   
6 concentrations (in  $\mu g/m^3$ ) and the coefficient of divergence (COD) are given in parentheses.  
7 Beneath these two measures of spatial variability, the number of observations used in the  
8 calculations of the statistics in part *c* of each figure is given. In order to maximize coverage,  
9 data were calculated for a number of sampling periods. Only Milwaukee, WI, and Salt Lake  
10 City, UT, had enough data for a 3 year average (1999 to 2001). Tampa, FL; Cleveland, OH;  
11 Steubenville, OH; Baton Rouge, LA; Portland, OR; and Riverside, CA had data for a 2 year  
12 average (2000 to 2001), as did Chicago, IL and Pittsburgh, PA (1999 to 2000). Other MSAs had  
13 only one year data (2000 or 2001).

14 The COD was defined mathematically and used earlier in Chapter 3 as a measure of the  
15 degree of similarity between two data sets. A COD of zero implies that values in both data sets  
16 are identical, and a COD of one indicates that two data sets are completely different. Values of  
17  $P_{90}$  provide a measure in absolute terms of differences in concentrations between sites, and  
18 CODs provide a relative measure of these differences. The maximum number of days of  
19 coincident data from paired sites were used to calculate correlation coefficients, values for  $P_{90}$ ,  
20 and CODs. The correlation coefficients were also calculated by using only concurrent  
21 measurements obtained at all of the monitoring sites within urban areas meeting the above  
22 selection criteria. The correlation coefficients that were calculated differed only in the third  
23 significant figure between the two methods.

24 Metrics used above for characterizing differences between separated monitors are applied  
25 to collocated monitors in Table 3A-1.

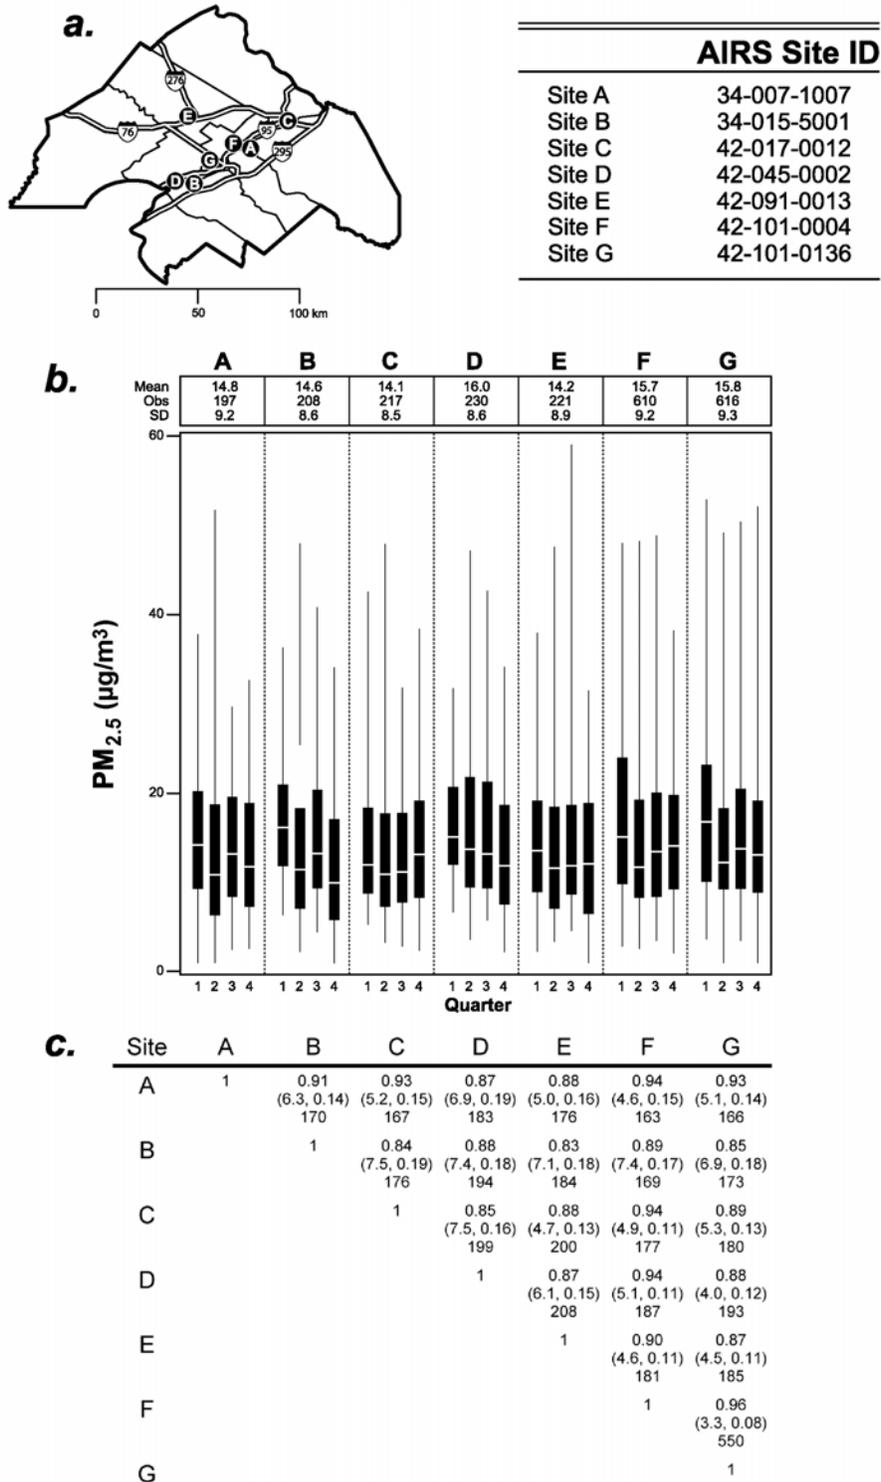

26 Information about the spatial and temporal variability of 24-h average  $PM_{10-2.5}$   
27 concentrations is summarized in Figures 3A-28 to 3A-44. Data are shown for a subset of MSAs  
28 included in the analyses for  $PM_{2.5}$ . Not all MSAs could be included because of a lack of data.  
29 A schematic map showing locations of sampling sites within each MSA is given in part *a*, at the  
30 top of each figure. Also included in the map are major highways and a distance scale. A key  
31 giving the AIRS site ID #'s is shown alongside each map. Box plots showing lowest, lower

1 quartile, median, upper quartile and highest  $PM_{2.5}$  concentrations for each calendar quarter are  
2 shown in part *b* of each figure. AIRS site ID #'s, annual mean concentrations, the number of  
3 observations, and the standard deviation of the data are shown above the box plots. Finally, in  
4 part *c* of each figure, statistics characterizing the spatial variability in  $PM_{2.5}$  concentrations are  
5 given. For each site-pair, the Pearson correlation coefficient ( $r$ ) is provided. Underneath each  
6 value for  $r$ , the 90<sup>th</sup> percentile of the absolute difference in  $PM_{10-2.5}$  concentrations, the COD, and  
7 number of observations is given. In some cases, because of negative concentration values, the  
8 COD may not be calculated. Dashes are shown for these cases.

## APPENDIX 3B

### Aerosol Composition Data from the Speciation Network

The United States Environmental Protection Agency (EPA), working with state and local air quality agencies, began implementing an ambient air monitoring network in 1999/2000 to provide a consistent data set for the characterization and evaluation of trends in PM components (chemical species). The network was designed to include about 52 core trends sites across the United States and to provide a stable ongoing national perspective. In 1999, an initial thirteen sites were installed and operated to be used as a model for the deployment of the more comprehensive network consisting of the 52 core trends sites and roughly two hundred additional locally relevant sites.

Data from the initial thirteen sites were presented in the Air Quality Criteria for Particulate Matter (3<sup>rd</sup> External Review Draft) by the EPA in 2001 for public comment and CASAC review. These sites were designed and operated to evaluate the suitability of various aerosol sampling devices for obtaining PM<sub>2.5</sub> composition data. These data were summarized in Appendix 3B of the 2001 3<sup>rd</sup> External Review Draft. Three types of collocated aerosol sampling devices were used in this study, which lasted from February 2000 through July 2000; data were obtained from the three sampling devices shown for each site. A complete description of the data, techniques used to analyze the filters, and the results of the evaluation of the performance of the sampling devices (including a number of caveats regarding the data) can be found in Coutant and Stetzer (2001) and the analyses of data in Coutant et al. (2001).

More recent measurements of ambient levels of PM<sub>2.5</sub> constituents are provided in the tables below. Table 3B-1 presents the locations and sample type for a different set of 13 monitoring sites representing a cross section of the country. Many of these sites were chosen because they are located in MSAs (or close to MSAs) in which risk assessments are to be performed. Sacramento, CA, and Riverside, CA, are located near San Francisco and Los Angeles, respectively. The data reported here are from the period October 2001 to September 2002. For this time period, a total of 51 sites (this includes both “Trends” and “non-Trends” sites) across the country have complete data (as defined by 50% of observations

1 available for every quarter for each of the major chemical species: sulfate, ammonium, nitrate,  
2 elemental carbon, organic carbon, and the five trace elements that go into the calculation of the  
3 crustal contribution to PM<sub>2.5</sub> (Al, Fe, Ca, Ti, and Si).

4 Summary statistics for concentrations of PM<sub>2.5</sub> and chemical species are given for each of  
5 the 13 sites in Table 3B-2. The number of samples (n) and the AIRS site code are given above  
6 each table. Entries in the tables give for each component the mean, minimum and maximum  
7 component concentrations, and minimum detection limits. Minimum detection levels (MDL)  
8 differ among the various sampling methods; these limits were estimated by Research Triangle  
9 Institute in July of 2001 and are subject to review, revision, and reinterpretation. Anions and  
10 cations (ammonium, nitrate, sodium, potassium, and sulfate) were determined by ion  
11 chromatography; carbonaceous species were determined by the thermal optical transmittance  
12 method (NIOSH method); and trace elements (aluminum through zirconium) were determined  
13 by X-ray fluorescence spectrometry. The sulfate (calculated) entry is based on the XRF  
14 determination of S. In general, relatively good agreement is found between the reconstructed  
15 mass and the PM<sub>2.5</sub> concentration measured by the collocated FRM monitor at each site.  
16 However, there are exceptions at several locations as can be seen from inspection of Table 3B-2.  
17 Somewhat different sampling trains are used in the different sampling systems. These  
18 differences can result in differences in performance metrics and in differences in the entities that  
19 are measured. All samplers use a denuder in front of the filter for species to be analyzed by ion  
20 chromatography. In the RAAS and SASS samplers the denuder is followed by a nylon filter;  
21 whereas in the MASS samplers (Chicago, Houston, Seattle) a teflon filter is followed by a nylon  
22 filter. Particulate nitrate is collected on the teflon filter and is referred to as nonvolatile nitrate.  
23 However, there may be volatilization of nitrate containing compound from the teflon filter which  
24 is then adsorbed on the nylon filter. Nitrate extracted from the nylon filter is referred to as  
25 volatile nitrate.

26 Organic carbon (OC) concentrations are multiplied by a factor of 1.4 when calculating  
27 mass to account for the presence of H, N, and O in organic compounds on all samplers.  
28 Carbonate carbon has never been detected in any of the samples. Field blank corrections that  
29 could be applied to elemental carbon (EC) and OC concentrations are shown in Table 3B-3 for  
30 different samplers. Blank corrections for OC and EC shown in Table 3B-3 were applied to  
31 concentrations shown in Table 3B-2. However, subtracting blank corrections from OC

1 concentrations results in negative values in several cases. A possible cause for results such as  
2 these could have been that not enough blank samples were obtained to fully characterize the  
3 blank levels. Although the concentrations of 47 elements could be obtained by X-ray  
4 fluorescence spectrometry, the concentrations of many of these elements are beneath MDLs and  
5 are not shown. The same elements shown in Appendix 6A of the 1996 PM AQCD are shown  
6 here. The usual practice of denoting table entry values below MDL by (—) is followed here.  
7 Missing data for PM<sub>2.5</sub> are also indicated by (—).  
8

## APPENDIX 3C

### Organic Composition of Particulate Matter

Although organic compounds typically constitute approximately 10 to 70% of the total dry fine particle mass in the atmosphere, organic PM concentrations, composition, and formation mechanisms are poorly understood. This is because particulate organic matter is an aggregate of hundreds of individual compounds spanning a wide range of chemical and thermodynamic properties (Saxena and Hildemann, 1996). The presence of multiphase or “semivolatile” compounds complicates collection of organic particulate matter. Furthermore, no single analytical technique currently is capable of analyzing the entire range of compounds present. Rigorous analytical methods frequently identify only 10 to 20% of the organic mass on the molecular level (Rogge et al., 1993). The data shown in Appendix 3C are meant to complement the data given for the inorganic components of particles in Appendix 6A of the 1996 PM AQCD (U. S. Environmental Protection Agency, 1996). Table 3C-1 lists a number of recent urban and some rural measurements of particulate organic and elemental carbon in  $\mu\text{g}$  of carbon/ $\text{m}^3$  ( $\mu\text{g C}/\text{m}^3$ ). Emphasis is placed on measurements published after 1995. The analysis method and artifact correction procedure, if any, are indicated. Table 3C-2 presents information on recent (post-1990) studies concerning concentrations (in  $\text{ng C}/\text{m}^3$ ) of particulate organic compounds found at selected U.S. sites.

A limited amount of rural data is presented. In some cases, total carbon (TC = OC + EC) is reported. OC concentrations must be multiplied by the average molecular weight per carbon weight to convert to mass of particulate organic compounds. The location and dates over which sampling occurred are provided. Averaging time refers to the sampling duration. Sampling method: Q – quartz fiber filter; QQ – two quartz fiber filters in series; Q+TQ – a quartz fiber filter in one port and a Teflon followed by a quartz filter in a parallel port; Imp – cascade impactor; DQQ – denuder followed by two quartz fiber filters; DQA – denuder followed by quartz fiber filter and adsorbent; VDQA – virtual impactor inlet followed by denuder, quartz filter, and adsorbent. Analysis method is reported as follows: TOR – thermal optical reflectance; TOT – thermal optical transmittance; TMO – thermal MnO<sub>2</sub> oxidation; EGA – evolved gas analysis; Th – Thermal analysis; Aeth – Aethalometer. na – data not available.

<sup>a</sup>Range is provided. It should be noted that samples were collected only during elevated pollution episodes and are not representative of average concentrations.

<sup>b</sup>Particulate OC was considered to be the sum of front and back quartz fiber filters.

<sup>c</sup>Sum of adsorbent and filter after correction for inlet losses and denuder efficiency.

<sup>d</sup>Corrected for adsorption by subtracting the Teflon-quartz back-up filter.

<sup>e</sup>Reported concentrations are corrected for adsorption by subtracting the quartz (TQ or QQ) back-up filter.

<sup>f</sup>Sampler contained two quartz fiber filters in series, but publication did not indicate whether the quartz back-up filter was subtracted to correct for adsorption.

<sup>g</sup>Corrected for adsorption using Micro-Orifice Uniform Deposit Impactor (MOUDI) data from a collocated sampler.

## APPENDIX 3D

### Composition of Particulate Matter Source Emissions

This appendix includes discussions of the elemental composition of emissions from various source categories discussed in Table 3-8. Discussions in this appendix incorporate material dealing with the inorganic components of source emissions from Chapter 5 of the 1996 PM AQCD (U. S. Environmental Protection Agency, 1996), updates to that material, and material describing the composition of organic components in source emissions. Primary emphasis is placed in the discussions on the composition of PM<sub>2.5</sub> sources.

#### *Soil and Fugitive Dust*

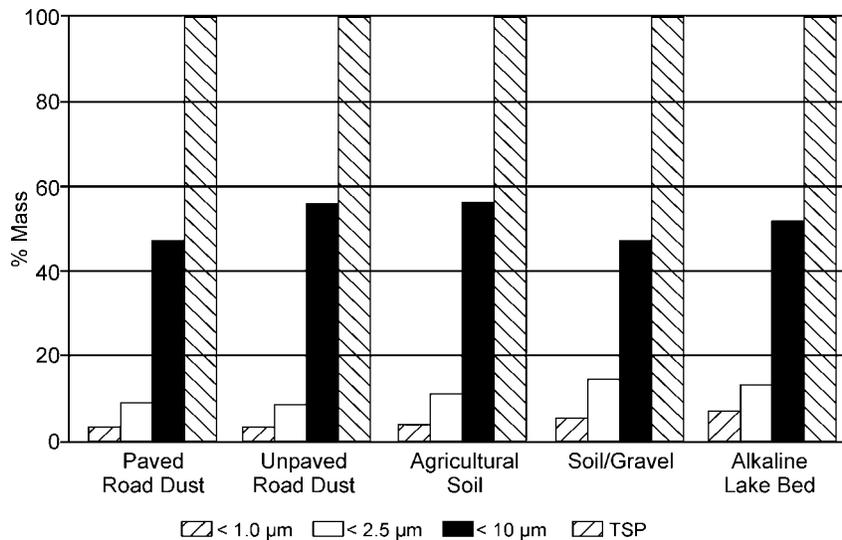

The compositions of soils and average crustal material are shown in Table 3D-1 (adapted from Warneck, 1988). Two entries are shown as representations of average crustal material. Differences from the mean soil composition shown can result from local geology and climate. Major elements in both soil and crustal profiles are Si, Al, and Fe, which are found in the form of various minerals. In addition, organic matter constitutes a few percent, on average, of soils. In general, the soil profile is similar to the crustal profiles, except for the depletion of soluble elements such as Ca, Mg, Na, and K. It should be noted that the composition of soils from specific locations can vary considerably from these global averages, especially for elements like Ca, Mg, Na, and K.

Fugitive dust emissions arise from paved and unpaved roads, building construction and demolition, parking lots, mining operations, storage piles, feed lots, grain handling, and agricultural tilling, in addition to wind erosion. Figure 3D-1 shows examples of size distributions in dust from paved and unpaved roads, agricultural soil, sand and gravel, and alkaline lake bed sediments, which were measured in a laboratory resuspension chamber as part of a study in California (Chow et al., 1994). This figure shows substantial variation in particle size among some of these fugitive dust sources. The PM<sub>1.0</sub> abundance (6.9%) in the total suspended PM (TSP) from alkaline lake bed dust is twice its abundance in paved and unpaved road dust. Approximately 10% of the TSP is in the PM<sub>2.5</sub> fraction and approximately 50% of

**TABLE 3D-1. AVERAGE ABUNDANCES OF MAJOR ELEMENTS IN SOIL AND CRUSTAL ROCK**

Elemental Abundances (ppmw)			
Element	Soil (1)	Crustal Rock	
		(2)	(3)
Si	330,000	277,200	311,000
Al	71,300	81,300	77,400
Fe	38,000	50,000	34,300
Ca	13,700	36,300	25,700
Mg	6,300	20,900	33,000
Na	6,300	28,300	31,900
K	13,600	25,900	29,500
Ti	4,600	4,400	4,400
Mn	850	950	670
Cr	200	100	48
V	100	135	98
Co	8	25	12

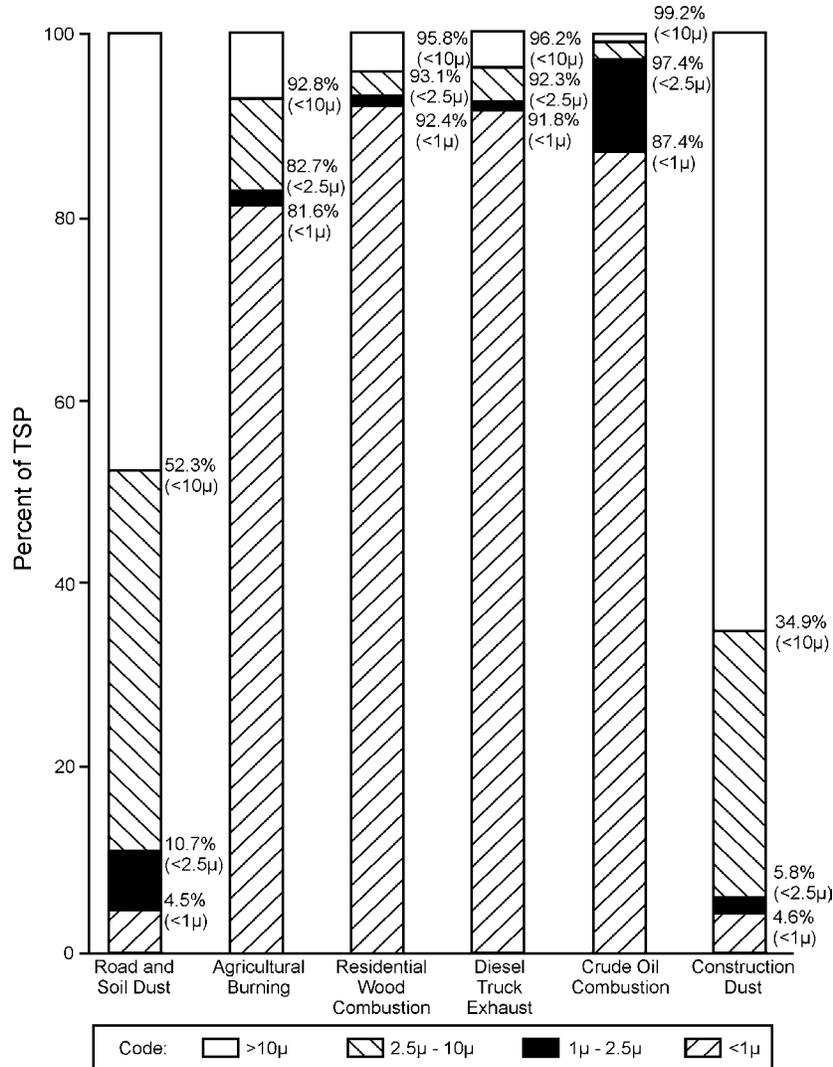

**Figure 3D-1. Size distribution of particles generated in a laboratory resuspension chamber.**

Source: Chow et al. (1994).

1 TSP is in the PM<sub>10</sub> fraction. The sand/gravel dust sample shows that 65% of the mass is in  
2 particles larger than the PM<sub>10</sub> fraction. The PM<sub>2.5</sub> fraction of TSP is approximately 30 to 40%  
3 higher in alkaline lake beds and sand/gravel than in the other soil types. The tests were  
4 performed after sieving and with a short (< 1 min) waiting period prior to sampling. It is  
5 expected that the fraction of PM<sub>1.0</sub> and PM<sub>2.5</sub> would increase with distance from a fugitive dust  
6 emitter, as the larger particles deposit to the surface faster than do the smaller particles.

7 The size distribution of samples of paved road dust obtained from a source characterization  
8 study in California is shown in Figure 3D-2. As might be expected, most of the emissions are in  
9 the coarse size mode. The chemical composition of paved road dust obtained in Denver, CO,  
10 during the winter of 1987-1988 is shown in Figure 3D-3. The chemical composition of paved  
11 road dust consists of a complex mixture of particulate matter from a wide variety of sources.  
12 Hopke et al. (1980) found that the inorganic composition of urban roadway dust in samples from  
13 Urbana, IL, could be described in terms of contributions from natural soil, automobile exhaust,  
14 rust, tire wear, and salt. Automobile contributions arose from exhaust emissions enriched in Pb;  
15 from rust as Fe; tire wear particles enriched in Zn; brake linings enriched in Cr, Ba, and Mn; and  
16 cement particles derived from roadways by abrasion. In addition to organic compounds from  
17 combustion and secondary sources, road dust also contains biological material such as pollen  
18 and fungal spores.

19 Very limited data exist for characterizing the composition in organic compounds found in  
20 resuspended paved road dust and soil dust. The only reported measurements are from Rogge  
21 et al. (1993a) and Schauer and Cass (2000), which consist of data for the fine particle fraction.  
22 The resuspended road dust sample analyzed by Rogge et al. (1993a) was collected in Pasadena,  
23 CA, during May of 1988. The sample analyzed by Schauer and Cass (2000) is a composite  
24 sample collected at several sites in the Central Valley of California in 1995. In both cases, road  
25 dust samples were resuspended in the laboratory. Samples were drawn through a PM<sub>2.0</sub> cyclone  
26 upstream of the collection substrate to remove particles with aerodynamic diameters greater than  
27 2.0 μm. It is unclear if these samples are representative of road dust in other locations of the  
28 United States. Table 3D-2 summarizes the organic compounds measured in these road dust  
29 samples.

1 **Stationary Sources**

2 The elemental composition of primary particulate matter emitted in the fine fraction from a  
 3 variety of power plants and industries in the Philadelphia area is shown in Table 3D-3 as a  
 4 representative example of emissions from stationary fossil combustion sources (Olmez et al.,  
 5 1988). Entries for the coal fired power plant show that Si and Al, followed by sulfate, are the  
 6 major primary constituents produced by coal combustion; whereas fractional abundances of  
 7 elemental carbon were much lower and organic carbon species were not detected. Sulfate is the

Source: Adapted from Olmez et al. (1988).

1 major particulate constituent released by the oil fired power plants examined in this study; and,  
2 again, elemental and organic carbon are not among the major species emitted. Olmez et al.  
3 (1988) also compared their results to a number of similar studies and concluded that their data  
4 should have much wider applicability to receptor model studies in other areas with some of the  
5 same source types. The high temperature of combustion in power plants results in the almost  
6 complete oxidation of the carbon in the fuel to CO<sub>2</sub> and very small amounts of CO. Combustion  
7 conditions in smaller boilers and furnaces allow the emission of unburned carbon and sulfur in  
8 more reduced forms such as thiophenes and inorganic sulfides. A number of trace elements are  
9 greatly enriched over crustal abundances in different fuels, such as Se in coal and V, Zn, and Ni  
10 in oil. In fact, the higher V content of the fuel oil than in coal could help account for the higher  
11 sulfate seen in the profiles from the oil-fired power plant compared to the coal-fired power plant  
12 because V at combustion temperatures found in power plants is known to catalyze the oxidation  
13 of reduced sulfur species. During combustion at lower temperatures, the emission of reduced  
14 sulfur species also occurs. For example, Huffman et al. (2000) identified sulfur species emitted  
15 by the combustion of several residual fuels oil (RFO) in a fire tube package boiler that is meant  
16 to simulate conditions in small institutional and industrial boilers. They found that sulfur was  
17 emitted not only as sulfate (26 to 84%), but as thiophenes (13 to 39%) with smaller amounts of  
18 sulfides and elemental S. They also found that Ni, V, Fe, Cu, Zn, and Pb are present mainly as  
19 sulfates in emissions. Linak et al. (2000) found, when burning RFO, that the fire tube package  
20 boiler produced particles with a bimodal size distribution in which about 0.2% of the mass was  
21 associated with particles smaller than 0.1 μm AD, with the rest of the mass lying between  
22 0.5 and 100 μm. Miller et al. (1998) found that larger particles consisted mainly of cenospheric  
23 carbon; whereas trace metals and sulfates were found concentrated in the smaller particles in a  
24 fire tube package boiler. In contrast, when RFO was burning in a refractory-lined combustor  
25 that is meant to simulate combustion conditions in a large utility residual oil fired boiler, Linak  
26 et al. (2000) found that particles were distributed essentially unimodally, with a mean diameter  
27 of about 0.1 μm.

28 Apart from emissions in the combustion of fossil fuels, trace elements are emitted as the  
29 result of various industrial processes such as steel and iron manufacturing and nonferrous metal  
30 production (e.g., for Pb, Cu, Ni, Zn, and Cd). As may be expected, emissions factors for the  
31 various trace elements are highly source-specific (Nriagu and Pacyna, 1988). Inspection of

1 Table 3D-3 reveals that the emissions from the catalytic cracker and the oil-fired power plant are  
2 greatly enriched in rare-earth elements (such as La) compared to other sources.

3 Emissions from municipal waste incinerators are heavily enriched in Cl, arising mainly  
4 from the combustion of plastics and metals that form volatile chlorides. The metals can  
5 originate from cans or other metallic objects, and some metals such as Zn and Cd are also  
6 additives in plastics or rubber. Many elements such as S, Cl, Zn, Br, Ag, Cd, Sn, In, Sb, and Pb  
7 are enormously enriched compared to their crustal abundances. A comparison of the trace  
8 elemental composition of incinerator emissions in Philadelphia, PA (shown in Table 3D-3) with  
9 those in Washington DC, and Chicago, IL (Olmez et al., 1988) shows agreement for most  
10 constituents to within less than a factor of two.

11 Very limited data exist for characterizing the chemical composition of organic compounds  
12 present in particulate emissions from industrial-scale stationary fuel combustion. Oros and  
13 Simoneit (2000) have presented the abundance and distribution of organic constituents in coal  
14 smokes that have been burned under laboratory conditions. This work provides the basis for  
15 further investigation addressing the emissions of coal fired boilers.

16 Rogge et al. (1997a) measured the composition of the organic constituents in the  
17 particulate matter emissions from a 50 billion kj/h boiler that was operating at 60% capacity and  
18 was burning number 2 distillate fuel oil. The fine carbon particulate matter emissions from this  
19 boiler over five tests were composed of an average of 14% organic carbon and 86% elemental  
20 carbon (Hildemann et al., 1991). Significant variability in the distribution of organic compounds  
21 present in the emissions from two separate tests was observed. Most of the identified organic  
22 mass consisted of n-alkanonic acids, aromatic acids, n-alkanes, PAH, oxygeanted PAH, and  
23 chlorinated compounds. It is unclear if these emissions are representative of typical fuel oil  
24 combustion units in the United States. Rogge et al. (1997b) measured the composition of hot  
25 asphalt roofing tar pots, and Rogge et al. (1993b) measured the composition of emissions from  
26 home appliances that use natural gas.

### 27 28 ***Motor Vehicles***

29 Exhaust emissions of particulate matter from gasoline powered motor vehicles and diesel  
30 powered vehicles have changed significantly over the past 25 years (Sawyer and Johnson, 1995;  
31 Cadle et al., 1999). These changes have resulted from reformulation of fuels, the wide  
32 application of exhaust-gas treatment in gasoline-powered motor vehicles, and changes in engine

1 design and operation. Because of these evolving tailpipe emissions, along with the wide  
2 variability of emissions between vehicles of the same class (Hildemann et al., 1991; Cadle et al.,  
3 1997; Sagebiel et al., 1997; Yanowitz et al., 2000), well-defined average emissions profiles for  
4 the major classes of motor vehicles have not been established. Two sampling strategies have  
5 been employed to obtain motor vehicle emissions profiles: (1) the measurement of exhaust  
6 emissions from vehicles operating on dynamometers and (2) the measurement of integrated  
7 emissions of motor vehicles driving through roadway tunnels. Dynamometer testing can be used  
8 to measure vehicle emissions operating over an integrated driving cycle and allows the  
9 measurement of emissions from individual vehicles. However, dynamometer testing requires  
10 considerable resources and usually precludes testing a very large number of vehicles. In  
11 contrast, a large number of vehicles can be readily sampled in tunnels; however, vehicles driving  
12 through tunnels operate over limited driving conditions, and the measurements represent  
13 contributions from a large number of vehicle types. As a result, except in a few cases, tunnel  
14 tests have not been effective at developing chemically speciated particulate matter emissions  
15 profiles for individual motor vehicle classes. Rather, several studies have measured the  
16 contribution of both organic and elemental carbon to the particulate matter emissions from  
17 different classes of motor vehicles operating on chassis dynamometers.

18 The principal components emitted by diesel and gasoline fueled vehicles are organic  
19 carbon (OC) and elemental carbon (EC) as shown in Tables 3D-4a and 4b. As can be seen, the  
20 variability among entries for an individual fuel type is large and overlaps that found between  
21 different fuel types. On average, the abundance of elemental carbon is larger than that of  
22 organic carbon in the exhaust of diesel vehicles; whereas organic carbon is the dominant species  
23 in the exhaust of gasoline fueled vehicles. Per vehicle mile, total carbon emissions from light  
24 and heavy duty diesel vehicles can range from 1 to 2 orders of magnitude higher than those from  
25 gasoline vehicles.

26 As might be expected, most of the PM emitted by motor vehicles is in the PM<sub>2.5</sub> size range.  
27 Particles in diesel exhaust are typically trimodal (consisting of a nuclei mode, an accumulation  
28 mode, and a coarse mode) and are log-normal in form (Kittelson, 1998). More than 90% of the  
29 total number of particles are in the nuclei mode, which contains only about 1 to 20% of the  
30 particle mass with a mass median diameter of about 0.02 μm; whereas the accumulation mode  
31 (with a mass median diameter of about 0.25 μm) contains most of the mass with a smaller

**TABLE 3D-4a. ORGANIC AND ELEMENTAL CARBON FRACTIONS OF DIESEL AND GASOLINE ENGINE PARTICULATE MATTER EXHAUST**

	Organic Carbon	Elemental Carbon
Heavy-duty diesel engines <sup>a</sup>	19 ± 8%	75 ± 10%
Heavy-duty diesel engines (SPECIATE) <sup>b</sup>	21 - 36%	52 - 54%
Light-duty diesel engines <sup>c</sup>	30 ± 9%	61 ± 16%
Light-duty diesel engines (SPECIATE) <sup>b</sup>	22 - 43%	51 - 64%
Gasoline engines (hot stabilized) <sup>a</sup>	56 ± 11%	25 ± 15%
Gasoline engines (“smoker” and “high emitter”) <sup>a,c</sup>	76 ± 10%	7 ± 6%
Gasoline engines (cold start) <sup>a</sup>	46 ± 14%	42 ± 14%

<sup>a</sup>Fujita et al. (1998) and Watson et al. (1998).

1 fraction (5 to 20%) contained in the coarse mode. Kerminin et al. (1997), Bagley et al. (1998),  
 2 and Kleeman et al. (2000) also have shown that gasoline and diesel fueled vehicles produce  
 3 particles that are mostly less than 2.0 µm in diameter. Cadle et al. (1999) found that 91% of PM  
 4 emitted by in-use gasoline vehicles in the Denver area was in the PM<sub>2.5</sub> size range, which  
 5 increased to 97% for “smokers” (i.e., light-duty vehicles with visible smoke emitted from their  
 6 tailpipes) and 98% for light-duty diesels. Durbin et al. (1999) found that about 92% of the PM  
 7 was smaller than 2.5 µm for smokers and diesels. The mass median diameter of the PM emitted  
 8 by the gasoline vehicles sampled by Cadle et al. (1999) was about 0.12 µm and increased to  
 9 0.18 µm for smokers and diesels. Corresponding average emissions rates of PM<sub>2.5</sub> found by  
 10 Cadle et al. (1999) were 552 mg/mile for diesels; 222 mg/mile for gasoline smokers; and  
 11 38 mg/mile for other gasoline vehicles. The values for gasoline smokers and for diesels appear  
 12 to be somewhat lower than those given in Table 3D-5; whereas the value for other gasoline  
 13 vehicles falls in the range given for low and medium gasoline vehicle emissions.

14 Examples of data for the trace elemental composition of the emissions from a number of  
 15 vehicle classes obtained December 1997 in Colorado, as part of the North Frontal Range Air  
 16 Quality Study (NFRAQS), are shown in Table 3D-5. As can be seen from Table 3D-5,  
 17 emissions of total carbon (TC), which is equal to the sum of organic carbon (OC) and elemental

- B. From Sagebiel et al. (1997). Hot start testing of vehicles identified as either high emitters of carbon monoxide or volatile organic compounds (VOCs).
- C. From Hildemann et al. (1991). Cold start tests.
- D. From Schauer et al. (1999). Hot start tests of medium duty vehicles operating on an FTP cycle.
- E. From Lowenthal et al. (1994). Only includes measurement of vehicles powered by diesel fuel operated without an exhaust particulate trap.

<sup>a</sup>A total of 195 light duty vehicles were tested that include both gasoline powered vehicles and diesel powered vehicles.

<sup>b</sup>Fraction of particulate matter consisting of organic carbon was measured with and without an organics denuder upstream of particulate filter. Results reported here represent measurement without an organics denuder for consistency with other measurements. Using an organics denuder, the organic carbon comprised 39% of the particulate matter carbon.

<sup>c</sup>Driving cycle comprised of multiple idle, steady acceleration, constant speed, deceleration steps (see reference for more details).

1 carbon (EC), from gasoline vehicles are highly variable. Gillies and Gertler (2000) point out that  
 2 there is greater variability in the concentrations of trace elements and ionic species than for OC  
 3 and EC among different source profiles (e.g., SPECIATE [U.S. Environmental Protection  
 4 Agency, 1999], Lawson and Smith [1998], Norbeck et al. [1998]). They suggest that this may  
 5 arise because emissions of trace elements are not related only to the combustion process, but also

Source: Lawson and Smith (1998).

1 to their abundances in different fuels and lubricants and to wear and tear during vehicle  
2 operation. Emissions from gasoline smokers are comparable to those from light-duty diesel  
3 vehicles. Thus, older, poorly maintained gasoline vehicles could be significant sources of PM<sub>2.5</sub>  
4 (Sagebiel et al., 1997; Lawson and Smith, 1998), in addition to being significant sources of  
5 gaseous pollutants (e.g., Calvert et al., 1993). Durbin et al. (1999) point out that although

1 smokers constitute only 1.1 to 1.7% of the light-duty fleet in the South Coast Air Quality  
2 Management District in California, they contribute roughly 20% of the total PM emissions from  
3 the light-duty fleet. In general, motor vehicles that are high emitters of hydrocarbons and carbon  
4 monoxide also will tend to be high emitters of PM (Sagebiel et al., 1997; Cadle et al., 1997).  
5 Particle emission rates, even in newer vehicles, also are correlated with vehicle acceleration; and  
6 emissions occur predominantly during periods of heavy acceleration (Maricq et al., 1999).

7 Although the data shown in Table 3D-5 indicate that S (mainly in the form of sulfate) is a  
8 minor component of PM<sub>2.5</sub> emissions, S may be the major component of the ultrafine particles  
9 that are emitted by either diesel or internal combustion engines (Gertler et al., 2000). It is not  
10 clear what the source of the small amount of Pb seen in the auto exhaust profile is. It is  
11 extremely difficult to find suitable tracers for automotive exhaust because Pb has been removed  
12 from gasoline. However, it also should be remembered that restrictions in the use of leaded  
13 gasoline have resulted in a dramatic lowering of ambient Pb levels.

14 Several tunnel studies have measured the distribution of organic and elemental carbon in  
15 the integrated exhaust of motor vehicle fleets comprising several classes of motor vehicles  
16 (Pierson and Brachaczek, 1983; Weingartner et al., 1997a; Fraser et al., 1998a). The study by  
17 Fraser et al. (1998a) found that organic carbon constituted 46% of the carbonaceous PM  
18 emissions from the vehicles operating in the Van Nuys tunnel in Southern California in the  
19 Summer of 1993. Although diesel vehicles constituted only 2.8% of the vehicles measured by  
20 Fraser et al. (1998a), the contribution of the organic carbon to the total particulate carbon  
21 emissions obtained in the Van Nuys tunnels is in reasonable agreement with the dynamometer  
22 measurements shown in Table 3D-4b.

23 Very few studies have reported comprehensive analyses of the organic composition of  
24 motor vehicle exhaust. The measurements by Rogge et al. (1993c) are the most comprehensive  
25 but are not expected to be the best representation of current motor vehicle emissions because  
26 these measurements were made in the mid-1980s. Measurements reported by Fraser et al.  
27 (1999) were made in a tunnel study conducted in 1993 and represent integrated diesel and  
28 gasoline powered vehicle emissions. In addition, exhaust emissions from two medium-duty  
29 diesel vehicles operating over an FTP cycle were analyzed by Schauer et al. (1999). A unique  
30 feature of both the measurements by Faser et al. (1999) and Schauer et al. (1999) is that they  
31 include the quantification of unresolved complex mixture (UCM), which comprises aliphatic and  
32 cyclic hydrocarbons that cannot be resolved by gas chromatography (Schauer et al., 1999).

Schauer et al. (1999) have shown that all of the organic compound mass in their diesel exhaust samples could be extracted and eluted by CG/MS techniques even though not all of the organic compound mass can be identified on a single compound basis. Table 3D-6 summarizes the composition of motor vehicle exhaust measured by Fraser et al. (1999) and Schauer et al. (1999).

**TABLE 3D-6. SUMMARY OF PARTICLE-PHASE ORGANIC COMPOUNDS  
EMITTED FROM MOTOR VEHICLES**

Source	Compound Class	Contribution to Particulate Mass (%)	Dominant Contributors to Emissions of Compound Class
Gasoline and diesel-powered vehicles driving through the Van Nuys Tunnel (Fraser et al., 1999) <sup>a</sup>	n-Alkanes	0.009	C <sub>21</sub> through C <sub>29</sub>
	Petroleum biomarkers	0.078	Hopanes and steranes
	PAH	0.38	No dominant compound
	Aromatic acids	0.29	Benzenedicarboxylic acids
	Aliphatic acids	0.21	Palmitic and stearic acids
	Substituted aromatic	0.042	No dominant compound
	UCM <sup>b</sup>	23.0	
Medium-duty diesel vehicles operated over an FTP Cycle (Schauer et al., 1999)	n-Alkanes	0.22	C <sub>20</sub> through C <sub>28</sub>
	Petroleum biomarkers	0.027	Hopanes and steranes
	PAH	0.54	No dominant compound
	Aliphatic acids	0.24	n-Octadecanoic acid
	Aromatic acids	0.014	Methylbenzoic acid
	Saturated cycloalkanes	0.037	C <sub>21</sub> through C <sub>25</sub>
	UCM <sup>b</sup>	22.2	

<sup>a</sup>Includes emissions of brake wear, tire wear, and resuspension of road dust associated with motor vehicle traffic.

<sup>b</sup>Unresolved complex mixture.

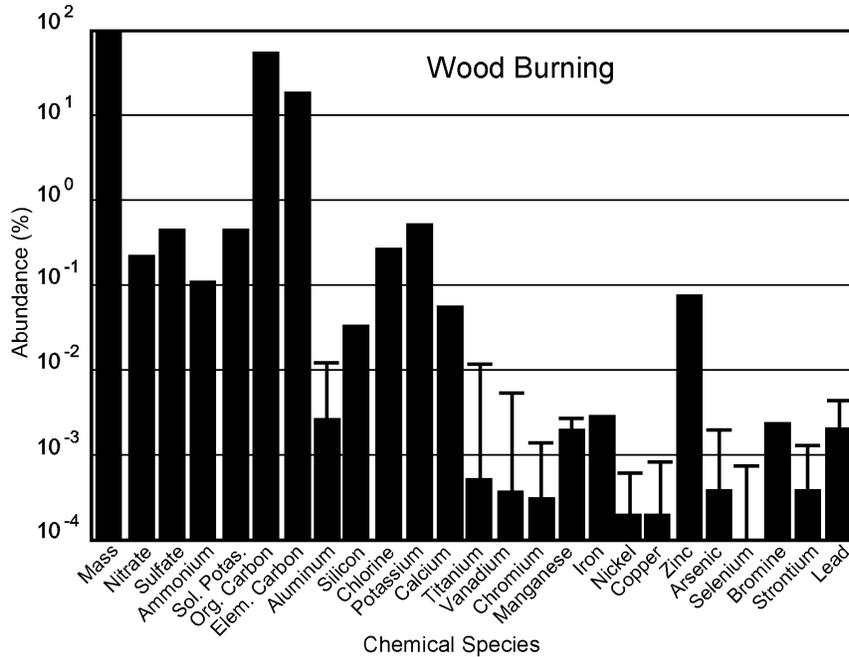

Several studies have measured the distribution of polycyclic aromatic hydrocarbons (PAHs) in motor vehicles exhaust from on-road vehicles (Westerholm et al., 1991; Lowenthal et al., 1994; Venkataraman et al., 1994; Westerholm and Egeback, 1994; Reilly et al., 1998; Cadle et al., 1999; Weingartner et al., 1997b; Marr et al., 1999). Cadle et al. (1999) found high

1 molecular weight PAHs (PAHs with molecular weights greater than or equal to 202 g/mole)  
2 constitute 0.1 to 7.0% of the particulate matter emissions from gasoline powered and diesel  
3 powered light duty vehicles. It is important to note, however, that PAHs with molecular weights  
4 of 202 (fluoranthene, acephenanthrylene, and pyrene), 226 (benzo[ghi]fluoranthene and  
5 cyclopenta[cd]pyrene), and 228 (benz[a]anthracene, chrysene, and triphenylene) exist in both the  
6 gas-phase and particle-phase at atmospheric conditions (Fraser et al., 1998b) although those with  
7 molecular weight of 228 are predominantly associated with particles, with only traces in the  
8 gas-phase (Arey et al., 1987). Excluding these semivolatile PAHs, the contribution of  
9 nonvolatile PAHs to the particulate matter emitted from the light-duty vehicles sampled by  
10 Cadle et al. (1999) ranges from 0.013 to 0.18%. These measurements are in good agreement  
11 with the tunnel study conducted by Fraser et al. (1999) and the heavy-duty diesel truck and bus  
12 exhaust measurements by Lowenthal et al. (1994), except that the nonvolatile PAH emissions  
13 from the heavy duty diesel vehicles tested by Lowenthal et al. (1994) were moderately higher,  
14 making up approximately 0.30% of the particulate matter mass emissions.

### 16 ***Biomass Burning***

17 In contrast to the mobile and stationary sources discussed earlier, emissions from biomass  
18 burning in wood stoves and forest fires are strongly seasonal and can be highly episodic within  
19 their peak emissions seasons. The burning of fuelwood is confined mainly to the winter months  
20 and is acknowledged to be a major source of ambient air particulate matter in the northwestern  
21 United States during the heating season. Forest fires occur primarily during the driest seasons of  
22 the year in different areas of the country and are especially prevalent during prolonged droughts.  
23 PM produced by biomass burning outside the United States (e.g., in Central America during the  
24 spring of 1988) also can affect ambient air quality in the United States.

25 An example of the composition of fine particles (PM<sub>2.5</sub>) produced by wood stoves is shown  
26 in Figure 3D-4. These data were obtained in Denver during the winter of 1987-1988 (Watson  
27 and Chow, 1994). As was the case for motor vehicle emissions, organic and elemental carbon  
28 are the major components of particulate emissions from wood burning. It should be remembered  
29 that the relative amounts shown for organic carbon and elemental carbon vary with the type of  
30 stove, the stage of combustion, and the type and condition of the fuelwood. Fine particles are  
31 dominant in smoke studies of wood burning emissions. For instance, the mass median diameter

**Figure 3D-4. Chemical abundances for PM<sub>2.5</sub> emissions from wood burning in Denver, CO. Solid bars represent fractional abundances, and the error bars represent variability in species abundances. Error bars represent detection limits when there are no solid bars.**

Source: Watson and Chow (1994).

1 of wood particles was found to be about 0.17  $\mu\text{m}$  in a study of the emissions from burning  
 2 hardwood, softwood, and synthetic logs (Dasch, 1982).

3 Kleeman et al. (1999) showed that the particles emitted by the combustion of wood in  
 4 fireplaces are predominately less than 1.0  $\mu\text{m}$  in diameter, such that the composition of fine PM  
 5 (PM<sub>2.5</sub>) emitted from fireplace combustion of wood is representative of the total particulate  
 6 matter emissions from this source. Hildemann et al. (1991) and McDonald et al. (2000) reported  
 7 that smoke from fireplace and wood stove combustion consists of 48% to 71% OC and 2.9% to  
 8 15% EC. Average elemental and organic carbon contents for these measurements are shown in  
 9 Table 3D-7. It should be noted that the two methods used for the measurements shown in  
 10 Table 3D-7 have been reported to produce different relative amounts of OC and EC for wood  
 11 smoke samples but show good agreement for total carbon (OC + EC) measurements (Chow  
 12 et al., 1993).

**TABLE 3D-7. MASS EMISSIONS, ORGANIC CARBON, AND ELEMENTAL CARBON EMISSIONS FROM RESIDENTIAL COMBUSTION OF WOOD**

Wood Type	Combustion Type	Average Mass Emission Rate (g kg <sup>-1</sup> of wood burned)	Number of Tests	Percent Organic Carbon <sup>a</sup>	Percent Elemental Carbon <sup>a</sup>	References
Softwood	Fireplace	13.0	2	48.4	5.2	Hildemann et al. (1991)
Softwood	Fireplace	5.14	5	58.5	15.0	McDonald et al. (2000)
Hardwood	Fireplace	5.28	3	48.4	2.9	Hildemann et al. (1991)
Hardwood	Fireplace	5.66	5	63.2	7.0	McDonald et al. (2000)
Hardwood	Wood Stove	3.96	8	71.2	9.0	McDonald et al. (2000)

<sup>a</sup>Hildemann et al. (1991) used the method described by Birch and Cary (1996) to measure EC and McDonald et al. (2000) used the method reported by Chow et al. (1993) to measure OC.

1 Hawthorne et al. (1988) and Hawthorne et al. (1989) measured gas-phase and particle-  
 2 phase derivatives of guaiacol (2-methoxyphenol), syringol (2,6-dimethoxyphenol), phenol, and  
 3 catechol (1,2-benzenediol) in the downwind plume of 28 residential wood stoves and fireplaces.  
 4 Rogge et al. (1998) reported a broad range of particle-phase organic compounds in the wood  
 5 smoke samples collected by Hildemann et al. (1991), which include n-alkanes, n-alkanoic acids,  
 6 n-alkenoic acids, dicarboxylic acids, resin acids, phytosterols, polycyclic aromatic hydrocarbons  
 7 (PAH), and the compounds reported by Hawthorne et al. (1989). Supplementing these  
 8 measurements, McDonald et al. (2000) reported the combined gas-phase and particle-phase  
 9 emissions of PAH and the compounds quantified by Hawthorne et al. (1989). The measurements  
 10 by Rogge et al. (1998), which represent a comprehensive data set of the organic compounds  
 11 present in wood smoke aerosol, are summarized in Table 3D-8. It should be noted, however,  
 12 that these nearly 200 compounds account for only approximately 15 to 25% of the organic  
 13 carbon particle mass emitted from the residential combustion of wood. Simoneit et al. (1999)  
 14 have shown that levoglucosan constitutes a noticeable portion of the organic compound mass not  
 15 identified by Rogge et al. (1998). In addition, Elias et al. (1999) used high-temperature gas  
 16 chromatography/mass spectrometry (HTGC-MS) to measure high-molecular-weight organic  
 17 compounds in smoke from South American leaf and stem litter biomass burning. These  
 18 compounds cannot be measured by the analytical techniques employed by Rogge et al. (1998)  
 19 and, therefore, are strong candidates to make up some of the unidentified organic mass in the

**TABLE 3D-8. SUMMARY OF PARTICLE-PHASE ORGANIC COMPOUNDS  
EMITTED FROM THE COMBUSTION OF WOOD IN FIREPLACES\***

Biomass Type	Compound Class	Contribution to Particulate Mass (%)	Dominant Contributors to Emissions of Compound Class
Fireplace combustion of softwood	n-Alkanes	0.039	C <sub>21</sub> through C <sub>31</sub>
	n-Alkanoic acids	0.45	C <sub>16</sub> , C <sub>18</sub> , C <sub>20</sub> , C <sub>21</sub> , C <sub>22</sub> , C <sub>24</sub>
	n-Alkenoic acids	0.12	Oleic and linoleic acid
	Dicarboxylic acids	0.36	Malonic acid
	Resin acids	1.28	Abietic, dehydroabietic, isopimaric, pimaric, and sandaracopimaric acids
	Substituted phenols	3.30	Benzenediols and guaiacols
	Phytosterols	0.37	β-Sitosterol
	PAH	0.092	Fluoranthene and pyrene
	Oxygenated PAH	0.019	1H-phenalen-1-one
Fireplace combustion of hardwood	n-Alkanes	0.044	C <sub>21</sub> through C <sub>29</sub>
	n-Alkanoic acids	1.33	C <sub>16</sub> , C <sub>22</sub> , C <sub>24</sub> , C <sub>26</sub>
	n-Alkenoic acids	0.049	Oleic and linoleic acid
	Dicarboxylic acids	0.42	Succinic acid
	Resin acids	0.11	Dehydroabietic acid
	Substituted phenols	8.23	Benzenediols, guaiacols, and syringols
	Phytosterols	0.21	β-sitosterol
	PAH	0.13	No dominant compounds
	Oxygenated PAH	0.020	1H-phenalen-1-one

\*Note: Measurements were made using a dilution sampler and no semivolatile organic compound sorbent.

Source: Rogge et al. (1998).

1 wood smoke samples analyzed by Rogge et al. (1998). These compounds, which include  
 2 triterpenyl fatty acid esters, wax esters, triglycerides, and high-molecular-weight n-alkan-  
 3 2-ones, are expected to be present in North American biomass smoke originating from  
 4 agricultural burning, forest fires, grassland fires, and wood stove/fireplace smoke.

1 Measurements of aerosol composition, size distributions, and aerosol emissions factors  
2 have been made in biomass burning plumes, either on towers (Susott et al., 1991) or aloft on  
3 fixed-wing aircraft (e.g., Radke et al., 1991) or on helicopters (e.g., Cofer et al., 1988). As was  
4 found for wood stove emissions, the composition of biomass burning emissions is strongly  
5 dependent on the stage of combustion (i.e., flaming, smoldering, or mixed), and the type of  
6 vegetation (e.g., forest, grassland, scrub). Over 90% of the dry mass in particulate biomass  
7 burning emissions is composed of organic carbon (Mazurek et al., 1991). Ratios of organic  
8 carbon to elemental carbon are highly variable, ranging from 10:1 to 95:1, with the highest ratio  
9 found for smoldering conditions and the lowest for flaming conditions. Emissions factors for  
10 total particulate emissions increase by factors of two to four in going from flaming to smoldering  
11 stages in the individual fires studied by Susott et al. (1991).

12 Particles in biomass burning plumes from a number of different fires were found to have  
13 three distinguishable size modes: (1) a nucleation mode, (2) an accumulation mode, and  
14 (3) a coarse mode (Radke et al., 1991). Based on an average of 81 samples, approximately 70%  
15 of the mass was found in particles  $<3.5 \mu\text{m}$  in aerodynamic diameter. The fine particle  
16 composition was found to be dominated by tarlike, condensed hydrocarbons; and the particles  
17 were usually spherical in shape. Additional information for the size distribution of particles  
18 produced by vegetation burning is shown in Figure 3D-2.

19 An example of ambient data for the composition of  $\text{PM}_{2.5}$  collected at a tropical site that  
20 was heavily affected by biomass burning is shown in Table 3D-9. The samples were collected  
21 during November of 1997 on the campus of Sriwijaya University, which is located in a rural  
22 setting on the island of Sumatra in Indonesia (Pinto et al., 1998). The site was subjected  
23 routinely to levels of  $\text{PM}_{2.5}$  well in excess of the U.S. NAAQS as a result of the Indonesian  
24 biomass fires from the summer of 1997 through the spring of 1998. As can be seen from a  
25 comparison of the data shown in Table 3D-9 with those shown in Figure 3D-4, there are a  
26 number of similarities and differences (especially with regard to the heavy metal content) in the  
27 abundances of many species. The abundances of some crustal elements (e.g., Si, Fe) are higher  
28 in Table 3D-9 than in Figure 3D-4, perhaps reflecting additional contributions of entrained soil  
29 dust.

30 Limited emissions data that include organic compound speciation information have been  
31 reported for agricultural burning (Jenkins et al., 1996), forest fires (Simoneit, 1985), and  
32 grassland burning (Standley and Simoneit, 1987). Jenkins et al. (1996) present PAH emissions

1 factors for the combustion of cereals (barley, corn, rice, and wheat), along with PAH emissions  
2 factors for wood burning. Profiles of organic compounds in emissions from meat cooking  
3 (Rogge et al., 1991) and cigarette smoke (Rogge et al., 1994) also have been obtained.

#### 5 *Natural Sources*

6 Although sea-salt aerosol production is confined to salt water bodies, it is included here  
7 because many marine aerosols can exert a strong influence on the composition of the ambient  
8 aerosol in coastal areas. In some respects, the production of sea-salt aerosols is like that of  
9 windblown dust, in that both are produced by wind agitation of the surface. The difference  
10 between the two categories arises because sea-salt particles are produced from the bursting of air  
11 bubbles rising to the sea surface. Air bubbles are formed by the entrainment of air into the water  
12 by breaking waves. The surface energy of a collapsing bubble is converted to kinetic energy in  
13 the form of a jet of water that can eject drops above the sea surface. The mean diameter of the

1 jet drops is about 15% of the bubble diameter (Wu, 1979). Bubbles in breaking waves range in  
2 size from a few  $\mu\text{m}$  to several mm in diameter. Field measurements by Johnson and Cooke  
3 (1979) of bubble size spectra show maxima in diameters at around 100  $\mu\text{m}$ , with the bubble size  
4 distribution varying as  $(d/d_0)^{-5}$  with  $d_0 = 100 \mu\text{m}$ .

5 Because sea-salt particles receive water from the surface layer, which is enriched in  
6 organic compounds, aerosol drops are composed of this organic material in addition to sea salt  
7 (about 3.5% by weight in seawater).  $\text{Na}^+$  (30.7%),  $\text{Cl}^-$  (55.0%),  $\text{SO}_4^{-2}$  (7.7%),  $\text{Mg}^{2+}$  (3.6%),  $\text{Ca}^{2+}$   
8 (1.2%),  $\text{K}^+$  (1.1%),  $\text{HCO}_3^-$  (0.4%), and  $\text{Br}^-$  (0.2%) are the major ionic species by mass in  
9 seawater (Wilson, 1975). The composition of the marine aerosol also reflects the occurrence of  
10 displacement reactions that enrich sea-salt particles in  $\text{SO}_4^{-2}$  and  $\text{NO}_3^-$  while depleting them of  
11  $\text{Cl}^-$  and  $\text{Br}^-$ .

12 Sea salt is concentrated in the coarse size mode with a mass median diameter of about  
13 7  $\mu\text{m}$  for samples collected in Florida, the Canary Islands, and Barbados (Savoie and Prospero,  
14 1982). The size distribution of sulfate is distinctly bimodal. Sulfate in the coarse mode is  
15 derived from sea water, but sulfate in the submicron aerosol arises from the oxidation of  
16 dimethyl sulfide ( $\text{CH}_3\text{SCH}_3$ ) or DMS. DMS is produced during the decomposition of marine  
17 micro-organisms. DMS is oxidized to methane sulfonic acid (MSA), a large fraction of which  
18 is oxidized to sulfate (e.g., Hertel et al., 1994).

19 Apart from sea spray, other natural sources of particles include the suspension of organic  
20 debris and volcanism. Profiles of organic compounds in vegetative detritus have been obtained  
21 by Rogge et al. (1993d). Particles are released from plants in the form of seeds, pollen, spores,  
22 leaf waxes, and resins, ranging in size from 1 to 250  $\mu\text{m}$  (Warneck, 1988). Fungal spores and  
23 animal debris, such as insect fragments, also are to be found in ambient aerosol samples in this  
24 size range. Although material from all the foregoing categories may exist as individual particles,  
25 bacteria usually are found attached to other dust particles (Warneck, 1988). Smaller bioaerosol  
26 particles include viruses, individual bacteria, protozoa, and algae (Matthias-Maser and Jaenicke,  
27 1994). In addition to natural sources, other sources of bioaerosol include industry (e.g., textile  
28 mills), agriculture, and municipal waste disposal (Spendlove, 1974). The size distribution of  
29 bioaerosols has not been characterized as well as it has for other categories of airborne particles.

30 Trace metals are emitted to the atmosphere from a variety of sources such as sea spray,  
31 wind-blown dust, volcanoes, wildfires and biotic sources (Nriagu, 1989). Biologically mediated  
32 volatilization processes (e.g., biomethylation) are estimated to account for 30 to 50% of the

1 worldwide total Hg, As, and Se emitted annually; whereas other metals are derived principally  
2 from pollens, spores, waxes, plant fragments, fungi, and algae. It is not clear, however, how  
3 much of the biomethylated species are remobilized from anthropogenic inputs. Median ratios of  
4 the natural contribution to globally averaged total sources for trace metals are estimated to be  
5 0.39 (As), 0.15 (Cd), 0.59 (Cr), 0.44 (Cu), 0.41 (Hg), 0.35 (Ni), 0.04 (Pb), 0.41 (Sb), 0.58 (Se),  
6 0.25 (V), and 0.34 (Zn), suggesting a significant natural source for many trace elements.  
7 It should be noted, however, that these estimates are based on emissions estimates that have  
8 uncertainty ranges of an order of magnitude.

## APPENDIX 3E

### Variability Observed in PM<sub>2.5</sub> and PM<sub>10-2.5</sub> Concentrations at IMPROVE Sites

In this appendix, the temporal variability of PM<sub>2.5</sub>, PM<sub>10-2.5</sub> and PM<sub>10</sub> concentrations is characterized on various time scales based on daily values in the PM data set obtained at 18 sites in the IMPROVE network. The purpose of these analyses is to provide concentrations of PM<sub>2.5</sub> and PM<sub>10-2.5</sub> that could be used for characterizing human and ecosystem exposures to PM under the least polluted conditions that are found in the United States and to provide limits on policy relevant background PM concentrations (cf., Section 3.3.3). This is accomplished by analyzing PM<sub>2.5</sub> and PM<sub>10-2.5</sub> concentrations and their variability at relatively remote monitoring sites that are not obviously influenced by local pollution sources in the United States. The potential for receiving contributions from anthropogenic sources exists at every monitoring site. However, we are interested in characterizing data obtained at the sites with lowest concentrations. Only those sites in which anthropogenic sources do not contribute extensively to the observations are considered. These sites will be referred to as relatively remote monitoring sites (RRMS). Thus, virtually all sites in the eastern United States would not fit into this definition. Data from these sites are included to permit comparison with sites in the West. More detailed analyses of the data are available in Lefohn et al. (2004).

Data stored in the IMPROVE database as of December 4, 2002 from 18 IMPROVE network sites were downloaded from the following internet address: [http://vista.cira.colostate.edu/IMPROVE/Data/IMPROVE/IMPLoactable\\_Data.asp?SortColumn=Site\\_Code](http://vista.cira.colostate.edu/IMPROVE/Data/IMPROVE/IMPLoactable_Data.asp?SortColumn=Site_Code). The locations of the sites chosen are shown in Figure 3E-1. Data at many sites are available from 1989, data at other sites are available for shorter periods of time. In addition, sites have been relocated within various national parks. The monitoring site in Yellowstone National Park was relocated in 1996; thus, the designations for the two locations are Yellowstone National Park1 and Yellowstone National Park2. The Voyageurs National Park site was also relocated. The designations for the two locations are similar to those used for Yellowstone National Park. The 24-hour average data were summarized on seasonal and annual

## IMPROVE SITES SELECTED FOR THE STUDY

**Figure 3E-1. Locations of the rural PM IMPROVE sites selected for the study.**

1 bases. The data capture requirement for the annual analysis required that there had to be at least  
2 13 valid days of data for a particular constituent for each quarter of a calendar year in order for  
3 the information to be included. For the seasonal analysis, all 24-hour average data were used.  
4 The percentile information was organized by minimum, 10th percentile concentration (P10),  
5 25<sup>th</sup> percentile concentration (P25), 50<sup>th</sup> percentile concentration (P50), 75<sup>th</sup> percentile  
6 concentration (P75), 90<sup>th</sup> percentile concentration (P90), 95<sup>th</sup> percentile concentration (P95), 99<sup>th</sup>  
7 percentile concentration (P99), and maximum concentration.

8 Information about the range of annual mean  $PM_{2.5}$ ,  $PM_{10-2.5}$  and  $PM_{10}$  concentrations is  
9 summarized in Table 3E-1, and the range of 90<sup>th</sup> percentile concentrations is summarized in  
10 Table 3E-2. As can be seen from Table 3E-1, the lowest average annual mean  $PM_{2.5}$   
11 concentrations among all sites examined were recorded at Denali National Park (AK), with  
12 concentrations there ranging from an annual mean of  $1.15 \mu\text{g}/\text{m}^3$  to  $3.14 \mu\text{g}/\text{m}^3$ . On the other  
13 hand, the highest annual mean  $PM_{2.5}$  concentrations in the 12 western sites studied were  
14 observed in Glacier National Park (MT); values there ranged from  $4.92$  to  $6.36 \mu\text{g}/\text{m}^3$ . The  
15 highest average annual mean  $PM_{2.5}$  concentrations in the continental United States were  
16 observed at Dolly Sods/Otter Creek Wilderness (WV), those ranging from  $10.03 \mu\text{g}/\text{m}^3$  to  
17  $14.24 \mu\text{g}/\text{m}^3$ . In general, the lowest average annual mean  $PM_{2.5}$  concentration increased in going

**TABLE 3E-1. THE RANGE OF ANNUAL MEAN PM<sub>2.5</sub>, PM<sub>10-2.5</sub>, AND PM<sub>10</sub> CONCENTRATIONS AT IMPROVE PARTICULATE MATTER MONITORING SITES (all units in µg/m<sup>3</sup>)**

Site Name	PM <sub>2.5</sub>	PM <sub>10-2.5</sub>	PM <sub>10</sub>
*Denali National Park, AK	1.15 - 3.14	1.09 - 5.37	2.36 - 8.19

*Bryce Canyon National Park, UT	2.68 - 3.65	2.48 - 5.74	5.23 - 8.66
*Canyonlands National Park, UT	2.73 - 4.03	3.25 - 8.05	6.12 - 11.79
*Lone Peak Wilderness, UT	4.13 - 5.81	3.25 - 6.19	7.37 - 11.60
*Three Sisters Wilderness, OR	2.63 - 4.19	1.92 - 4.43	4.57 - 7.74
*Redwood National Park, CA	3.62 - 5.43	3.33 - 6.50	7.20 - 12.19
*Lassen Volcanic National Park, CA	2.10 - 5.47	1.86 - 6.47	4.42 - 8.68
*Gila Wilderness, NM	3.46 - 4.86	2.55 - 4.94	5.91 - 9.17
Boundary Waters Canoe Area, MN	4.28 - 5.88	2.24 - 3.72	7.19 - 9.35
Voyageurs National Park1, MN	5.01 - 6.60	3.98 - 4.22	10.08 - 13.25
Voyageurs National Park2, MN	4.48 - 7.82	2.71 - 3.03	6.93 - 7.14
Dolly Sods/Otter Creek Wilderness, WV	10.03 - 14.24	2.29 - 5.3	13.26 - 18.92
Acadia National Park, ME	4.23 - 8.50	1.84 - 6.04	7.28 - 15.03
Lye Brook Wilderness, VT	5.33 - 8.43	1.58 - 4.88	6.84 - 13.16
Brigantine National Wildlife Refuge, NJ	10.20 - 12.63	7.90 - 14.87	18.49 - 26.63

\* Western monitoring sites

1 to the midwestern and then to the eastern United States, and the range of annual average  
2 concentrations tends to be lower at western than at eastern sites. Over the period of the  
3 observational record, a substantial range in annual mean concentrations in all three size ranges is  
4 observed, indicating the importance of examining a number of years in attempting to  
5 characterize long term averages. Inspection of Table 3E-1 shows that the range in annual average  
6 PM<sub>10-2.5</sub> concentrations was generally larger than for PM<sub>2.5</sub>. However, it should be noted that  
7 PM<sub>10-2.5</sub> concentrations are obtained by a difference technique and so is more strongly affected by  
8 errors in the determination of both PM<sub>2.5</sub> and PM<sub>10</sub>.

**TABLE 3E-2. THE RANGE OF 24-HOUR PM<sub>2.5</sub>, PM<sub>10-2.5</sub>, AND PM<sub>10</sub> AVERAGE CONCENTRATIONS AT THE 90<sup>TH</sup> PERCENTILE LEVEL AT IMPROVE PARTICULATE MATTER MONITORING SITES (all units in µg/m<sup>3</sup>)**

Site Name	PM <sub>2.5</sub>	PM <sub>10-2.5</sub>	PM <sub>10</sub>
*Denali National Park, AK	2.18 - 7.44	1.92 - 11.65	4.31 - 17.94
*Glacier National Park, MT	8.05 - 11.00	8.36 - 27.60	17.66 - 36.82
*Bridger Wilderness, WY	3.94 - 5.77	4.80 - 12.26	8.32 - 15.14
*Yellowstone National Park1, WY	4.67 - 6.58	8.78 - 16.53	12.34 - 21.34
*Yellowstone National Park2, WY	4.06 - 6.04	4.22 - 5.94	7.42 - 10.82
*Bryce Canyon National Park, UT	4.40 - 5.92	5.03 - 11.99	8.93 - 13.60
*Canyonlands National Park, UT	4.48 - 6.38	6.30 - 14.68	10.89 - 18.46

Lye Brook Wilderness, VT	11.44 - 16.46	3.31 - 5.85	15.66 - 22.88
Brigantine National Wildlife Refuge, NJ	16.20 - 22.72	13.60 - 32.19	31.37 - 45.28

\*Western monitoring sites.

1 As can be seen from Table 3E-2, concentrations of PM in all three size fractions at the  
2 90<sup>th</sup> percentile level are often several times higher than the mean concentrations at all sites.  
3 In addition, the range of values at the 90<sup>th</sup> percentile level is much greater than that at lower  
4 levels. These findings indicate that extreme events are important for shaping the frequency  
5 distribution of PM that is observed. Wildfires play a major role in defining the year-to-year  
6 variability at specific sites, especially in the West. Notable examples include the massive forest  
7 fire in 1988 in Yellowstone National Park and those that occurred in 2000 in many western  
8 states. Dust storms also play a role in arid climates. The variability in annual average PM<sub>10-2.5</sub>  
9 concentrations is again related to several factors. Variability in factors that govern the

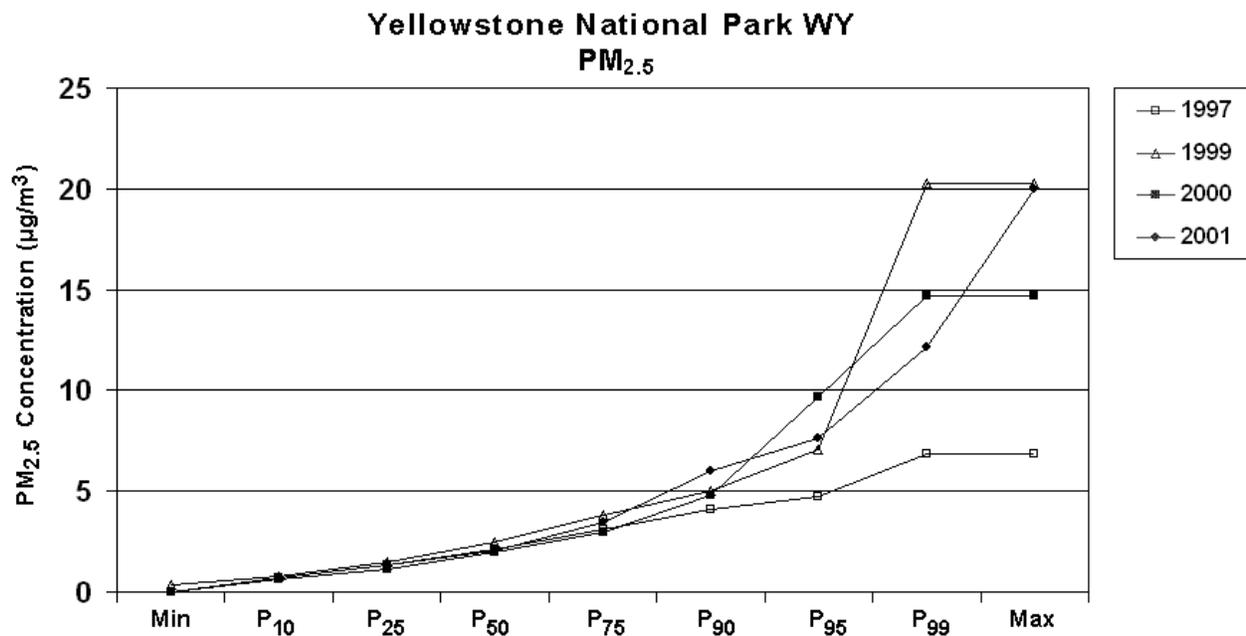

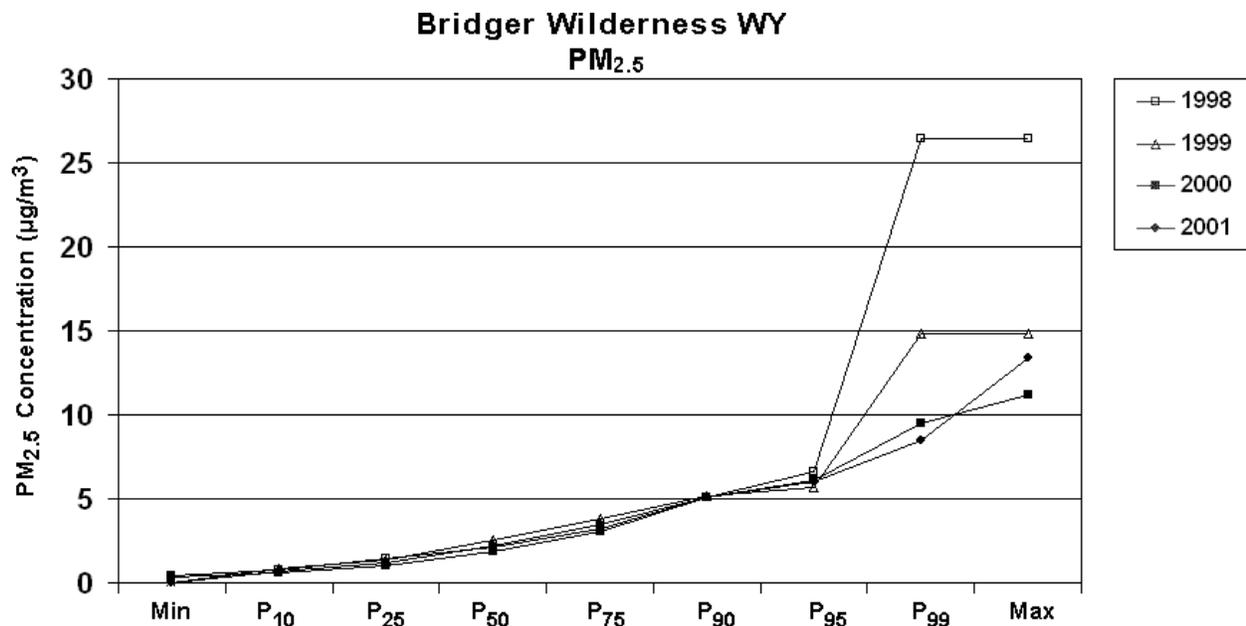

1 production of soil dust from the surface and the production of primary biological aerosol  
2 particles may be largely responsible. Wildfires also produce PM in this size range (cf.,  
3 Appendix 3D).

4 The interannual variability in the percentile distributions of PM<sub>2.5</sub> concentrations for 1997  
5 through 2001 is shown in Figures 3E-2(a-d) for four sites. The corresponding interannual  
6 variability in PM<sub>10-2.5</sub> concentrations at these sites is shown in Figures 3E-3(a-d). As can be seen,  
7 at concentrations less than the P90 level, year-to-year differences can be less than 1 µg/m<sup>3</sup> at  
8 sites such as Bridger, WY. Differences at the P90 level are much larger, both on an absolute and  
9 on a relative basis at eastern sites.

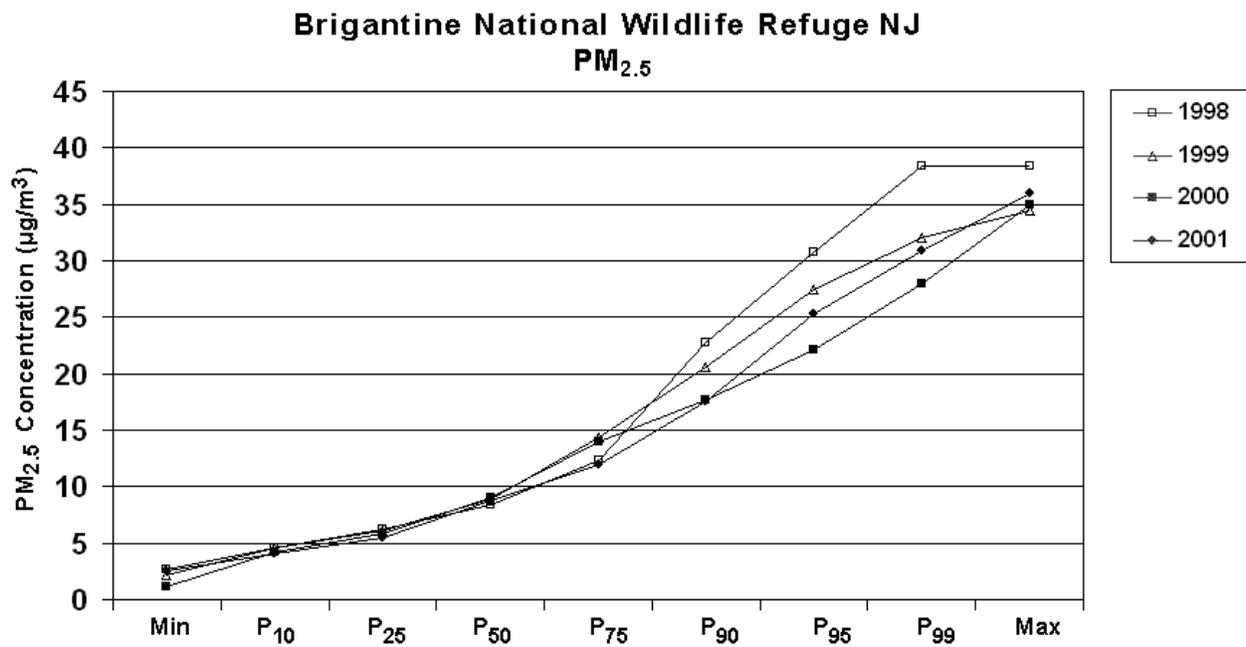

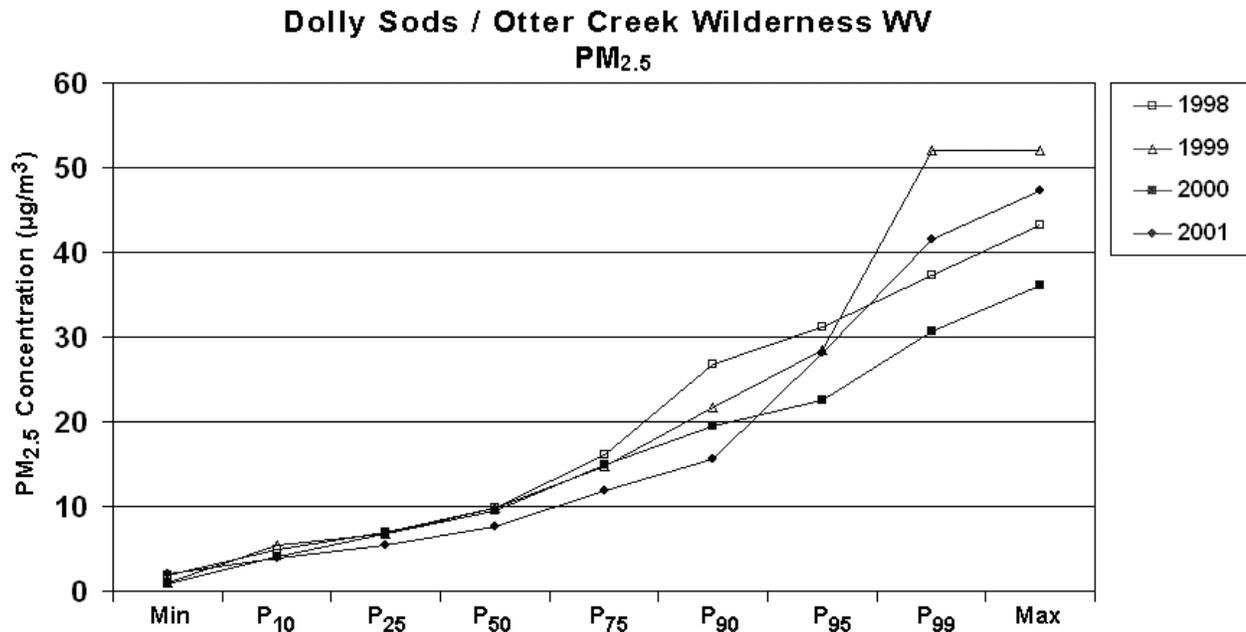

10 Percentile distributions by season are shown in Figure 3E-4(a-d) for PM<sub>2.5</sub> and  
11 Figures 3E-5(a-d) for PM<sub>10-2.5</sub>. For most sites, the variability in concentrations on a quarterly  
12 basis increases substantially beyond the 90<sup>th</sup> percentile level, as can be seen from inspection of  
13 Figures 3E-4(a-d) for PM<sub>2.5</sub> and Figures 3E-5(a-d) for PM<sub>10-2.5</sub>. Perhaps the most striking  
14 features seen in Figures 3E-4(a-d) and Figures 3E-5(a-d) are the concentration changes  
15 associated with the P<sub>95</sub> and P<sub>99</sub> events, which represent extreme value events. Most of these  
16 events occur in the third calendar quarter; however, at some sites high concentrations occur  
17 during the second and fourth calendar quarters. If locally derived climatologic seasons were  
18 used instead of calendar quarters, a more accurate depiction of the seasonal variability of these  
19 events may have been obtained. In most cases, there is consistency in the behavior of PM<sub>2.5</sub> and  
20 PM<sub>10</sub>, which suggests that the episodes of higher concentrations could be associated with sources  
21 that produce mainly PM<sub>2.5</sub> such as wildfires and/or anthropogenic combustion sources. Wildfires  
22 are limited to hotter and drier times of the year, but anthropogenic sources can contribute to high  
23 concentrations during other seasons. Additional factors which would tend to produce a 3<sup>rd</sup>  
24 quarter maximum include: the enhanced production of secondary particulate matter from  
25 anthropogenic and biogenic precursors during summer months; wildfires that are located in the  
26 East or elsewhere during summer; and surface dust produced locally and/or in northern Africa.

# 4. ENVIRONMENTAL EFFECTS OF AIRBORNE PARTICULATE MATTER

## 4.1 INTRODUCTION

This chapter assesses information providing inputs to U.S. EPA decision making on secondary National Ambient Air Quality Standards (NAAQS) aimed at protecting against welfare effects of ambient airborne particulate matter (PM). Specifically, it assesses the effects of atmospheric PM on the environment, including: (a) direct and indirect effects on vegetation and natural ecosystem integrity; (b) effects on visibility; and (c) effects on man-made materials, as well as (d) relationships of atmospheric PM to climate change processes. The 1997 EPA revisions to the U.S. PM NAAQS, discussed in Chapter 1 (Introduction), included establishment of PM<sub>2.5</sub> secondary standards identical to the primary PM<sub>2.5</sub> NAAQS set at that time. The 1997 FR notice promulgating these standards noted “The new secondary standards, in conjunction with a regional haze program, will provide appropriate protection against PM-related public welfare effects including soiling, material damage, and visibility impairment.”

## 4.2 EFFECTS OF AMBIENT AIRBORNE PM ON VEGETATION AND NATURAL ECOSYSTEMS

### Introduction

The effects of airborne particles are manifested via physical and chemical effects exerted at the individual plant level. However, plants are key members of ecosystems, structurally complex communities comprised of populations of plants, animals (including humans), insects, and microorganisms that interact with one another and with their non-living (abiotic) chemical and physical environment in which they exist (Odum, 1989; U.S. Environmental Protection Agency, 1993). All life on Earth is dependent on chemical energy in the form of carbon compounds to sustain their life processes. Terrestrial vegetation, via the process of photosynthesis, provides approximately half of the carbon that annually cycles between the Earth and the atmosphere (Chapin and Ruess, 2001).

1 Ecosystems respond to stresses through their constituent organisms. The responses of  
2 plant species and populations to environmental perturbations (such as those caused by  
3 atmospheric PM) depend on their genetic constitution (genotype), their life cycles, and the  
4 microhabitats in which they are growing. Stresses that produce changes in their physical and  
5 chemical environment apply selection pressures on individual organisms (Treshow, 1980). The  
6 changes that occur within populations and plant communities reflect these new and different  
7 pressures. A common response in a community under stress is the elimination of the more  
8 sensitive populations and an increase in abundance of species that tolerate or are favored by  
9 stress (Woodwell, 1970, Guderian et al., 1985).

10 The present section is organized to discuss: (1) factors affecting deposition of airborne PM  
11 on plants and ecosystems and then (2) the effects of PM deposition on individual plants, plant  
12 populations, forest trees and terrestrial ecosystems. As such, the section is organized to follow,  
13 in rough outline, the Framework for Assessing and Reporting on Ecological Condition  
14 recommended in a report by the Ecological Processes and Effects Committee (EPEC) of EPA's  
15 Science Advisory Board (Science Advisory Board, 2002), which states "The purpose of this  
16 report is to provide the Agency with a sample framework that may serve as a guide for designing  
17 a system to assess, and then report on, ecological condition at local, regional, or national scale.  
18 The sample framework is intended as an organizing tool that may help the Agency decide what  
19 ecological attributes to measure and how to aggregate those measurements into an  
20 understandable picture of ecological integrity." This framework is not actually a risk assessment  
21 per se, but it can be used to "construct a report of ecological condition" that characterizes the  
22 ecological integrity of an ecosystem based on "the relationship between common anthropogenic  
23 stressors and one or more of the six Essential Ecological Attributes." It nevertheless does  
24 provide a useful approach for organizing discussions of stressor effects on ecosystem  
25 components at successive levels of complexity.

#### 27 **4.2.1 Ecological Attributes**

28 The EPEC Framework provides a checklist of generic ecological attributes that should be  
29 considered when evaluating the integrity of ecological systems (see Table 4-1). The six generic  
30 ecological attributes, termed Essential Ecological Attributes (EEA), represent groups of related  
31 ecological characteristics (Science Advisory Board, 2002; Harwell et al., 1999) and include:

**TABLE 4-1. ESSENTIAL ECOLOGICAL ATTRIBUTES AND REPORTING CATEGORIES**

1 Chemical and Physical Characteristics; Biotic Conditions; Landscape Conditions; Ecological  
2 Processes; Hydrology and Geomorphology; and Natural Disturbance Regimes. All of the EEAs  
3 are interrelated (i.e., changes in one EEA may directly or indirectly affect other EEAs).

1           The first three ecological attributes listed in Table 4-1 are primarily “patterns,” whereas the  
2 last three are “processes.” Ecological science has used “patterns” and “processes” as terms to  
3 describe features of ecological systems for many years (e.g., Bormann and Likens, 1979). Of  
4 main concern in this chapter are relationships between a certain class of diverse airborne  
5 stressors from anthropogenic sources, termed particulate matter (PM), and one or more of the  
6 EEAs. Changes in patterns resulting from responses of vegetation and ecosystems to the effects  
7 of fine and coarse PM deposition, along with known or possible effects on ecological processes  
8 associated with changes in the patterns, are discussed in the subsections that follow.

9           The reader is also referred to several other sources for more detailed discussions of several  
10 topics only briefly alluded to or addressed here. For example, an extensive discussion of various  
11 types of effects of acidic deposition is presented in the U.S. National Acid Precipitation  
12 Assessment Program (NAPAP) Biennial Report to Congress: An Integrated Assessment  
13 Program (National Scientific and Technology Council, 1998). Additionally, ecological effects  
14 of acidic precipitation and nitrate deposition on aquatic systems are discussed in the EPA Air  
15 Quality Criteria Document for Nitrogen Oxides (U.S. Environmental Protection Agency, 1993);  
16 and sulfate deposition and effects, as related to wetlands and aquatic habitats, are discussed in  
17 U.S. Environmental Protection Agency (1982). Effects of lead on crops, vegetation, and  
18 ecosystems are assessed in the EPA document, Air Quality Criteria for Lead (U.S.  
19 Environmental Protection Agency, 1986). Lastly, effects of “certain pesticides, metal  
20 compounds, chlorinated organic compounds, and nitrogen compounds” are discussed in  
21 Deposition of Air Pollutants to the Great Waters, Third Report to Congress (U.S. Environmental  
22 Protection Agency, 2000a).

#### 23 24 **4.2.2 Ecosystem Exposures – Particle Deposition**

25           Airborne particles, their precursors, and their transformation products are removed from  
26 the atmosphere by wet and dry deposition processes. This atmospheric cleansing process  
27 fortunately lowers the long-term buildup of lethal concentrations of these pollutants in the air  
28 and moderates the potential for direct human health effects caused by their inhalation.  
29 Unfortunately, these deposition processes also mediate the transfer of PM pollutants to other  
30 environmental media where they can and do alter the structure, function, diversity, and  
31 sustainability of complex ecosystems.

1           The potential effects of PM deposition on vegetation and ecosystems encompass the full  
2 range, scales, and properties of biological organization listed under Biotic Condition, Table 4-1.  
3 Exposure to a given mass concentration of airborne PM, however, may lead to widely differing  
4 responses, depending on the particular mix of deposited particles. Particulate matter is not a  
5 single pollutant, but rather a heterogeneous mixture of particles differing in size, origin, and  
6 chemical composition. This heterogeneity exists across individual particles within samples from  
7 individual sites and, to an even greater extent, between samples from different sites. Thus far,  
8 atmospheric PM has been defined, for regulatory purposes, mainly by size fractions and less  
9 clearly so in terms of chemical nature, structure, or source. While size is related to the mode and  
10 magnitude of deposition to vegetated landscapes and may be a useful surrogate for chemical  
11 constitution, PM size classes do not necessarily have specific differential relevance for  
12 vegetation effects (Whitby, 1978; U.S. Environmental Protection Agency, 1996a); that is, both  
13 fine- and coarse-mode particles may affect plants. Much of the burden of sulfates, nitrates,  
14 ammonium salts, and hydrogen ions resides in the atmosphere either dissolved in fog water or as  
15 liquid or solid aerosols. Therefore, assessment of atmospheric PM deposition and effects on  
16 vegetation unavoidably include discussion of nitrates and sulfates and associated compounds  
17 involved in acidic and acidifying deposition. Other important issues relate to trace elements and  
18 heavy metals often found in ambient airborne PM.

#### 19 20 **4.2.2.1 Fine and Coarse Particulate Matter**

21           Particulate matter in current U.S. regulatory standards is classified as fine PM ( $PM_{2.5}$ ;  
22  $\leq 2.5 \mu\text{m}$  aerodynamic diameter) and coarse PM (2.5–10  $\mu\text{m}$ ). These combined fractions  
23 constitute  $PM_{10}$  (U.S. Environmental Protection Agency, 1996a,b).

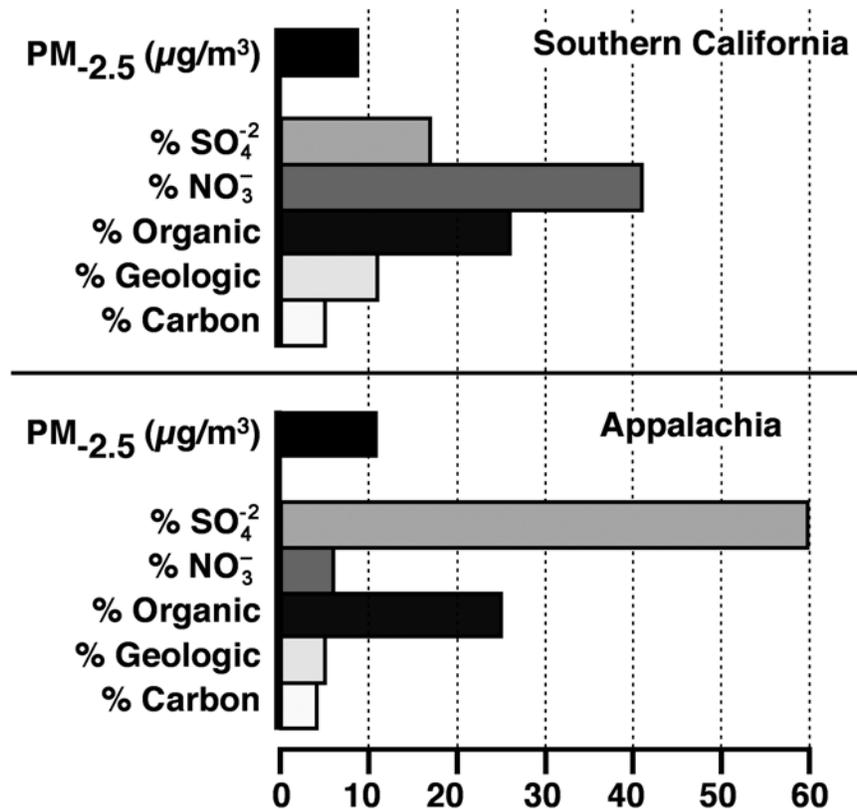

24           Fine and coarse PM have a number of contrasting properties that affect their impact on  
25 vegetated systems (see Chapter 2, Table 2-1 of this document). The model results of Wiman and  
26 Agren (1985) and the measurements of Lovett and Lindberg (1993) addressing the complexity of  
27 deposition processes in patchy forested landscapes and vertical stratification within canopies  
28 reveal clear distinctions between the deposition behavior of fine and coarse particles. For one,  
29 coarse particles settle nearer their site of formation than do fine particles. Also, the chemical  
30 constitution of individual particles is strongly correlated with size (i.e., most S and much N is  
31 present on fine particles, whereas much of the base cation and heavy metal burden is present on

1 coarse particles) and influences the predicted landscape loading of specific elements.  
2 Atmospheric PM may also act as a carrier for other directly phytotoxic materials (e.g.,  
3 herbicides). Fine PM dominates the surface area of particles suspended in the atmosphere, while  
4 coarse PM dominates the mass of such airborne particles. Surface area may become more  
5 central to ecological impact assessment as recognition of the oxidizing capacity of fine particles,  
6 their interactions with other pollutants such as ozone, and their adsorption of phytoactive organic  
7 compounds such as herbicides become more fully appreciated. Fine and coarse particles respond  
8 to changes in atmospheric humidity, precipitation, and wind through different mechanisms,  
9 differentially altering their deposition characteristics.

10 Fine PM may exhibit similar mass concentrations at different sites (Figure 4-1) and yet be  
11 composed of very different constituents. In eastern North America, sulfate typically is the major  
12 component of this fraction, in contrast to the West where nitrate is a key component (Figure 4-1;  
13 cf., the eastern Appalachian site and the western California site). On the other hand, in the urban  
14 center of Mexico City (Hidy et al., 2000), an environment more similar to the western than  
15 eastern U.S., concentrations of fine PM of about  $300 \mu\text{g m}^{-3}$  are found, and sulfate concentrations  
16 are 3 times that of nitrate. In contrast to sulfur and nitrogen, the contributions of organic and  
17 elemental carbon to the eastern and western U.S. sites were similar (Figure 4-1); soil-derived  
18 geologic material was greater at the more arid western site.

19 Fine PM is typically more diverse than coarse PM and is secondary in nature, having  
20 condensed from the vapor phase or been formed by chemical reaction from gaseous precursors  
21 in the atmosphere (see Chapter 2). Fine PM derives from atmospheric gas-to-particle conversion  
22 reactions involving nucleation, condensation, and coagulation, and from evaporation of water  
23 from contaminated fog and cloud droplets. Sulfur and nitrogen oxides ( $\text{SO}_x$  and  $\text{NO}_x$ ) are often  
24 oxidized to their respective acids and neutralized with ammonium cations as particulate salts.  
25 Fine PM may also contain condensates of volatile organic compounds, volatilized metals, and  
26 products of incomplete combustion (see Chapter 3).

27 Coarse PM, in contrast, is mainly primary in nature, having been emitted from area or  
28 point sources as fully formed particles derived from abrasion and crushing processes, soil  
29 disturbances, desiccation of marine aerosol from bursting bubbles, hygroscopic fine PM  
30 expanding with humidity to coarse mode, and/or gas condensation directly onto pre-existing  
31 coarse particles (see Chapters 2 and 3). Suspended primary coarse PM may contain iron, silica,

**Figure 4-1. The diversity of fine PM from sites in the western and eastern U.S.**

Modified from Sisler and Malm (2000).

1 aluminum, and base cations from soil, plant and insect fragments, pollen, fungal spores, bacteria,  
 2 and viruses, as well as fly ash, brake linings, debris, and automobile tire fragments. Coarse-  
 3 mode particles can be altered by chemical reactions and/or physical interactions with gaseous or  
 4 liquid contaminants.

5 The coating of coarse particles with semivolatile materials can substantially affect their  
 6 deposition and potential for biological effects. For example, nitrogen exhibits a strongly  
 7 bimodal size distribution: the peak above 1 μm can be attributed to HNO<sub>3</sub> adsorption onto coarse  
 8 alkaline particles; and that below 1 μm can be attributed to gas phase condensation of ammonia  
 9 with either sulfuric or nitric acid yielding either (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> or NH<sub>4</sub>NO<sub>3</sub> aerosol. HNO<sub>3</sub> has an  
 10 extremely high deposition velocity, nearly independent of the physiology of the surface.

1 Therefore, formation of ammonium nitrate reduces nitrogen deposition, because the deposition  
2 velocity of these particles is much less than that of  $\text{HNO}_3$  gas.

3 Similarly, anthropogenic emissions of sulfur are mostly as sulfur dioxide ( $\text{SO}_2$ ), which is  
4 hydrophilic, rapidly hydrated, and subsequently oxidized to sulfate ( $\text{SO}_4^{2-}$ ), which is about  
5 30-fold less phytotoxic than  $\text{SO}_2$ . The ratio of  $\text{SO}_4^{2-}$ :  $\text{SO}_2$  increases with aging of the air mass  
6 and, therefore, with distance from the source. Sulfate is thus a widespread regional/global  
7 pollutant and is sufficiently hygroscopic, that in humid air it exists significantly in the coarse PM  
8 fraction. It is unusual for injurious levels of particulate sulfate to be deposited upon vegetation,  
9 while direct injury due to  $\text{SO}_2$  is commonly observed near uncontrolled point sources. Gas-to-  
10 particle conversion in this case is of benefit to vegetation. The chemical composition of gaseous  
11 precursors of particulate matter and the formation of sulfates and nitrates is discussed in Section  
12 2.1.3 of Chapter 2.

13 Since enactment of the 1990 Clean Air Act Amendments, the atmospheric mix of PM  
14 precursors in the United States has changed substantially. That is, as emissions of  $\text{SO}_2$  have  
15 declined, emissions of oxides of nitrogen ( $\text{NO}_x$ ) have remained about the same, but emissions of  
16 cations have increased. This is almost certainly due to increased suspension of wind-borne  
17 geologic material from exposed soils.

18 For characterization of tropospheric chemistry, deposition of  $\text{O}_3$ ,  $\text{NO}_x$ , peroxides, and  
19 ammonia are first-order problems, followed by deposition of organics,  $\text{SO}_2$ , and particulate  
20 sulfate and nitrate (Wesely and Hicks, 2000). For impact on vegetation, however, the order may  
21 be different and may include different species — notably  $\text{SO}_2$ , fluoride where it still exists as a  
22 problem, particulate heavy metals, base cations, sulfate and nitrate. In spite of the current  
23 regulatory focus on non-speciated PM, exposure to a given mass concentration of PM may lead  
24 to widely differing phytotoxic outcomes depending upon the particular mix of PM constituents  
25 involved. This variability has not been characterized adequately. Though effects of specific  
26 chemical fractions of PM have been described, there has been relatively little research aimed at  
27 defining the effects of unspciated PM on plants or ecosystems.

#### 28 29 **4.2.2.2 Diversity of Deposition Modes**

30 Atmospheric deposition of particles to ecosystems takes place via both wet and dry  
31 processes, through three major routes: (1) wet, by precipitation scavenging in which particles

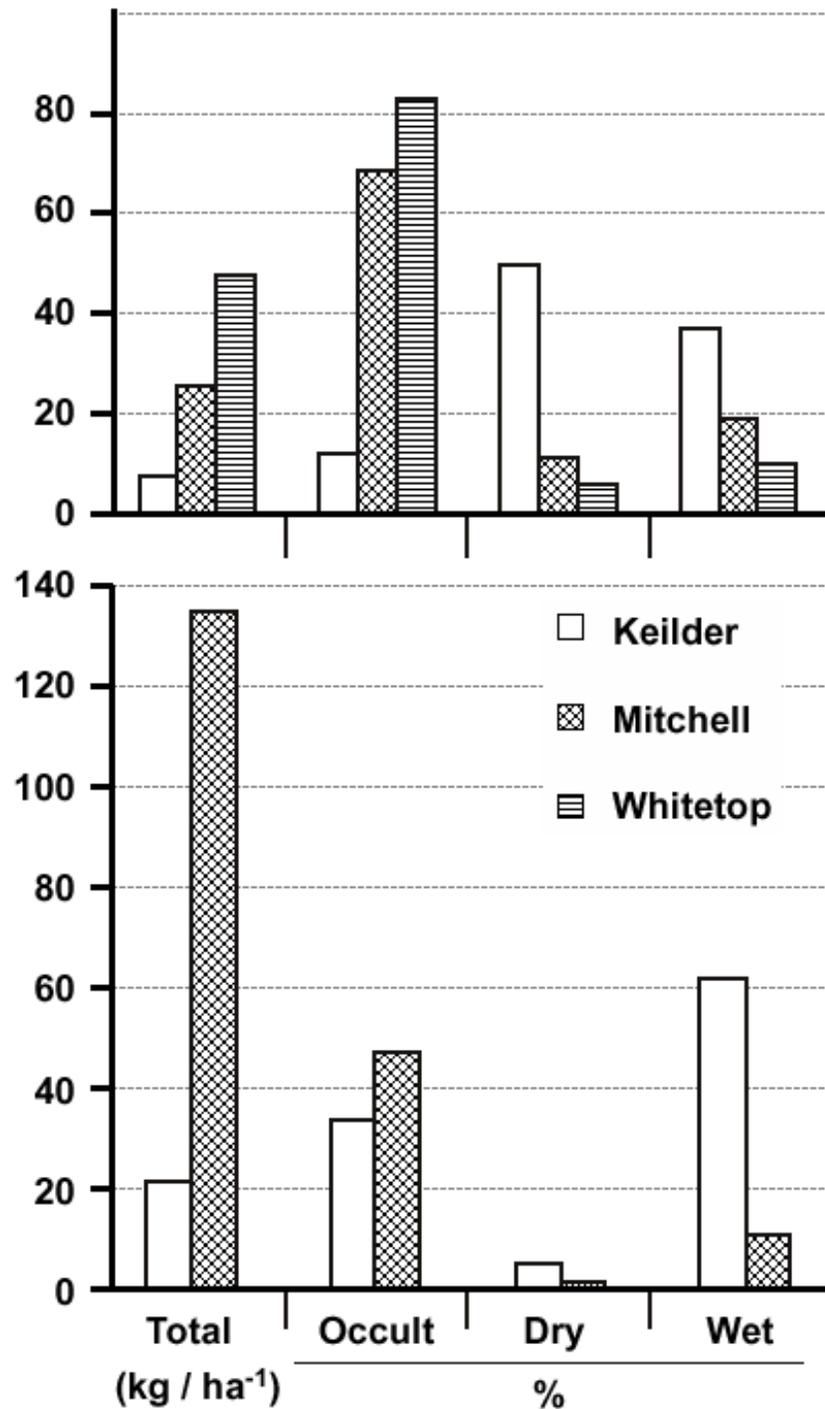

1 are deposited in rain and snow; (2) much slower dry deposition; and (3) occult deposition (so  
2 named because it was hidden from measurements which determined the previous two types of  
3 deposition) by fog, cloud-water, and mist interception (Table 4-2). Unlike gaseous dry  
4 deposition, neither the solubility of the particle nor the physiological activity of the surface are  
5 likely to be of first order importance in determining particulate dry deposition velocity ( $V_d$ ).  
6 Factors that contribute to surface wetness or stickiness may be critical determinants of deposition  
7 efficiency. Available tabulations of deposition velocity are highly variable and suspect. Recent  
8 evidence indicates that all three modes of deposition (wet, occult, and dry) must be considered in  
9 determining inputs to watersheds or ecosystems because each may dominate over specific  
10 intervals of time or space and ultimately, by interception and impaction onto vegetation or other  
11 rough elements in the landscape.

12 The distribution of deposition between wet, dry, and occult modes varies substantially  
13 between locations for both nitrogen and sulfur (Figure 4-2). Clearly, rainfall and snowfall will  
14 determine the magnitude of wet deposition. Precipitation events clean the air so that dry  
15 deposition is eliminated or reduced during subsequent dry periods. Occult deposition depends  
16 upon landscape interception of the cloud base (Cape, 1993). This may occur at high elevation  
17 sites, in coastal areas subject to onshore advection, or in low-lying interior areas subject to  
18 radiation fogs. Thus, ecosystem exposure is determined by the mode, and to some extent the  
19 magnitude, of deposition. Total deposition particularly for nitrogen, among mountain sites is  
20 related to the magnitude of the occult deposition, particularly for nitrogen (Figure 4-2).  
21 Topography and vegetation characteristics influence the deposition modes differently  
22 (Table 4-3). In general, dry deposition is the most sensitive and wet deposition is the least  
23 sensitive to features of the vegetated surface.

24 Comparison of micrometeorological and other methods for estimating particle deposition  
25 velocity (Erisman et al., 1997) suggests that there is little discrepancy between contrasting  
26 methodologies for estimating particle deposition and that this conclusion holds for both anions  
27 and cations, with the exception of nitrogenous species, which appear to interact with foliage in  
28 more complex ways. These comprehensive studies in the Speulder forest in the Netherlands  
29 indicated that aerosol deposition represents a considerable fraction of total deposition to the  
30 landscape. At this location, occult deposition was relatively insignificant, but dry deposition  
31 accounted for about one-fourth of alkaline-earth cation deposition.

**TABLE 4-2. TYPES AND DETERMINANTS OF PARTICULATE DEPOSITION  
AND IMPACT TO VEGETATION**

<b>Type of Deposition</b>	<b>Determinant of Deposition</b>	<b>Quantifiable Factors</b>
<i>Dry Deposition</i>	Ambient Concentration	Distance from Source Emission Strength

<i>Occult Deposition</i>	As Above	Combination of Above Factors

**Figure 4-2. Relative importance of three modes of deposition of nitrate (A) and sulfate (B) at high elevation sites (Unsworth and Wilshaw, 1989; Fowler et al., 1989; Mueller, 1988; Aneja and Murthy, 1994).**

**TABLE 4-3. RELATIVE IMPORTANCE OF WET, DRY, PARTICULATE, AND TOTAL DEPOSITION TO THREE FOREST SITES<sup>a</sup>**

Site	Deposition							
	Total Nitrogen <sup>b</sup>				Total Sulfur <sup>c</sup>			
	Wet (%)	Dry (%)	Particle (%)	Total (kg ha <sup>-1</sup> )	Wet (%)	Dry (%)	Particle (%)	Total (kg ha <sup>-1</sup> )
Duke Forest	75	25	0.11	9.87	64	33	2.7	17.20
Cary Forest	71	20	0.94	5.80	76	20	4.2	7.60
Austin Forest	71	29	0.58	6.57	83	13	4.3	7.79

<sup>a</sup>Data from Allen et al. (1994). Sampling was by triple filter pack so that fine-mode particles could be sampled preferentially. An average particle deposition velocity of 0.9 cm s<sup>-1</sup> was derived as in Hicks et al. (1987).

<sup>b</sup>Wet nitrogen consists of NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup>; dry nitrogen consists of vapor phase HNO<sub>3</sub> and NO<sub>2</sub>; and particulate nitrogen consists of NO<sub>3</sub>.

<sup>c</sup>Wet sulfur consists of SO<sub>4</sub><sup>-2</sup>, dry sulfur consists of vapor phase SO<sub>2</sub>, and particulate sulfur consists of pSO<sub>4</sub><sup>-2</sup>.

## 1 Wet Deposition

2 Wet deposition results from the incorporation of atmospheric particles and gases into cloud  
3 droplets and their subsequent precipitation as rain or snow, or from the scavenging of particles  
4 and gases by raindrops or snowflakes as they fall (Lovett, 1994). Precipitation scavenging, in  
5 which particles are incorporated in hydrometers and deposited in the resulting rain and snow,  
6 includes rainout (within-cloud incorporation by nucleation) and washout (below-cloud  
7 scavenging by impaction). Wet deposition generally is confounded by fewer factors than dry or  
8 occult deposition and has been easier to quantify. Total inputs from wet deposition to vegetative  
9 canopies can be significant (Table 4-3), although not all wet deposition involves particle  
10 scavenging because gaseous pollutants also dissolve in raindrops during precipitation events  
11 (Lovett, 1994). This contribution is obscured during measurements because wet deposition is  
12 measured simply by chemical analysis of total precipitation collected in clean, non-reactive  
13 buckets. Exclusion of dry deposited material (as opposed to dissolved gaseous species) requires  
14 closure or covering of the vessels except during precipitation.

15 Wet deposition is largely a function of precipitation amount and ambient pollutant  
16 concentrations. It is not affected by surface properties (Table 4-2) as much as dry or occult  
17 deposition although leaves (depending on their surface properties of wettability, exposure, and  
18 roughness) retain liquid and solubilized PM. Extensive vegetative canopies typically develop

1 leaf area indices (LAI; ratio of projected leaf area to ground area) much greater than 1. Thus any  
2 material deposited via precipitation to the upper stratum of foliage likely will be intercepted by  
3 several foliar surfaces before reaching the soil.

4 Landscape characteristics may also be important. Forested hillsides receive four- to  
5 six-fold greater inputs of wet deposition than short vegetation in nearby valleys. This is due to a  
6 variety of orographic effects (Unsworth and Wilshaw, 1989) and closer aerodynamic coupling to  
7 the atmosphere of tall forest canopies than of the shorter canopies in the valleys. This leads to  
8 more rapid foliar drying, which reduces the residence time but concentrates the solubilized  
9 particulate materials available for foliar uptake on the cuticular surface more quickly; and  
10 concentration increases the thermodynamic driving force for foliar uptake (Fowler et al., 1991;  
11 Unsworth, 1984; Schönherr and Huber, 1977). Following wet deposition, humidity and  
12 temperature conditions strongly influence the extent of biological effects, because of the  
13 competing effects of drying versus concentrating the solutions, and influence the rate of  
14 metabolic uptake of surface solutes (Swietlik and Faust, 1984). The net consequence of these  
15 factors on direct physical effects of wet deposited PM on leaves is not known.

16 Rainfall both introduces new wet deposition and redistributes throughout the canopy  
17 previously dry-deposited particulate material, particularly coarse particles which are  
18 preferentially deposited in the upper foliage (Peters and Eiden, 1992). Both effects scale the  
19 likelihood of foliar contact and potential direct PM effects on vegetation nearly linearly with  
20 canopy leaf area. The concentrations of suspended and dissolved materials are typically highest  
21 at the onset and decline with duration of individual precipitation events (Lindberg and  
22 McLaughlin, 1986; Hansen et al., 1994). Sustained rainfall removes much of the accumulation  
23 of dry-deposited PM from foliar surfaces, reducing direct foliar effects and combining the  
24 associated chemical burden with the wet-deposited material (Lovett and Lindberg, 1984; Lovett,  
25 1994) for transfer to the soil. Intense rainfall may contribute substantial total particulate inputs  
26 to vegetated land surfaces, mostly via the soil, but is less effective as a source of directly  
27 bioavailable or injurious pollutants to foliar surfaces. This washing effect, combined with  
28 differential foliar uptake and foliar leaching of different chemical constituents of PM alters the  
29 composition of the rainwater that reaches the soil. Low intensity precipitation events, in  
30 contrast, may deposit significantly more particulate pollutants to foliar-surfaces than high  
31 intensity precipitation events. Because of the short duration and limited atmospheric cleansing,

1 the concentration of PM in the final precipitation that remains in contact with foliar surfaces may  
2 be high. Additionally, such events may facilitate foliar uptake by hydrating some previously  
3 dry-deposited particles without removing them. This combination of dry deposition to foliage  
4 and subsequent wet removal increases the potential for PM to exert effects via soil pathways:  
5 first by enhancing dry deposition relative to adjacent unvegetated surfaces; and second by  
6 accelerating passage along with wet deposited material of the deposited PM by throughfall and  
7 stemflow to the soil. In the soil, PM may affect important ecosystem-level biogeochemical  
8 cycles of major, minor, and trace elements.

### 10 **Dry Deposition**

11 Dry deposition of atmospheric particles to plant and soil is a much slower process than wet  
12 or occult deposition, but it acts nearly continuously and affects all exposed surfaces (Hicks,  
13 1986). In dry deposition, particles at the large end of the spectrum (i.e.,  $> 5 \mu\text{m}$  diameter) are  
14 deposited mainly by gravitational sedimentation and inertial impaction. Smaller particles,  
15 especially those with diameters between  $\approx 0.2$  and  $2 \mu\text{m}$ , are not readily dry-deposited and tend  
16 to travel long distances in the atmosphere until their eventual deposition, most likely by  
17 incorporation into precipitation. This long-distance transport of fine aerosols is largely  
18 responsible for the regional nature of acid deposition (Lovett, 1994). A major conclusion from  
19 atmospheric deposition research is the realization that dry deposition is usually a significant and,  
20 in some cases, a dominant portion of total atmospheric deposition to an ecosystem (Lovett,  
21 1994). Plant parts of all types, including those not currently physiologically active, along with  
22 exposed soil and water surfaces, receive steady deposits of dry dusts, elemental carbon  
23 encrustations, grease films, tarry acidic coatings, and heterogeneous secondary particles formed  
24 from gaseous precursors (U.S. Environmental Protection Agency, 1982). The range of particle  
25 sizes, the diversity of canopy surfaces, and the variety of chemical constituents in airborne PM  
26 have slowed progress in both prediction and measurement of dry particulate deposition.  
27 Particulate deposition is a complex, poorly characterized process controlled primarily by  
28 atmospheric stability, macro- and micro-surface roughness, particle diameter, and surface  
29 characteristics (Table 4-2; Hosker and Lindberg, 1982). Deposition of particles suspended  
30 regionally and throughout the full depth of the planetary boundary layer (PBL) is controlled by  
31 different mechanisms within the three distinct atmospheric transport zones above the surface.

1 In the lower atmosphere, fine particles are transported by turbulent eddies of mechanical and  
2 convective origin. In the relatively unstirred, laminar boundary layer surrounding individual  
3 surface elements, Brownian diffusion dominates. Near the surface, actual deposition and contact  
4 with the surface is mediated by impaction (El-Shobokshy, 1985).

5 Deposition fluxes may be calculated from measurements, estimates, or modeled values of  
6 mass concentration (C) at a specified measurement height and the total conductance or  
7 deposition velocity ( $V_d$ ) from this height to the surface (Eq. 4-1; Hicks et al., 1987). These  
8 modeling techniques are closely allied with the micrometeorological techniques used to measure  
9 such fluxes. The flux (F) may be inferred as:

$$11 \quad F = V_d * (C_z - C_o), \quad (4-1)$$

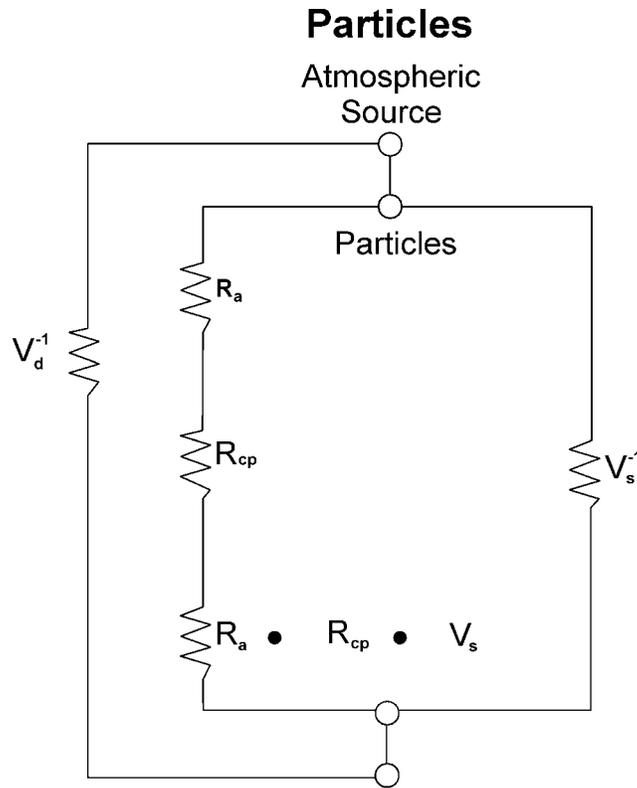

12  
13 where F is flux to the surface,  $C_z$  is the particle concentration at measurement height z,  $C_o$  is the  
14 particle concentration at receptor sites in the canopy (usually assumed equal to 0), and  $V_d$  is the  
15 overall deposition velocity. The flux is controlled by  $V_d$  and  $C_z$ .

16 Vertical transport of particles through the lower atmosphere to the vicinity of the  
17 vegetation elements is by turbulence and sedimentation, such that:

$$19 \quad V_d = V_t + V_s \quad (4-2)$$

20  
21 in which  $V_t$  (inner, left hand pathway of Figure 4-3) is a turbulent diffusion term, and  $V_s$  is a  
22 sedimentation term that dominates deposition of very coarse particles (Figure 4-4) and increases  
23 with particle size (Figure 4-5; dotted line). Sedimentation may be considered a pathway parallel  
24 to turbulent transport (Figure 4-4), but this is an over simplification.  $V_s$  affects the concentration  
25 of particles near the surface where eddy transport may occur and also governs the redeposition of  
26 some fraction of the particles lost to resuspension or rebound following deposition by impaction.  
27 For this reason,  $V_s$  is included (Figure 4-3) in the composite surface resistance term ( $R_a R_{cp} V_s$ ) as  
28 well as in the parallel sedimentation term.

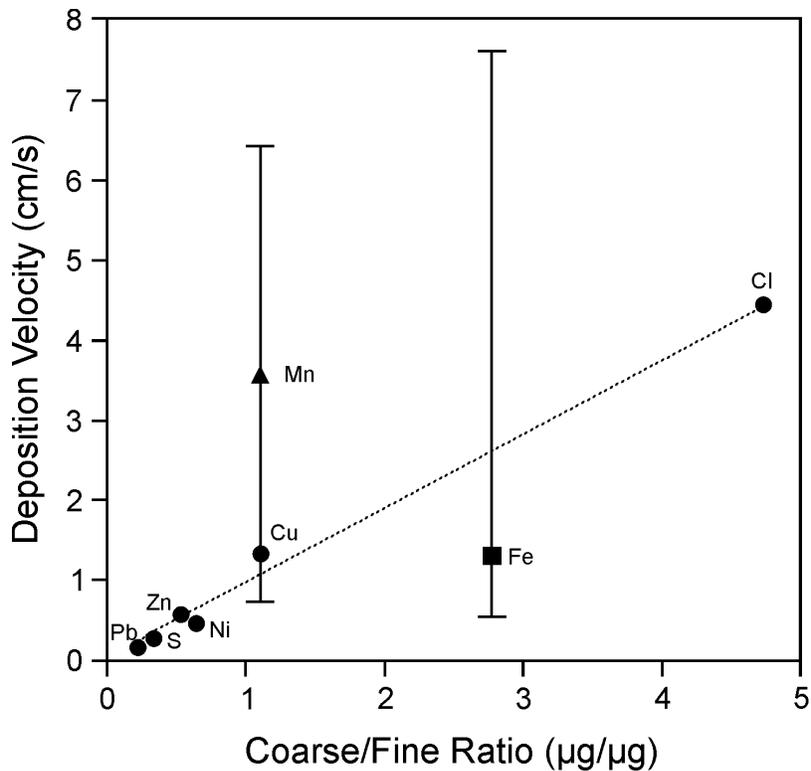

29 For submicron particles for which sedimentation is negligible (Hicks et al., 1987; Monteith  
30 and Unsworth, 1990; Wesely, 1989), the Ohm's Law Analogy (resistance catena) analogous to  
31 that used to describe transport of heat, momentum, or gases may be adequate, as:

**Figure 4-3. A simplified resistance catena representing the factors controlling deposition of particles to the surface. Vegetation-specific parameters are not explicitly considered. Modified after Hicks et al. (1987).**

1 
$$V_d = V_t = [r_a + r_b + r_c]^{-1}, \quad (4-3)$$

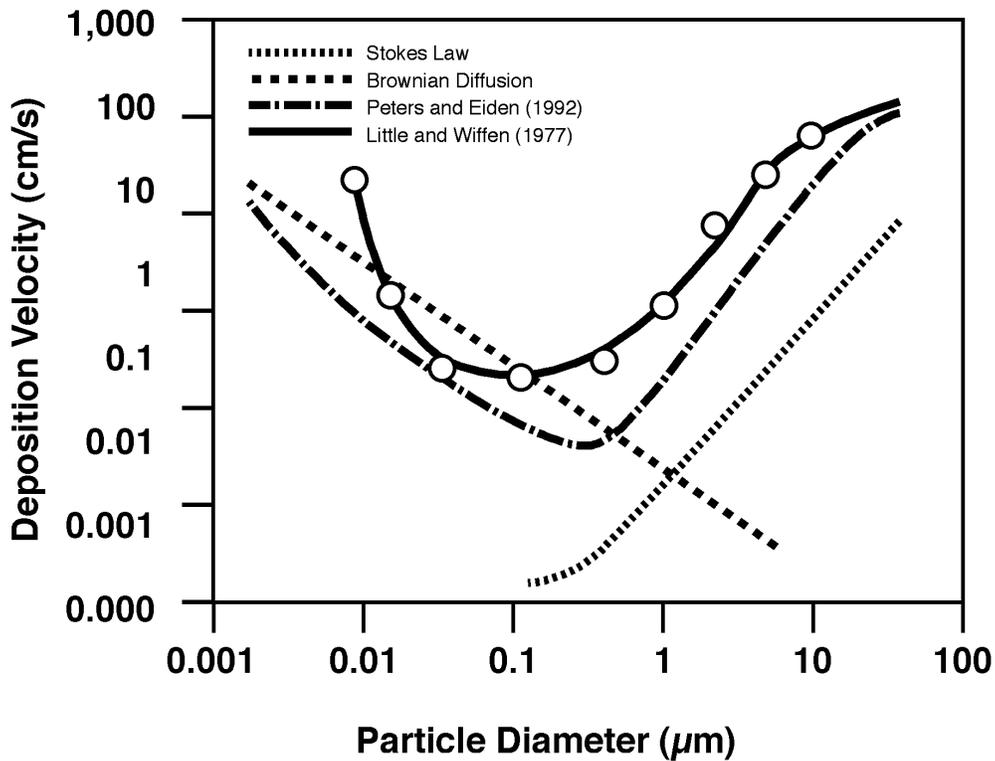

2  
3 where  $V_t$  is the deposition velocity due to turbulent transport of particles or other entities through  
4 the atmosphere;  $r_a$  is aerodynamic resistance (inverse of conductance or velocity) associated with  
5 the efficiency of turbulent transport above the canopy;  $r_b$  is the boundary layer resistance  
6 associated with diffusional transport through the still air layer immediately adjacent to canopy  
7 elements; and  $r_c$  is canopy resistance associated with physiological control of leaf porosity via  
8 stomata in the leaf surface. Significant departures from the analogy arise near the surface  
9 (Chamberlain, 1975; Sehmel, 1980), as particles that were transported efficiently by turbulent  
10 eddies are slowed substantially in the laminar boundary layer that reduces the efficiency of  
11 impaction. The preservation of momentum in this zone declines with decreasing diameter;

**Figure 4-4. The relationship between deposition velocity of selected particulate materials and the distribution of the material between the coarse- and fine-aerosol fractions. Data from Foltescu et al. (1994). Ranges for Mn and Fe are from Davidson and Wu (1989).**

1 however, this is offset by an increase in Brownian diffusivity with decreasing diameter  
 2 (Figure 4-3). Aerodynamic streamlines are parallel to the surface of each roughness element, so  
 3 that deposition ultimately depends on diffusion to the surface. The transition from impaction to  
 4 diffusion is likely blurred in the presence of leaf pubescence extending beyond the boundary  
 5 layer. These conflicting trends lead to a broad range over which empirical measurements of  $V_d$   
 6 and particle size are relatively independent (Figure 4-3), further demonstrating the importance of  
 7 the quasilaminar boundary layer (Lamaud et al., 1994; Shinn, 1978).

8 The aerodynamic term ( $r_a$ ) decreases with increasing wind speed, turbulence, and friction  
 9 velocity and increases with measurement height and atmospheric stability. It describes the  
 10 capacity of turbulent eddies to transport material, momentum, and heat between the  
 11 measurement height and the roughness height of the surface. Coarse particles may not be carried  
 12 efficiently by the high frequency eddies near the surface and may fall more rapidly than they

**Figure 4-5.** The relationship between particle diameter and deposition velocity for particles. Values measured in wind tunnels by Little and Wiffen (1977) over short grass with wind speed of  $2.5 \text{ m s}^{-1}$  closely approximate the theoretical distribution determined by Peters and Eiden (1992) for a tall spruce forest. These distributions reflect the interaction of Brownian diffusivity (descending dashed line), which decreases with particle size and sedimentation velocity (ascending dotted line from Stokes Law), which increases with particle size. Intermediate-sized particles ( $\approx 0.1$  to  $1.0 \text{ }\mu\text{m}$ ) are influenced strongly by both, and deposition is independent of size.

1 diffuse by either Brownian or turbulent processes. Thus, the relevance of  $r_a$  breaks down as  $V_s$   
 2 increases. Indeed because  $V_s$  (Eq. 4-2) is independent of a concentration gradient, the electrical  
 3 analogy is a theoretically flawed approximate approach (Venkatram and Pleim, 1999).

4

### 5 Deposition Velocity

6 Because the final stage of deposition for particles involves either impaction following  
 7 deceleration through a quasi-laminar boundary layer or diffusion through this boundary layer, its

1 effective depth is a critical determinant of  $V_d$  (Wiman et al., 1985; Peters and Eiden, 1992). The  
2 term corresponding to the boundary layer resistance for gases ( $r_b$ ; equation 4-3) incorporates the  
3 absence of form drag for gases. This parameter decreases with increasing turbulence and  
4 particle diffusivity but is poorly characterized for gases, depending critically on canopy  
5 morphology, vertical wind profiles, and gust penetration, and is of extremely limited usefulness  
6 for particles.

7       Once delivered by turbulent transport or sedimentation to the vicinity of vegetative surface  
8 elements, a variety of particle size-dependent mechanisms come into play, some differing  
9 substantially from those governing gaseous deposition. The concepts of  $r_b$  (the still air or  
10 boundary layer resistance) and  $r_c$  (the canopy or surface resistance) are not generally applicable  
11 to deposition of polydisperse particles. Because of the roles of momentum and bounce-off and  
12 complication by reentrainment back into the airstream following deposition of a particle to the  
13 surface, the factors determining the effective  $r_b$  and  $r_c$  for particle deposition are not as  
14 independent as for gases. They are replaced in some resistance formulations (e.g., Hicks et al.,  
15 1987) by the term,  $r_{cp}$ , that combines near-surface and surface effects and by a mathematically  
16 derived composite term,  $R_a R_{cp} V_s$ , that combines atmospheric, surface, and sedimentation effects  
17 (Figure 4-4). This latter term was insignificant for the submicron sulfate component considered  
18 originally in its derivation (Hicks et al., 1987), but it scales with the square of particle diameter,  
19 so that its general applicability to polydisperse particles is unclear. In general, transport between  
20 the turbulent air column and the leaf surface through the laminar boundary layer remains  
21 difficult to describe (Lindberg and McLaughlin, 1986).

22       Current estimates of regional particulate dry deposition (e.g., Edgerton et al., 1992; Brook  
23 et al., 1999) infer fluxes from the product of (variable and uncertain) measured or modeled  
24 particulate concentrations and (even more variable and uncertain) measured or modeled  
25 estimates of dry deposition velocity parameterized for a variety of specific surfaces (e.g., Brook  
26 et al., 1999). However, even for specific sites and well defined particles, uncertainties in  $F$  are  
27 largest in the values of  $V_d$ , which are typically characterized by the large ranges and variances  
28 described in other sources (e.g., Bytnerowicz et al., 1987a,b, Hanson and Lindberg, 1991, for  
29 nitrogen-containing particles; McMahon and Denison, 1979, Hicks et al., 1987, for general  
30 treatment). The nature of the vegetative cover to which particulate deposition occurs has a  
31 moderate to substantial effect on the components of  $V_d$ . The surface resistance (Hicks et al.,

1 1987) is a significant and highly site-specific component of total resistance that is difficult to  
2 predict along with site, seasonal, and diurnal effects on the atmospheric components of total  
3 resistance.

4 Early models of dry particulate deposition to vegetation (e.g., U.S. Environmental  
5 Protection Agency, 1982; Chamberlain, 1975; Davidson and Friedlander, 1978; Garland, 1978;  
6 Little and Wiffen, 1977; McMahon and Denison, 1979; Sehmel, 1980; Sehmel and Hodgson,  
7 1976; and Slinn, 1977, 1978) used this paradigm (e.g., Eq. 4-3) to deal with transport to the near-  
8 surface regime explicitly including conventional micrometeorological and particle size  
9 considerations. Alternative modeling treatments have attempted to parameterize the geometry of  
10 vegetative receptor surfaces and within-canopy micrometeorology (Wiman and Ågren, 1985;  
11 Peters and Eiden, 1992). Chemical reactivity, particle shape and density, rates of physiological  
12 sequestration, and reentrainment by gusts of wind remain to be addressed. Modeling the  
13 deposition of particles to vegetation is at a relatively early stage of development, and it is not  
14 currently possible to identify a best or most generally applicable modeling approach. These  
15 approaches have been further elaborated with canopy-specific choices among the available  
16 models and with specific incorporation of capture efficiencies by Brook et al. (1999).

### 17 18 **Methods of Measuring Dry Deposition**

19 Methods of measuring dry deposition of particles are more restricted than for gaseous  
20 species and fall into two major categories (Davidson and Wu, 1990). Surface extraction or  
21 washing methods characterize the accumulation of particles on natural receptor surfaces of  
22 interest or on experimental surrogate surfaces. These techniques rely on methods designed  
23 specifically to remove only surface-deposited material (Lindberg and Lovett, 1985). Total  
24 surface rinsate may be equated to accumulated deposition or to the difference in concentrations  
25 in rinsate between exposed and control (sheltered) surfaces and may be used to refine estimates  
26 of deposition (John et al., 1985; Dasch, 1987). In either case, foliar extraction techniques may  
27 underestimate deposition to leaves because of uptake and translocation processes that remove  
28 pollutants from the leaf surface (Taylor et al., 1988; Garten and Hanson, 1990). Foliar extraction  
29 methods also cannot distinguish sources of chemicals (e.g., N) deposited as gases from those  
30 deposited as particles (e.g., nitric acid [HNO<sub>3</sub>] or nitrate [NO<sub>3</sub><sup>-</sup>] from nitrogen dioxide [NO<sub>2</sub>], or  
31 ammonia [NH<sub>3</sub>] from ammonium [NH<sub>4</sub><sup>+</sup>]; Bytnerowicz et al., 1987a,b; Dasch, 1987; Lindberg

1 and Lovett, 1985; Van Aalst, 1982). Despite these limitations, these methods are often used in  
2 the development of in-canopy deposition models (McCartney and Aylor, 1987).

3 Deposition of pollutants by wet deposition is relatively straightforward to determine  
4 through analysis of precipitation samples. Dry deposition of pollutants, on the other hand, is  
5 more difficult to measure. A significant limitation on current capacity to estimate regional  
6 impacts of PM is inadequate knowledge of the mechanism and factors governing particle dry  
7 deposition to diverse surfaces. This has hindered efforts to develop robust measurement  
8 techniques for particle deposition (distinct from atmospheric concentration) and has  
9 compromised efforts to develop generally applicable deposition models for particles. The  
10 National Dry Deposition Network (NDDN) was established in 1986 to document the magnitude,  
11 spatial variability, and trends in dry deposition across the United States. Currently, the network  
12 operates as a component of the Clean Air Status and Trends Network (CASTNet; Clarke et al.,  
13 1997).

14 Dry deposition is not measured directly, but is determined by an inferential approach (i.e.,  
15 fluxes are calculated as the product of measured ambient concentration and a modeled deposition  
16 velocity). This method is appealing and widely used because atmospheric concentrations are  
17 relatively easy to measure when compared to dry deposition fluxes, and models have been  
18 developed to calculate deposition velocities (Lovett, 1994). Ambient pollutant concentrations,  
19 meteorological conditions, and land use data required for the inferential model are routinely  
20 collected at CASTnet dry deposition sites. Monitored chemical species include ozone, sulfate,  
21 nitrate, ammonium, sulfur dioxide, and nitric acid. The temporal resolution for the ambient  
22 concentration measurements and dry deposition flux calculations is hourly for ozone and weekly  
23 for the other chemical substances (Clarke et al., 1997). Isotopic labeling of dry deposited PM  
24 (e.g., sulfate with <sup>35</sup>S) prior to experimental surface exposures and extractions (Garten et al.,  
25 1988) can provide more precise differentiation between the deposition rates of related chemical  
26 species (e.g., sulfate [SO<sub>4</sub><sup>-2</sup>] from sulfur dioxide [SO<sub>2</sub>]).

27 At the whole-canopy level, natural surface washing by rainfall may be used to estimate dry  
28 deposition of PM and gases during the preceding dry period (Cape et al., 1992; Davidson and  
29 Wu, 1990; Draaijers and Erisman, 1993; Erisman, 1993; Fahey et al., 1988; Lindberg and Lovett,  
30 1992; Lovett and Lindberg, 1993; Reiners and Olson, 1984; Sievering, 1987). Collection and  
31 analysis of stem flow and throughfall provides useful estimates of particulate deposition when

1 compared to directly sampled precipitation. The method is most precise for strictly PM  
2 deposition when gaseous deposition is a small component of the total dry deposition and when  
3 leaching or uptake of compounds of interest out of or into the foliage (i.e., N, S, base cations) is  
4 not a significant fraction of the total depositional flux (Davidson and Wu, 1990; Draaijers and  
5 Erisman, 1993; Lindberg and Lovett, 1992; Lovett and Lindberg, 1993). Throughfall sampling  
6 of sulfate deposition (Garten et al., 1988; Lindberg and Garten, 1988; Lindberg et al., 1990)  
7 often suggests substantial foliar exchange. Other throughfall studies (e.g., Erisman, 1993; Fahey  
8 et al., 1988) may lack sufficient specificity for dry particle deposition.

9 Careful timing of throughfall and stemflow measurements after prolonged dry periods,  
10 with simultaneous direct measurement of (unchanged) precipitation, can be used to determine  
11 the magnitude of dry deposition between precipitation events. Indeed, this foliar washing  
12 technique, whether using subsequent precipitation or experimental lavage, is one of the best  
13 currently available methods to determine dry deposition of PM to vegetated ecosystems. Major  
14 limitations are the extreme site specificity of the measurements, the substantial labor  
15 requirement that normally precludes regional coverage, and the restriction to elements that are  
16 conserved within the vegetative system (thereby excluding semivolatile organics, ammonium  
17 salts, and gases such as ozone).

18 Deposition to surrogate surfaces deployed in extensive plant canopies provides a measure  
19 of particle deposition to the surrounding foliage or soil surfaces. For example, a uniform  
20 population of 0.8  $\mu\text{m}$  gold colloid particles were deposited similarly to leaves of *Phaseolus*  
21 *vulgaris* and to upward facing inert surfaces (Klepper and Craig, 1975). However, comparison  
22 of dry deposition of particles to foliage and to inert surrogate surfaces (polycarbonate Petri  
23 dishes) in a deciduous forest demonstrated greater accumulation on the inert surfaces; with both  
24 surfaces having accumulated particles of a similar range of sizes (Lindberg and Lovett, 1985).  
25 These differences in deposition/accumulation remain to be fully characterized and hinder efforts  
26 to use these surrogate techniques to provide quantitative estimates of deposition. Surrogate  
27 surfaces have not been found that can adequately replicate essential features of natural surfaces;  
28 and therefore the surfaces currently used do not produce reliable estimates of particle deposition  
29 to the landscape.

30 Micrometeorological methods employ an eddy covariance, eddy accumulation, or flux  
31 gradient protocol in contrast to washing or extracting of receptor surfaces to quantify dry

1 deposition. These techniques require measurements of PM concentrations and of atmospheric  
2 transport processes. They are currently well developed for ideal conditions of flat,  
3 homogeneous, and extensive landscapes and for chemical species for which accurate and rapid  
4 sensors are available. Additional studies have expanded the range of such species and extended  
5 these techniques to more complex terrain (McMillen, 1988; Hicks et al., 1984; Wesely and  
6 Hicks, 1977).

7 The eddy covariance technique measures vertical fluxes of gases and fine particles directly  
8 from calculations of the mean covariance between the vertical component of wind velocity and  
9 pollutant concentration (Wesely et al., 1982). It is particularly limited by a requirement for  
10 sensors capable of acquiring concentration data at 5-20 Hz. For the flux-gradient or profile  
11 techniques, vertical fluxes are calculated from a concentration difference and an eddy exchange  
12 coefficient determined at discrete heights (Erisman et al., 1988; Huebert et al., 1988). Businger  
13 (1986), Baldocchi (1988), and Wesely and Hicks (1977) evaluate the benefits and pitfalls of  
14 these micrometeorological flux measurements for gases. Most measurements of eddy transport  
15 of PM have used chemical sensors (rather than mass or particle counting) to focus on specific  
16 PM components. These techniques have not been well developed for generalized particles and  
17 may be less suitable for coarse PM<sub>10</sub> transported efficiently in high frequency eddies (Gallagher  
18 et al., 1988) for the same reasons that limit mathematical description of particle deposition.

## 19 20 **Factors Affecting Dry Deposition**

21 **Ambient Concentration.** The ambient concentration of particles ( $C_z$ ; Eq. 4-1), the  
22 parameter for which there is the most data (for example, see Chapter 3, this document), is at best  
23 an indicator of exposure. However, it is the amount of PM actually entering the immediate plant  
24 environment that determines the biological effect. The linkage between ambient concentration  
25 and delivery to vegetation is the deposition velocity ( $V_d$ ; Eq. 4-1).  $C_z$  is determined by regional  
26 and local emission sources, regional circulation, and weather. It may be locally sensitive to  
27 removal from the atmosphere by deposition, but the effect is generally small. Average annual  
28 concentrations for NO<sub>3</sub><sup>-</sup> exhibit much more variability than SO<sub>4</sub><sup>-2</sup> and a definite pattern of higher  
29 concentrations in the midwest than elsewhere. The highest concentrations are observed (i.e., > 2  
30 μg m<sup>-3</sup>) in the agricultural areas of the midwest, while the lowest are seen at forested sites in  
31 New England and the southern Appalachian Mountains. Annual average concentrations SO<sub>4</sub><sup>-2</sup> of

1 5.0  $\mu\text{g m}^{-3}$  are observed over nearly the entire eastern U.S. from New York and Michigan to  
2 northern Mississippi and Alabama (Edgerton et al., 1992).

3 Deposition increases linearly with the concentration of many materials over a broad range.  
4 This allows atmospheric cleansing to take place and accounts for the greater surface impact of  
5 pollutants during pollution episodes. A serious limitation of the  $V_d$  formulation used to infer  
6 deposition of specific chemical species that exist in a range of particle sizes is an appropriate  
7 specification of their concentration. Most sulfur emissions are readily oxidized to sulfite,  
8 bisulfite, and sulfate. In the presence of atmospheric ammonia, particulate ammonium sulfate is  
9 formed. However, this material is hygroscopic and will increase in mass and diameter in the  
10 presence of high humidity and alter its deposition behavior. Similarly, coalescence of small  
11 particles into larger aggregates and adsorption of gaseous pollutants onto existing coarse  
12 particles complicate the association of particle size with concentration of individual chemical  
13 species.

14 Distance and the resulting residence time in the atmosphere control the relative  
15 concentrations of surface reactive materials ( $\text{NO}$ ,  $\text{SO}_2$ ) of secondary particles that take some time  
16 to form in the atmosphere and of coarse particles that exhibit high rates of deposition by  
17 sedimentation near the source. These interacting processes affect the time required for the  
18 formation of secondary particles by gas-to-particle conversion reactions and result in a greater  
19 ratio of dry to wet deposition near emission sources where gaseous sulfur dioxide ( $\text{gSO}_2$ )  
20 deposition predominates than at greater distances where rainout of particulate  $\text{SO}_4^{-2}$  ( $\text{pSO}_4^{-2}$ ) may  
21 dominate (Barrie et al., 1984) and where dry deposition of  $\text{pSO}_4^{-2}$  may be greater than that of  
22  $\text{gSO}_2$ . The effect of gas-to-particle conversion on dry deposition of a specific chemical species  
23 can be substantial because  $V_d$  for  $\text{SO}_2$  is approximately  $0.33 \pm 0.17 \text{ cm s}^{-1}$ ; whereas it is  
24 approximately  $0.16 \pm 0.08 \text{ cm s}^{-1}$  for  $\text{SO}_4^{-2}$ . These phase conversions affect both  $C_z$  and the  
25 effective  $V_d$  which together control dry depositional fluxes (Eq. 4-1). The neutralization of  
26 acidic gaseous and particulate species by alkaline coarse particles has been described in arid  
27 regions, but it may be more prevalent in urban New York where coarse particles are observed to  
28 be neutral because alkaline cations approximately balance gaseous acidic species (Lovett et al.,  
29 2000). The deposition of the acidic materials in the urban environment is likely enhanced by  
30 incorporation into these previously formed coarse particles.

1 Similarly, the ratio of coarse to fine particle concentrations determines the effective  $V_d$  for  
2 chemically speciated particles (Figure 4-4). This reflects the size-dependent deposition  
3 processes that govern delivery of PM to receptor surfaces (Fig. 4-5). For example,  $\text{SO}_4^{2-}$  was  
4 found predominantly on fine submicron particles; whereas potassium ion ( $\text{K}^+$ ), calcium ( $\text{Ca}^{+2}$ ),  
5 and nitrate ( $\text{NO}_3^-$ ) were associated most often with coarse particles larger than  $2 \mu\text{m}$  (Lindberg  
6 and Lovett, 1985). However, concentrations of particulate S and  $\text{K}^+$  within a coniferous canopy  
7 were strongly correlated (Wiman and Lannefors, 1985), suggesting a primary source of  
8 coarse-mode sulfur particles. However, many researchers reported mass-size distributions of  
9  $\text{NO}_3^-$  were bimodal with one peak in the fine mode and the other peak in coarse mode (Wu and  
10 Okada, 1994). The behavior of  $\text{NO}_3^-$  in ambient aerosols depends not only on the concentrations  
11 of gaseous nitric acid and ammonia, but also on the chemical composition of the particles and  
12 atmospheric conditions (Tang, 1980). When sea-salt particles were transported from the Pacific  
13 Ocean in the Nagoya, Japan, area, the amount of nitrate in the coarse particle size range  
14 increased. Coarse particle formation on sea salt under these conditions becomes a major  
15 pathway for nitrate. The heterogeneous reaction of NaCl with gaseous  $\text{HNO}_3$  is considered to be  
16 the dominating path (Wu and Okada, 1994). As a result, marine and continental particle size  
17 spectra for both N and S differ substantially: a peak in the coarse mode is generally apparent  
18 near marine sources (Milford and Davidson, 1987). The issue for  $\text{NO}_3^-$  is further confounded by  
19 uncertain discrimination between gaseous and particulate species in current sampling methods.  
20 The substantial effect of particle size on  $V_d$  (Figure 4-5) implies a need for size resolution as  
21 well as chemically speciated ambient particulate concentrations even within the  $\text{PM}_{10}$  fraction.  
22

23 **Particle Effects on  $V_d$ .** Particle size is a key determinant of  $V_d$  as noted above; but,  
24 unfortunately, the size spectra may be quite complex. The particles in the study of Lindberg and  
25 Lovett (1985) at Walker Branch Watershed had median diameters ranging from 3 to  $5 \mu\text{m}$ ; but  
26 approximately 25% of the particles had diameters less than  $1 \mu\text{m}$  ( $0.2$  to  $0.3 \mu\text{m}$ ), and 5 to 20%  
27 of the particles were much larger aggregates. The aggregated particles are significant in that  
28 chemically they reflect their fine particle origins, but physically they behave like large particles  
29 and deposit by sedimentation. Direct observations with SEM demonstrate that particle  
30 morphology can be highly variable. Many submicron particles can be observed on trichomes  
31 (leaf hairs), although most particles are in the  $5$  to  $50 \mu\text{m}$  diameter range. Large aggregated

1 particles in excess of 100  $\mu\text{m}$  also are seen, and carbonaceous aggregate particles are especially  
2 common (Smith, 1990a). Trichomes are efficient particle receptors; however, they are reduced  
3 in size by “weathering” and occasionally are completely broken off during the growing season.

4 In the size range around 0.1 to 1.0  $\mu\text{m}$ , where  $V_d$  is relatively independent of particle  
5 diameter (Fig. 4-5), deposition is controlled by macroscopic roughness properties of the surface  
6 and by the stability and turbulence of the atmospheric surface layer. The resistance catena  
7 (Figure 4-3) is less useful in this size range and, in some treatments, has been abandoned entirely  
8 (e.g., Erisman et al., 1994; Eq. 4-4). Impaction and interception dominate over diffusion, and the  
9  $V_d$  is considerably (up to two orders of magnitude; Figure 4-2) lower than for particles either  
10 smaller or larger (Shinn, 1978). The deposition velocity may be parameterized in this size range  
11 as a function of friction velocity,

$$13 \quad V_d = (a/b)u^*, \quad (4-4)$$

14  
15 where  $a$  depends on atmospheric stability and  $b$  depends on surface roughness (Wesely et al.,  
16 1985; Erisman et al., 1994). Similar formulations have been presented in terms of turbulence  
17 (standard deviation of wind direction) and wind speed (e.g., Wesely et al., 1983), both  
18 determinants of  $u^*$ .

19 Deposition of particles between 1 and 10  $\mu\text{m}$  diameter, including the coarse mode of  $\text{PM}_{10}$ ,  
20 is strongly dependent on particle size (Shinn, 1978). Larger particles within this size range are  
21 collected more efficiently at typical wind speeds than are smaller particles (Clough, 1975),  
22 suggesting the importance of impaction. Impaction is related to wind speed, the square of  
23 particle diameter, and the inverse of receptor diameter as a depositing particle fails to follow the  
24 streamlines of the air in which it is suspended around the receptor. When particle trajectory  
25 favors a collision, increasing wind speed or ratio of particle size to receptor cross section makes  
26 collision nearly certain; and, as these parameters become very small, the probability of collision  
27 becomes negligible. However, the shape parameter for the more common range of situations  
28 between these extremes remains poorly characterized (Peters and Eiden, 1992; Wiman and  
29 Ågren, 1985).

30 As particle size increases above 1  $\mu\text{m}$ , deposition is governed increasingly by  
31 sedimentation (Figure 4-5) and decreasingly by turbulence and impaction. Particles between

1 ~10 and 24  $\mu\text{m}$  (Gallagher et al., 1988) are both small enough to be transported efficiently by  
2 turbulent eddies to the surface and large enough to impact with sufficient momentum to  
3 overcome boundary layer effects. These particles deposit highly efficiently and relatively  
4 independently of particle size. Deposition of the largest suspended particles (e.g.,  $> 50 \mu\text{m}$ ) is  
5 governed, through sedimentation and the corresponding terminal settling velocity ( $V_s$ ), almost  
6 entirely by size. These particles are not transported efficiently by small-scale eddies near the  
7 surface.

8 Theoretically based models for predicting particle deposition velocities have been  
9 published by Bache (1979a,b), Davidson et al. (1982), Noll and Fang (1989), Slinn (1982), and  
10 Wiman (1985). These models deal primarily with low canopies or individual elements of  
11 canopy surfaces. Wiman and Ågren (1985) have developed an aerosol deposition model that  
12 specifically treats the problem of particle deposition to forests where turbulence plays a  
13 particularly important role, especially at roughness transitions such as forest edges. They found  
14 that deposition of supermicron particles is controlled by complex interactions among particle  
15 size and concentration, forest structure, and aerodynamics; whereas deposition of fine particles  
16 (submicron) is controlled by particle concentration and forest structure.

17 At the present time, empirical measurements of  $V_d$  for fine particles under wind tunnel and  
18 field conditions are often several-fold greater than predicted by available theory (Unsworth and  
19 Wilshaw, 1989). A large number of transport phenomena, including streamlining of foliar  
20 obstacles, turbulence structure near surfaces, and various phoretic transport mechanisms remain  
21 poorly parameterized in current models. The discrepancy between measured and predicted  
22 values of  $V_d$  may reflect such model limitations or experimental limitations in specification of  
23 the effective size and number of receptor obstacles, as suggested by Slinn (1982).

24 Available reviews (Davidson and Wu, 1990; McMahan and Denison, 1979; Nicholson,  
25 1988; Sehmel, 1980; Slinn, 1982; U.S. Environmental Protection Agency, 1982, 1996a) suggest  
26 the following generalizations: (1) particles larger than 10  $\mu\text{m}$  exhibit a variable  $V_d$  between  $\approx 0.5$   
27 and  $1.1 \text{ cm s}^{-1}$  depending on friction velocities; whereas a minimum particle  $V_d$  of  $0.03 \text{ cm s}^{-1}$   
28 exists for particles in the size range 0.1 to 1.0  $\mu\text{m}$ ; (2) the  $V_d$  of particles is approximately a  
29 linear function of friction velocity; and (3) deposition of particles from the atmosphere to a  
30 forest canopy is from 2 to 16 times greater than deposition in adjacent open terrain (i.e.,  
31 grasslands or other vegetation of low stature).

1           **Leaf Surface Effects on  $V_d$ .** The term  $r_c$  (Equation 4-3) reflects the chemical, physical, or  
2 physiological characteristics of the surface that govern its ability to capture, denature, or  
3 otherwise remove particulate material from the atmospheric surface layer. For gases, relevant  
4 surface properties involve the physiological state of the vegetation, including stomatal opening  
5 and mesophyll antioxidant activity, and the chemical reactivity of the exposed surface with the  
6 specific gas. For particles, relevant surface properties involve stickiness, microscale roughness,  
7 and cross-sectional area. These properties determine the probability of impaction and bounce  
8 (e.g., Shinn, 1978). The chemical composition of PM is not usually a primary determinant of  
9 deposition velocity. At the microscopic scale where Van der Waals forces may determine  
10 particle bounce and reentrainment, the chemical properties of both surface and particle may be  
11 significant but remain poorly understood.

12           Stickiness may itself depend on previous deposition of deliquescent particles that prolong  
13 leaf wetness, on the wettability of foliar surfaces, and on the presence of sticky residues such as  
14 honeydew deposited by aphids. These factors increase deposition by decreasing bounce-off,  
15 wind reentrainment, and, to some extent, wash-off by precipitation.

16           The distribution of particles on and the efficiency of deposition to vegetation also varies  
17 based on leaf shape and plant part. Particles are more prevalent on the adaxial (upper facing of  
18 the twig) surface than on the abaxial (lower away from the twig) surface. Peripheral leaf areas  
19 tend to be the cleanest most particles accumulate in the midvein, central portion of leaves. The  
20 rough area surrounding the stomatal pores was not found to be a preferential site for particle  
21 deposition or retention (Smith and Staskawicz, 1977). Most particles were located near veins  
22 with smaller particles localized on the trichomes. The greatest particulate loading on  
23 dicotyledonous leaves is frequently on the adaxial (upper) surface at the base of the blade, just  
24 above the petiole junction. It is probable that precipitation washing plays an important role in  
25 this distribution pattern. Lead particles accumulated to a larger extent on older than younger  
26 needles and twigs of white pine, indicating that wind and rain were insufficient to fully wash the  
27 foliage. Fungal mycelia (derived from windborne spores) were frequently observed in intimate  
28 contact with other particles on other leaves (Smith and Staskawicz, 1977), which may reflect  
29 shelter by the particles minimizing reentrainment of the spores, mycelia development near  
30 sources of soluble nutrients provided by the particles, or codeposition. This pattern is significant  
31 and could yield further insight into deposition mechanisms.

1 Leaves with complex shapes collect more particles than those with regular shapes. Conifer  
2 needles are more effective than broad leaves in accumulating particles. The edge to area ratio  
3 (Woodcock, 1953) is also a key determinant of salt deposition to individual artificial leaves.  
4 A strong negative correlation was observed under wind tunnel conditions between the area of  
5 individual leaves and deposition of coarse particles (Little, 1977). Small twigs and branches  
6 were more effective particle collectors than were large branches and trunks of trees (Smith,  
7 1984). Lead particles accumulated 20-fold more on woody stems than on leaves of white pine  
8 (*Pinus strobus*), even though leaves displayed a 10-fold greater total area (Heichel and Hankin,  
9 1976). Deposition is heaviest at tips of individual leaves.

10 Rough, pubescent broadleaf discs collected coarse (5.0- $\mu\text{m}$ ) particles up to sevenfold more  
11 efficiently than glabrous leaf discs (Little, 1977). Laminae, petioles, and stems, all differed in  
12 collection efficiency. Pubescent leaves of sunflower (*Helianthus annuus*) collected coarse  
13 particles nearly an order of magnitude more efficiently than the glabrous leaves of tulip poplar  
14 (*Liriodendron tulipifera*) under wind tunnel conditions (Wedding et al., 1975). Rough pubescent  
15 leaves of nettle (*Urtica dioica*) were more effective in capturing coarse  $\text{PM}_{10}$  than were the  
16 densely tomentose leaves of poplar (*Populus alba*) or smooth leaves of beech (*Fagus sylvatica*).

17 Conifer needles are more efficient than broad leaves in collecting particles by impaction.  
18 This reflects the small cross section of the needles relative to larger leaf laminae of broadleaves  
19 and the greater penetration of wind into conifer than broadleaf canopies. Conifers were more  
20 effective in removing coarse ( $\approx 20 \mu\text{m}$ ) particles of ragweed pollen from the atmosphere than  
21 were broadleaf trees (Steubing and Klee, 1970) and in intercepting the even coarser particles of  
22 rain (Smith, 1984). Conifers are also more effective in retaining and accumulating particles  
23 against reentrainment by wind and removal by rain, particularly on foliar surfaces where they are  
24 likely to be most biologically active. Seedlings of white pine (*Pinus strobus*) and oak (*Quercus*  
25 *rubra*) initially retained between a quarter (pine) and a third (oak) of very coarse (88 to 175  $\mu\text{m}$ )  
26  $^{134}\text{Cs}$ -tagged quartz particles applied under field conditions (Witherspoon and Taylor, 1971).  
27 After 1 h, the pine retained over 20% of the  $^{134}\text{Cs}$ -tagged particles; whereas the oak retained only  
28 approximately 3%. Long-term retention of the particles was concentrated at the base of the  
29 fascicles in pine and near the surface roughness caused by the vascular system on leaves of oak.  
30 The sheltered locations available in the conifer foliage contribute substantially to greater

1 retention of particles. For similar reasons, grasses also are efficient particle collectors (Smith  
2 and Staskawicz, 1977) with long-term retention mostly in the ligule and leaf sheath.

3 Because of the strong relationship between particle size and deposition, the sharply  
4 increasing humidity gradient near transpiring foliar surfaces may cause hygroscopic particles to  
5 behave, at the immediate surface, as larger particles than reflected in ambient measurements at  
6 reference heights. This needs to be further considered (Wesely and Hicks, 2000). Recent  
7 deposition models (Ruijgrok et al., 1997; Zhang et al., 2001) have introduced the role of ambient  
8 humidity but lack sufficient emphasis on the role of vegetation itself in modifying humidity near  
9 the surface. This may be significant, as the size of a dry, 0.5- $\mu\text{m}$  particle of ammonium sulfate  
10 may increase to about 3.5  $\mu\text{m}$  at saturated humidity (Ruijgrok et al., 1997). Kinetic analyses  
11 have suggested that full (95% to 100%) equilibration to the new diameter will occur during the  
12 deposition process.

13 Wind tunnel studies also demonstrated equivalent deposition properties of 3.36- $\mu\text{m}$   
14 particles of dense lead chloride and 6.77- $\mu\text{m}$  particles of less dense uranine dye. These particles  
15 were shown to be aerodynamically equivalent, substantiating the use of aerodynamic diameter as  
16 a classification parameter for particle deposition.

17  
18 **Canopy Surface Effects on  $V_d$ .** In general, surface roughness contributes to greater  
19 particulate deposition. As a result,  $V_d$  is typically greater for a forest than for a field or  
20 nonwoody wetland and greater for a field than for a water surface. The contrasting transport  
21 properties and deposition velocities of different size particles lead to predictable patterns of  
22 deposition. For coarse particles, the upwind leading edges of forests, hedge rows, and individual  
23 plants, as well as of individual leaves, are primary sites of deposition. Impaction at high wind  
24 speed and the sedimentation that follows the reduction in wind speed and carrying capacity of  
25 the air in these areas lead to preferential deposition of larger particles.

26 Air movement is slowed in proximity to vegetated surfaces. Resulting log profiles of wind  
27 and pollutant concentrations in the near-surface turbulent boundary layer above canopies reflect  
28 surface characteristics of roughness length, friction velocity, and displacement height. Plasticity,  
29 streamlining, and oscillations of foliar elements also alter the aerodynamic roughness and the  
30 level of within-canopy turbulence. Canopies of uneven age or with a diversity of species are  
31 typically aerodynamically rougher and receive larger inputs of pollutants than do smooth, low, or

1 monoculture vegetation (Garner et al., 1989; Wiman and Ågren, 1985). Canopies on slopes  
2 facing the prevailing winds and individual plants on the windward edges of discontinuities in  
3 vegetative cover over which roughness increases receive larger inputs of pollutants than more  
4 sheltered, interior canopy regions. For example, some 80% of coarse particulate sea salt was  
5 deposited on the upwind edge of a hedgerow (Edwards and Claxton, 1964), and the  
6 concentration of ragweed (*Ambrosia spp.*) pollen was reduced by 80% within 100 m of the  
7 leading edge of a forest (Neuberger et al., 1967).

8 Beier et al. (1992) and Beier (1991) discussed two methods for estimating the dry  
9 deposition of base cations to forest edges: (1) a difference method between measured  
10 precipitation and throughfall concentrations of base cations, and (2) a calculation method based  
11 on known ratios of  $\text{Na}^+$  deposition in wet and dry forms (Ulrich, 1983). A combination of these  
12 two approaches produced the best estimates of  $\text{SO}_4^{-2}$ ,  $\text{Ca}^{+2}$ ,  $\text{Mg}^{+2}$ , and  $\text{K}^+$  particle deposition.  
13 Using these methods, particulate  $\text{SO}_4^{-2}$  (Beier, 1991) and particulate  $\text{Ca}^{+2}$ ,  $\text{Mg}^{+2}$ , and  $\text{K}^+$  (Beier  
14 et al., 1992) were found to decrease by an order of magnitude from the forest edge to the forest  
15 interior. A number of authors also have shown that particle deposition is elevated at forest edges  
16 when compared to a uniform forest canopy (Draaijers et al., 1988; Grennfelt, 1987; Lindberg and  
17 Owens, 1993), and Draaijers et al. (1992) reported that differences are likely to exist between  
18 forest types because of variable canopy structure. Draaijers et al. (1988) further emphasized that  
19 enhanced particle deposition at or near forest edges is strongly dependent on the velocity and  
20 wind direction during observations.

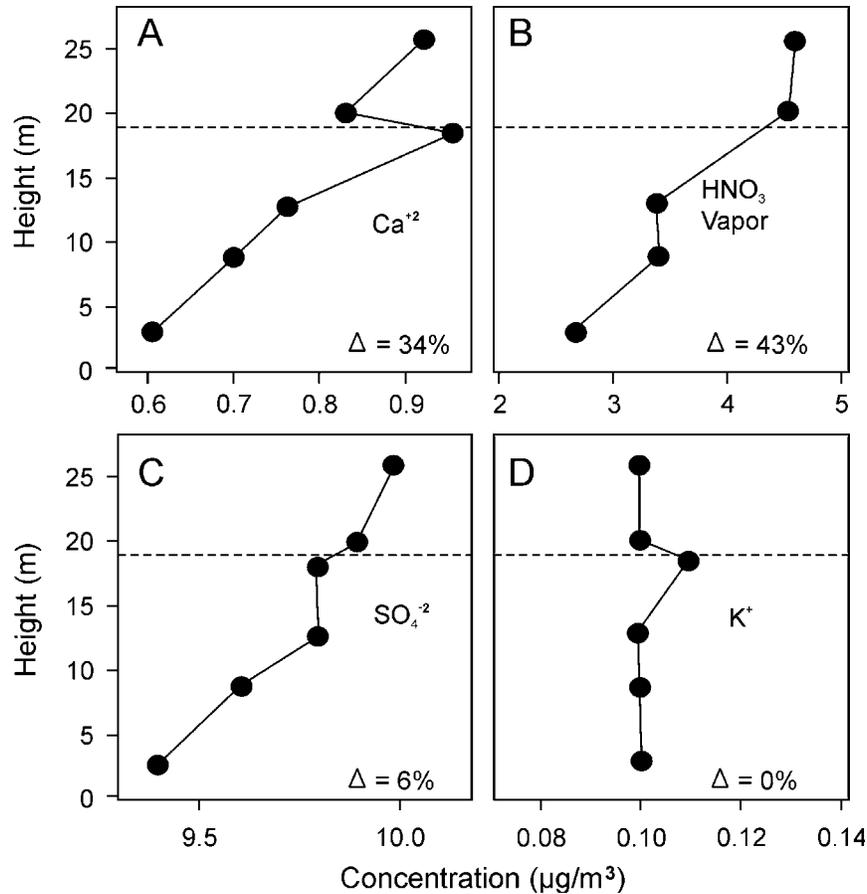

21 The factors leading to horizontal gradients are confounded by time- and distance-related  
22 sedimentation. For example, geologic dust (mostly around 7  $\mu\text{m}$  aerodynamic diameter) collects  
23 on stems of wild oats (*Avena spp.*; Davidson and Friedlander, 1978) and on eastern white pine  
24 (*Pinus strobus*; Heichel and Hankin, 1972; Smith 1973) downwind of roadways. Rapid  
25 sedimentation of coarse crustal particles suggests that potential direct effects may be restricted to  
26 roadway margins, forest edges, and, because of the density of unpaved roads in agricultural  
27 areas, crop plants.

28 Simulated deposition to an ecologically complex, mixed canopy was considerably higher  
29 than to a pure spruce stand in which most of the leaf area was concentrated in regions of low  
30 wind speed. Limitations to the application of these models to predict deposition over large  
31 regions include a limited understanding both of the nature of microscopic particle-surface

1 interactions and of the effects of complex terrain and species composition on macroscopic  
2 transport processes.

3 Macroscopic turbulent transport processes, related to  $r_a$  at successive layers through the  
4 canopy can be separated from microscopic processes, related to  $r_b$  and  $r_c$  (or  $r_{cp}$ ) at each  
5 deposition surface (e.g., Peters and Eiden, 1992; Wiman and Lannefors, 1985). The  
6 macroscopic approach deals with deposition as the product of a turbulent diffusion coefficient  
7 and a concentration ( $C_z$ ) at each canopy layer, both of which vary with particle size and with  
8 height ( $Z$ ) in the canopy. The microscale parameters involve those factors that determine  
9 absorption of a particle at each surface as captured imperfectly by  $r_c$ . Shelter effects caused by  
10 the crowding of foliar elements within the canopy can be ignored if the wind speed within each  
11 canopy layer is specified. This approach requires knowledge of the vertical distribution of  
12 particle concentration and foliage density in the canopy airspace along with profiles of wind  
13 speed or turbulence.

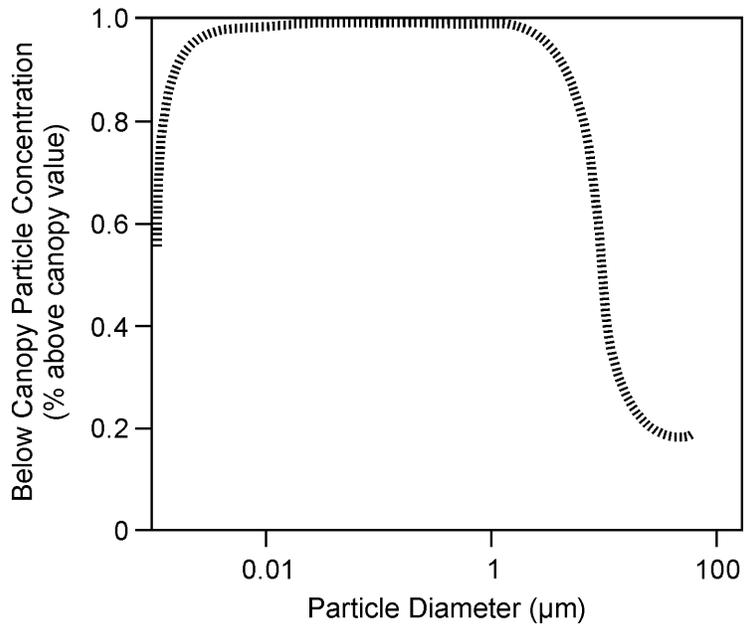

14 Once introduced into a forest canopy, elements associated with coarse particles tend to  
15 decrease markedly with canopy depth; whereas elements associated with fine particles do not  
16 (Lovett and Lindberg, 1992). Trace elements and alkaline-earth elements are enriched below the  
17 canopies of both southern (Lindberg et al., 1986) and northern (Eaton et al., 1973) hardwood  
18 forests. Vertical gradients in concentration of coarse particles and of elements associated with  
19 coarse particles were observed in a mixed conifer/birch forest canopy (Wiman and Lannefors,  
20 1985; Wiman et al., 1985) and in a mixed oak forest (e.g.,  $Ca^{+2}$ , Figure 4-6A; Lovett and  
21 Lindberg, 1992). The highly reactive gas  $HNO_3$  also exhibited a vertical gradient but with a  
22 steep decline at the top of the canopy (Figure 4-6B). Lovett and Lindberg (1992) studied  
23 concentration profiles of various gases and particles within an closed canopy forest and  
24 concluded that coarse particle concentrations associated with elements like  $Ca^{+2}$  would decrease  
25 markedly with depth in the canopy, but they found only minor reductions with depth in the  
26 concentrations of fine aerosols containing  $SO_4^{-2}$ ,  $NH_4^+$ , and  $H^+$ . These data suggest that all foliar  
27 surfaces within a forest canopy are not exposed equally to particle deposition: upper canopy  
28 foliage would receive maximum exposure to coarse and fine particles, but foliage within the  
29 canopy would receive primarily fine aerosol exposures. Fine-mode particles (e.g., sulfate,  
30 Figure 4-6C) and unreactive gases typically do not exhibit such vertical profiles, suggesting that  
31 uptake is smaller in magnitude and more evenly distributed throughout the canopy. In multilayer

**Figure 4-6. Vertical stratification of diverse, chemically speciated particles in a mixed oak forest. Nitric acid vapor, as a highly reactive, nonparticulate species, is shown for comparison. The horizontal dotted line indicates canopy height, and  $\Delta$  indicates the percent depletion from above to below the canopy. Data from Table 2-4 of Lovett and Lindberg (1992).**

1 canopies, simultaneous reentrainment and deposition may effectively uncouple deposition from  
 2 local concentration. Polydisperse size distributions of many chemical species effectively prevent  
 3 the use of a single estimate of  $V_d$  for any element if highly accurate results are required.

4 Although gradients (Figures 4-6 and 4-7) may be related to local  $V_d$  within the canopy  
 5 (Bennett and Hill, 1975), the absence of a gradient may reflect either low rates of deposition or  
 6 very high rates relative to turbulent replenishment from above the canopy (Tanner, 1981).  
 7 Below- or within-canopy emissions may confound interpretation of vertical gradients. Linear  
 8 gradients of the gaseous pollutants hydrogen fluoride (HF) and ozone ( $O_3$ ) reflected large uptake

**Figure 4-7. The relationship between particle size and concentration below a spruce canopy with wind velocity at a height of 16.8 m equaling  $5 \text{ m s}^{-1}$ . Modified from Peters and Eiden (1992).**

1 rates; whereas small gradients in NO suggested little uptake by foliage (Bennett and Hill, 1973,  
 2 1975). However, soil efflux of NO could have complicated the latter interpretation. The lack of  
 3 a vertical gradient and a peak near the top of the active canopy in particulate  $\text{K}^+$  (Figure 4-6D)  
 4 was interpreted as evidence for a biogenic source within the deciduous forest canopy with  
 5 moderate rates of deposition (Lindberg et al., 1986; Lovett and Lindberg, 1992).

6 The size dependence of this vertical stratification of particulate concentration (see  
 7 Figure 4-7) is reflected in current simulation models (Wiman et al., 1985; Peters and Eiden,  
 8 1992). The model of Wiman and Ågren (1985) predicts a uniform vertical distribution of  
 9 fine-mode particles and a pronounced vertical gradient of coarse-mode particles which is in  
 10 agreement with observations (Lovett and Lindberg, 1992).

11 Simulation of the horizontal deposition patterns at the windward edge of a spruce forest  
 12 downwind of an open field with the canopy between 1 and 25 m above the ground indicated that  
 13 deposition was maximal at the forest edge where wind speed and impaction were greatest.  
 14 Simulation of the vertical deposition pattern was more complex. Deposition was not greatest at

1 the top of the canopy where wind speed was highest, but at  $z = 0.75 h$  where the balance between  
2 leaf area (obstacles for impaction) and wind speed (momentum for impaction) was optimal,  
3 although neither parameter alone was maximal. Simulated deposition in this spruce forest  
4 increased considerably with increasing LAI at the forest edge, where wind speed was insensitive  
5 to LAI but the number of obstacles increased. Inside the forest, where both wind speed and  
6 impaction increasingly were attenuated by increasing LAI, deposition increased only marginally  
7 in spite of the increase in obstacle frequency.

8 To scale surface-specific measurements of particle deposition to forest or crop canopies,  
9 conversions of the following type have been suggested:

$$11 \quad V_{d,\text{canopy}} = V_{d,\text{surface}} * \text{scaling factor}, \quad (4-5)$$

12  
13 with empirical scaling factors proposed by Lindberg et al. (1988).

14 To appropriately scale surface-specific measurements of particle deposition to landscapes,  
15 one must consider the complexity of grassland, crop, and forest canopies in order to avoid  
16 serious over- or under-estimates of particle deposition. Individual species exposed to similar  
17 ambient concentrations may receive a range of particulate loading that is more closely related to  
18 foliar damage than the ambient concentration (Vora and Bhatnagar, 1987).

19 Both uptake and release of specific constituents of PM may occur within a single canopy  
20 (e.g.,  $K^+$ ; Lovett and Lindberg, 1992). The leaf cuticular surface is a region of dynamic  
21 exchange processes through leaching and uptake. Exchange occurs with epiphytic  
22 microorganisms and bark and through solubilization and erosion of previously deposited PM.  
23 Vegetation emits a variety of particulate and particulate precursor materials. Terpenes and  
24 isoprenoids predominate and, on oxidation, become condensation nuclei for heterogeneous  
25 particle formation. Salts and exudates on leaves and other plant parts continually are abraded  
26 and suspended as particles, as are plant constituents from living and dead foliage (Rogge et al.,  
27 1993a). Soil minerals, including radioactive strontium, nutrient cations and anions, and trace  
28 metals are transferred to the active upper foliage and then to the atmosphere in this way.  
29 Although not representing a net addition to an ecosystem, particle release from vegetation is a  
30 mechanism for redistributing chemical pollutants derived from the soil or prior deposition within  
31 a canopy, potentially enhancing direct effects and confounding estimates of  $V_d$ .

## 1 **Range of Deposition Velocity**

2 As noted in an earlier criteria document (U.S. Environmental Protection Agency, 1982)  
3 and in McMahon and Denison (1979), estimates of  $V_d$  for  $PM_{10}$  particles to vegetation are  
4 variable and suggest a minimum between 0.1 and 1.0  $\mu\text{m}$  as predicted from first principles  
5 (Monteith and Unsworth, 1990; Sehmel, 1980). Determinations in wind tunnels with passive  
6 collectors and micrometeorological methods tend to converge in this range. The range of  $V_d$  for  
7 sulfate from passive collectors was found to be from 0.147 to 0.356  $\text{cm s}^{-1}$ ; and, from eddy  
8 covariance techniques, a mean  $V_d$  of 0.27  $\text{cm s}^{-1}$  was observed (Dolske and Gatz, 1984).  
9 Micrometeorological techniques over grass (Wesely et al., 1985); indirect, inert collector  
10 techniques within an oak forest (Lindberg and Lovett, 1985); and many other empirical  
11 determinations (e.g., McMahon and Denison, 1979; Table 4-4) generally support this range.  
12 Over aerodynamically smooth snow (Duan et al., 1988; Table 4-5), measurements of  $V_d$  were an  
13 order of magnitude smaller. Very coarse particles, often non-size-specified primary geologic  
14 material, frequently exhibit  $V_d$  greater than 1.0  $\text{cm s}^{-1}$  (e.g., Clough, 1975). The increase in  $V_d$   
15 with decreasing size below 0.1  $\mu\text{m}$  is probably hidden in most empirical determinations of  $V_d$   
16 because the total mass in this fraction is very small despite the large number of individual  
17 particles. Table 4-6 shows published estimates of  $V_d$  with variability estimates for fine particles  
18 of specified aerodynamic diameters dominated by a range of chemical species.

19 Ibrahim et al. (1983) evaluated the deposition of ammonium sulfate particles to a range of  
20 surfaces and found that particles having a mean diameter of 0.7  $\mu\text{m}$  had deposition velocities  
21 ranging from 0.039 to 0.096  $\text{cm s}^{-1}$ . Larger particles (having mean diameters of 7  $\mu\text{m}$ ) had  
22 greater deposition velocities (between 0.096 and 0.16  $\text{cm s}^{-1}$ ). The authors further concluded that  
23 the hygroscopic nature of the sulfate particle could increase its size and enhance deposition near  
24 sources of water (e.g., snow). Using eddy correlation approaches, Hicks et al. (1989) found a  
25 mean daily  $V_d$  for sulfur-containing PM to be 0.6  $\text{cm s}^{-1}$ . However, they suggested that the  $V_d$   
26 value could be as high as 1  $\text{cm s}^{-1}$  during the day and near zero at night.

27 Lindberg et al. 1990 found a wide discrepancy between deposition velocities for  $\text{NO}_3^-$   
28 between study sites in Oak Ridge, TN ( $\approx 2 \text{ cm s}^{-1}$ ) and Göttingen, Germany ( $\approx 0.4 \text{ cm s}^{-1}$ ). They  
29 suggest that the increased  $V_d$  at Oak Ridge could be explained by the primary occurrence of  $\text{NO}_3^-$   
30 in coarse particles that exhibit greater  $V_d$  than fine particles (Davidson et al., 1982). Large

1 values of  $V_d$  for base-cation-containing particles ( $> 1 \text{ cm s}^{-1}$ ) suggest their occurrence in coarse  
2 particles (Lindberg and Lovett, 1985).

3 The several attempts to estimate  $V_d$  for  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ , and  $\text{NH}_4^+$  with the throughfall mass  
4 balance approach (Davidson and Wu, 1990; Gravenhorst et al., 1983; Höfken and Gravenhorst,  
5 1982) have produced higher  $V_d$  values that are considered suspect. They have not been included  
6 in Tables 4-4 and 4-6. Overestimates of  $V_d$  for  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  particles derived from throughfall  
7 mass balance approaches may be the result of gaseous  $\text{SO}_2$  and  $\text{HNO}_3$  gaseous deposition to  
8 foliar surfaces (Lindberg and Lovett, 1985). A similar contribution of  $\text{NH}_3$  deposition may lead  
9 to erroneously high  $V_d$  values for  $\text{NH}_4^+$  when the throughfall method is attempted in areas of  
10 high  $\text{NH}_3$  concentrations. Dolske's (1988) reported  $V_d$  values for  $\text{NO}_3^-$  deposition to soybean  
11 ranged from 0.4 to 31 with a mean of  $0.24 \text{ cm s}^{-1}$ . However, because Dolske's leaf extraction  
12 measurements included a component of  $\text{HNO}_3$  vapor, the  $V_d$  values may represent more than  
13 deposition caused by aerosol nitrate alone.

14 The quantitative importance of dry particulate deposition depends upon the chemical  
15 species, topography, precipitation regime, and surface characteristics, including vegetation  
16 properties. Across the diverse landscapes of the Integrated Forest Study (Johnson and Lindberg,  
17 1992a), the relative contribution of dry deposition for  $\text{Ca}^{+2}$  ranged from about 0% to nearly 90%  
18 (Figure 4-8). In contrast, for S the total range was from just over 0% to about 30%. An average  
19 for these forest systems demonstrates that deposition of (usually coarse) base cations was nearly  
20 50% by dry particulate deposition (Figure 4-9). Both N and S were around 15%. While the  
21 relative significance of dry particle deposition varies from site to site, it cannot be excluded from  
22 the analysis at any site.

23 In a recent review, Wesely and Hicks (2000) concluded that a comprehensive  
24 understanding of particulate deposition remains a distant goal. In general, there is only modest  
25 confidence in available particulate deposition parameterizations at this time, although recent  
26 experimental and theoretical efforts to improve this situation have been made (e.g., Erisman  
27 et al., 1997, and companion articles; Zhang et al., 2001; Kim et al., 2000).

28 The successful treatment of dry deposition of gaseous pollutants (e.g.,  $\text{SO}_2$  and  $\text{O}_3$ ) linking  
29 turbulent deposition to surface physiological properties has allowed incorporation of these  
30 models into landscape and regional scale models. This has allowed gaseous deposition to be  
31 scaled up for purposes of atmospheric chemistry and vegetation damage assessment. These

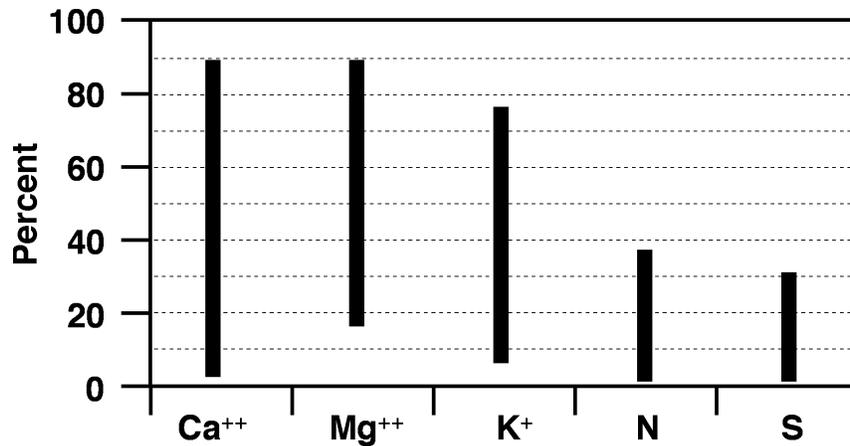

Figure 4-8. Range of percent of total deposition delivered in the dry particulate fraction, across the sites of the Integrated Forest Study (after Johnson and Lindberg, 1992a).

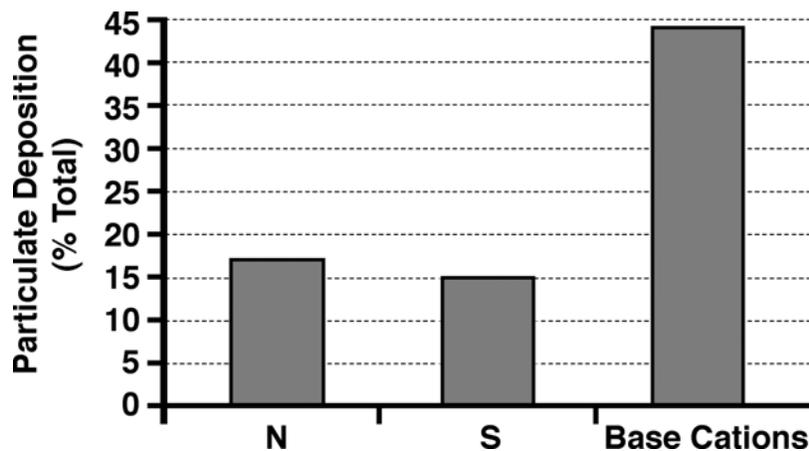

Figure 4-9. Contribution of particulate deposition to total deposition of nitrogen, sulfur, and base cations (after Johnson and Lindberg, 1992a; Lovett, 1992; Lovett and Lindberg, 1993; Lindberg et al., 1990; Kelly and Meagher, 1986).

1 advances have not been matched by progress in deposition of PM. A serious remaining  
 2 impediment is the lack of suitable techniques for measuring deposition of heterogeneous and  
 3 polydisperse particles, such as the gradient and eddy covariance techniques that are used for

1 gaseous pollutant species. As with gaseous pollutants, parameterization of particle deposition in  
2 hilly terrain, to patchy surfaces (small agricultural fields, forest edges), and under extremely  
3 windy conditions, remains to be fully developed. These limitations must be addressed before a  
4 full accounting of regional PM effects on vegetation in natural and managed ecosystems can be  
5 achieved.

## 6 **Occult Deposition**

8 Gaseous pollutant species may dissolve in the suspended water droplets of fog and clouds.  
9 The stability of the atmosphere and persistence of the droplets often allow a gas/liquid phase  
10 equilibrium to develop. This permits the use of air mass history or ambient concentrations of  
11 specific pollutants to estimate fog or cloud water concentrations. Further estimates of the  
12 deposition velocity of the polluted droplets allows calculation of depositional fluxes.  
13 Unfortunately, interception of fog or cloud droplets by plant parts or other receptor surfaces  
14 remains difficult to predict and to measure. Fog formation influences the total atmospheric  
15 burden and deposition of particulate matter (Pandis and Seinfeld, 1989) by accreting and  
16 removing particles from the air, by facilitating particle growth through aqueous oxidation  
17 reactions, and by enhancing deposition as noted. Aqueous condensation may occur onto  
18 preexisting fine particles, and such particles may coalesce or dissolve in fog or cloud droplets.  
19 Material transported in fog and cloud water and intercepted by vegetation escapes detection by  
20 measurement techniques designed to quantify either dry or wet deposition; hence it is hidden  
21 (i.e., “occult”) from the traditional measurements.

22 Occult deposition of fog and cloud droplets is by impaction and gravitational settling in  
23 concert with the instantaneous particle (droplet) size. This mode of deposition may be  
24 significant at high elevation sites, particularly near the base of orographic clouds. While coastal  
25 fog may be generally more pristine than high-elevation continental fogs, this is not true in areas  
26 subject to inland radiation fog (e.g., the increasingly polluted San Joaquin Valley of Central  
27 California) and in areas where the marine layer is advected through a highly polluted urban area  
28 (e.g., the Los Angeles basin of Southern California). Fog water in these areas may be at least as  
29 contaminated as that occurring at higher elevations.

30 Low elevation radiation fog has different formation and deposition characteristics than  
31 high elevation cloud or coastal fog water droplets. A one-dimensional deposition model has

1 recently been described for a radiation fog episode (Von Glasow and Bott, 1999).

2 A substantially greater concentration of key polluting species (e.g.,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , organics) may  
3 be observed in smaller than in larger droplets in fog (Collett et al., 1999). Acidity differences  
4 exceeding 1 pH unit were also observed in the San Joaquin Valley winter radiation fog, with  
5 smaller particles being more acidic. This has implications for aqueous phase oxidation of sulfur  
6 and nitrogen compounds, in particular, while sulfur oxidation by ozone (the dominant reaction in  
7 this environment even during winter) is well known in typically acidic fog droplets. However,  
8 the alkaline larger droplets in the San Joaquin Valley could lead to greater nitrate production  
9 through aqueous ozonation reactions (Collett et al., 1999). The size class distinctions have  
10 substantial implications for deposition of particulate pollutant species in the fog droplets due to  
11 the larger  $V_d$  for impaction and occult deposition of the larger fog particles.

12 Acidic cloud water deposition has been associated with forest decline in industrialized  
13 areas of the world (Anderson et al., 1999). Clouds can contain high concentrations of acids and  
14 other ions. The four most prevalent ions found in cloud water samples, in decreasing order of  
15 concentration, were usually sulfate ( $\text{SO}_4^{2-}$ ), hydrogen ( $\text{H}^+$ ), ammonium ( $\text{NH}_4^+$ ), and nitrate  
16 ( $\text{NO}_3^-$ ). The concentrations of these major ions tend to co-vary within cloud events, and  
17 typically there was an inverse relationship between liquid water content (LWC) of the cloud and  
18 ionic concentration of the cloud water. Cloud water typically is 5 to 20 times more acid than  
19 rain water. This can increase pollutant deposition and exposure of vegetation and soils at  
20 high-elevation sites by more than 50% when compared with rainfall and dry deposition.

21 The widespread injury to mountain forests documented in West Germany since the 1970s  
22 and other parts of Europe and more recently in the Appalachian Mountains has been attributed to  
23 exposure to the cloud water reducing cold tolerance of red spruce. Forest injury also has been  
24 attributed to increased leaching of cations and amino acids and increased deposition of nitrogen  
25 and aluminum toxicity resulting from acidic deposition and the combined effect of acidic  
26 precipitation, acid fog, oxidants, and heavy metals (Anderson et al., 1999). The Mountain Acid  
27 Deposition Program (MADPro) was initiated in 1993 as part of the Clean Air Status and Trends  
28 Network (CASTnet). MADPro monitoring efforts focused on the design and implementation of  
29 an automated cloud water collection system in combination with continuous measurement of  
30 cloud liquid water content (LWC) and meteorological parameters relevant to the cloud  
31 deposition process.

1 Results from the MADPro automated cloud-water collectors at three selected mountain  
2 sites (Whiteface Mt., NY; Whitetop Mt., Va; and Clingman's Dome, TN) taken hourly from  
3 nonprecipitating clouds during non-freezing seasons of the year from 1994 to 1997 were  
4 promptly analyzed for pH, conductivity, and concentration of dissolved ions give an indication  
5 of exposures at the three sites. Cloud LWC was measured at each site. The mean cloud water  
6 frequencies and LWC were higher at Whiteface Mountain, NY, than in the southern  
7 Appalachians. The four most prevalent ions found in cloud water samples, in order of  
8 decreasing concentrations, usually were sulfate ( $\text{SO}_4^{2-}$ ), hydrogen ( $\text{H}^+$ ), ammonium ( $\text{NH}_4^+$ ), and  
9 nitrate ( $\text{NO}_3^-$ ). The concentrations of these ions tended to co-vary within cloud events and  
10 typically there was an inverse relationship between LWC of the cloud and ionic concentration of  
11 the cloud water. Highest ionic concentrations were seen in mid-summer. Ionic concentrations  
12 of samples from southern sites were significantly higher than samples from Whiteface Mountain,  
13 but further analysis indicated that this was due at least in part to North to South differences in the  
14 LWC of clouds (Anderson et al., 1999).

15 Several factors make occult deposition particularly effective for delivery of dissolved and  
16 suspended materials to vegetation. Concentrations of particulate-derived materials are often  
17 many-fold higher in cloud or fog water than in precipitation or ambient air in the same area due  
18 to orographic effects and from gas-liquid partitioning coefficients of specific chemical species.  
19 Fog and cloud water deliver PM in a hydrated and, therefore, bioavailable form to foliar  
20 surfaces. Previously dry-deposited PM may also become hydrated through delinquency or by  
21 dissolution in the film of liquid water from fog deposition. The presence of fog itself maintains  
22 conditions of high relative humidity and low radiation, thus reducing evaporation and  
23 contributing to the persistence of these hydrated particles on leaf surfaces. Deposition of fog  
24 water is very efficient (Fowler et al., 1991) with a  $V_d$  (fog 10-24  $\mu\text{m}$ ; Gallagher et al., 1988)  
25 essentially equal to the aerodynamic conductance for momentum transfer ( $r_a$ )<sup>-1</sup>. This greatly  
26 enhances deposition by sedimentation and impaction of submicron aerosol particles that exhibit  
27 very low  $V_d$  prior to fog droplet formation (Fowler et al., 1989). The near equivalence of  $V_d$  and  
28 ( $r_a$ )<sup>-1</sup> simplifies calculation of fog water deposition and reflects the absence of vegetative  
29 physiological control over surface resistance. Fog particles outside this size range may exhibit  
30  $V_d$  below ( $r_a$ )<sup>-1</sup>. For smaller particles, this decline reflects the increasing influence of still air and  
31 boundary layer effects on impaction as particle size and momentum decline. For larger particles,

1 momentum is sufficient to overcome these near surface limitations, but  $V_d$  may decline as  
2 turbulent eddy transport to the surface becomes inefficient with increasing inertia (Gallagher  
3 et al., 1988). The deposition to vegetation for PM in fog droplets is directly proportional to wind  
4 speed, droplet size, concentration, and fog density (liquid water content per volume air) although  
5 the latter two may be inversely related. In some areas, typically along foggy coastlines or at high  
6 elevations, occult deposition represents a substantial fraction of total deposition to foliar surfaces  
7 (Fowler et al., 1991, Figure 4-2).

#### 9 **4.2.2.3 Magnitude of Deposition**

10 Dry deposition of PM is most effective for coarse particles including primary geologic  
11 material and for elements such as iron and manganese. Wet deposition is most effective for fine  
12 particles of atmospheric (secondary) origin (e.g., nitrogen and sulfur, Table 4-6) and elements  
13 such as cadmium, chromium, lead, nickel, and vanadium (Reisinger, 1990; Smith, 1990a,b,c;  
14 Wiman and Lannefors, 1985). The occurrence of occult deposition is more restricted. The  
15 relative magnitudes of the different deposition modes varies with ecosystem type, location,  
16 elevation, and chemical burden of the atmosphere. For the Walker Branch Watershed, a  
17 deciduous forest in rural eastern Tennessee, dry deposition constituted a major fraction of the  
18 total annual atmospheric input of cadmium and zinc ( $\approx 20\%$ ), lead ( $\approx 55\%$ ), and manganese  
19 ( $\approx 90\%$ ). Whereas wet deposition fluxes during precipitation events exceeded dry deposition  
20 fluxes by one to four orders of magnitude (Lindberg and Harriss, 1981), dry deposition was  
21 nearly continuous. Immersion of high-elevation forests in cloud water may occur for 10% or  
22 more of the year, significantly enhancing transfer of PM and dissolved gases to the canopy.  
23 Occult deposition in the Hawaiian Islands dominated total inputs of inorganic N (Heath and  
24 Huebert, 1999). Much of this N was volcanically derived during the generation of volcanic fog  
25 in part through reactions with seawater. In this humid climate, the dominance of occult rather  
26 than wet deposition is notable.

27 High-elevation forests receive larger particulate deposition loadings than equivalent low  
28 elevation sites. Higher wind speeds enhance the rate of aerosol impaction. Orographic effects  
29 enhance rainfall intensity and composition and increase the duration of occult deposition.  
30 Coniferous species in these areas with needle-shaped leaves also enhance impaction and  
31 retention of PM delivered by all three deposition modes (Lovett, 1984).

1 In more arid regions, such as the western United States, the importance of dry deposition  
2 may be larger. In the San Gabriel Mountains of southern California, for example, while annual  
3 deposition of  $\text{SO}_4^{-2}$  (partly of marine origin) was dominated by wet deposition (Fenn and Kiefer,  
4 1999), deposition of  $\text{NO}_3^-$  was dominated by dry deposition, as was that of  $\text{NH}_4^+$  at two of three  
5 sites. Similarly, at a series of low elevation sites in southern California (Padgett et al., 1999),  
6 dry deposition of  $\text{NO}_3^-$  was dominated by dry deposition. In both cases, however, the  
7 contribution of gaseous  $\text{HNO}_3$  was probably substantial.

### 9 **Nitrates, Sulfates and Cations**

10 Much particulate sulfate and nitrate is found on particles in the 0.1- to 1.0- $\mu\text{m}$  size range  
11 (U.S. Environmental Protection Agency, 1982). However, most sulfate and nitrate, base cation  
12 and heavy metal inputs to forested ecosystems results from the deposition of larger particles  
13 (Chapter 2; Lindberg and Lovett, 1985; Lindberg et al., 1982). The influence of aerodynamic  
14 diameter is particularly critical for nitrogen species, because they exist as a wide range of  
15 particle sizes in the atmosphere (Milford and Davidson, 1987). For example, at many sites in  
16 North America,  $\text{NO}_3^-$  is characterized by a bimodal size distribution with modes above and  
17 below 1  $\mu\text{m}$ . The supermicron particles are often the result of reactions between  $\text{HNO}_3$  and  
18 coarse alkaline aerosols (Wolff, 1984) as, for example, in the San Joaquin Valley of California  
19 (Lindberg et al., 1990). Although the annual deposition of  $\text{NH}_4^+$  is distributed similarly among  
20 the fine and coarse particles, particulate  $\text{NO}_3^-$  is found predominantly in the coarse-particle  
21 fraction (Table 4-7). Similar to the pattern for  $\text{NH}_4^+$ , the estimated annual deposition of  $\text{SO}_4^{-2}$   
22 particles occurs in both the fine- and coarse-particulate fractions (Table 4-8), while base cation  
23 deposition is virtually restricted to contributions from coarse particles (Table 4-9).

24 Although the annual chemical inputs to ecosystems from particle deposition is significant  
25 by itself, it is important to compare it with the total chemical inputs from all sources of  
26 atmospheric deposition (i.e., precipitation, particles, and gaseous dry deposition). Figure 4-10  
27 shows the mean percentage contribution of  $\text{NO}_3^-$  and  $\text{NH}_4^+$ ,  $\text{SO}_4^{-2}$ , and base cation-containing  
28 particles to the total nitrogen, sulfur, and base cation deposition load to forest ecosystems  
29 (derived from Tables 4-7 through 4-9). Although the mean contribution of particulate deposition  
30 to cumulative nitrogen and sulfur deposition is typically less than 20% of annual inputs from all

<sup>a</sup>Includes K<sup>+</sup>, Na<sup>+</sup>, Ca<sup>+2</sup>, and Mg<sup>+2</sup>.

<sup>b</sup>Includes deposition from precipitation, gases, and particles.

<sup>c</sup>1 = Ragsdale et al. (1992), 2 = Johnson and Lindberg (1992a), 3 = Lindberg et al. (1986).

<sup>d</sup>Includes H<sup>+</sup>, K<sup>+</sup>, Na<sup>+</sup>, Ca<sup>+2</sup>, Mg<sup>+2</sup> for the growing season from April to October 1987.

<sup>e</sup>Includes only Ca<sup>+2</sup> and K<sup>+</sup>.

**Figure 4-10. Mean ( $\pm$ SE) percent of total nitrogen, sulfur, or base cation deposition contributed by fine plus coarse particles. Data are means from Tables 4-7 through 4-9.**

1 atmospheric sources, particulate inputs of base cations average half the total base cations  
 2 entering forest ecosystems from the atmosphere.

3 An extensive comparison of particle to total chemical deposition is provided by the  
 4 Integrated Forest Study (IFS; Johnson and Lindberg, 1992a; Lovett, 1994; Lovett and Lindberg,  
 5 1993; Lindberg and Lovett, 1992; Ragsdale et al., 1992). Other similar data sets are available  
 6 (Kelly and Meagher, 1986; Miller et al., 1993; Lindberg et al., 1986, 1990). These data in  
 7 (Tables 4-7 through 4-9) clearly indicate that the contribution of coarse and fine aerosols to  
 8 deposition to forest ecosystems is strongly dependent on the chemical species.

9 Dry deposition is an important flux of sulfur and nitrogen compounds at all of the IFS sites  
 10 and ranges from 9 to 59% of total (wet + dry + cloud) deposition for sulfur, 25% to 70% for  
 11  $\text{NO}_3^-$  and 2% to 33% for  $\text{NH}_4^+$ . For only  $\text{NH}_4^+$  is wet deposition consistently greater than dry  
 12 deposition (Lovett, 1994).

13 After emission from their sources, air pollutants are transformed and transported by  
 14 atmospheric processes (i.e, atmospheric meteorology) until deposited from the atmosphere to an

1 aquatic or terrestrial ecosystem. As a result, ground-level concentrations of an air pollutant  
2 depend on the proximity to the sources, prevailing meteorology, and nature and extent of  
3 atmospherical reactions between the source and the receptor (Holland et al., 1999). A more  
4 direct relationship exists between source strength and downwind ambient concentrations for  
5 primary air pollutants (e.g., SO<sub>2</sub>) than for secondary pollutants (e.g., sulfate, SO<sub>4</sub><sup>-2</sup>). Interaction  
6 of the chemical and physical atmospheric processes and source locations for all of the pollutants  
7 have a tendency to produce data patterns that show large spatial and temporal variability.

8 Holland et al. (1999) analyzed CASTnet monitoring data and using generative additive  
9 models (GAM) estimated the form and magnitude of trends of airborne concentrations of SO<sub>2</sub>,  
10 SO<sub>4</sub><sup>-2</sup>, and nitrogen from 1989 to 1995 at 34 rural long-term CASTnet monitoring sites in the  
11 eastern United States. These models provide a highly flexible method for describing potential  
12 nonlinear relationships between concentrations, meteorology, seasonality, and time (e.g., how  
13 weekly SO<sub>2</sub> varies as a function of temperature). For most of the 34 sites in the eastern United  
14 State, estimates of change in SO<sub>2</sub> concentrations showed a decreasing functional form in 1989-  
15 1990, followed by a relatively stable period during 1991-1993), then a sharper decline beginning  
16 in 1994 (Holland et al., 1999).

17 Regional trends of seasonal and annual wet deposition and precipitation-weighted  
18 concentrations (PWCs) of sulfate in the United States over the period 1980-1995 were developed  
19 by Shannon (1999) from monitoring data and scaled to a mean of unity. In order to reduce some  
20 effects of year to year climatological variability, the unitless regional deposition and PWC trends  
21 were averaged (hereafter referred to a CONCDEP). During the 16 year period examined in the  
22 study, estimated aggregate emissions of SO<sub>2</sub> in the United States and Canada fell approximately  
23 12% from about 1980 to 1982, it remained roughly level for a decade and then fell  
24 approximately another 15% from 1992 to 1995 — for an overall decrease of about 18%. Eastern  
25 regional trends of sulfate concentrations and deposition and their average CONCDEP, also  
26 exhibited patterns of initial decrease, near steady state, and final decrease with year to-to-year  
27 variability. The overall relative changed in CONCDEPs are greater than the changes in SO<sub>2</sub>  
28 emissions.

29 Concentrations and calculated deposition (concentration times amount of water) of SO<sub>4</sub><sup>-2</sup> at  
30 the Hubbard Brook Experiment Forest (HBEF) in the White Mountains of central New  
31 Hampshire have been measured since June of 1964 (Likens et al., 2001). These measurements

1 represent the longest continuous record of precipitation chemistry in North America. The  
2 long-term measurements generally concur with those of Shannon (1999) discussed above. Major  
3 declines in emissions of SO<sub>2</sub> have been observed during recent decades in the eastern United  
4 States and have been correlated with significant decreases in SO<sub>4</sub><sup>-2</sup> concentrations in  
5 precipitation (Shannon, 1999).

6 Deposition of sulfates and nitrates are very clearly linked to emissions. Reduction in  
7 emissions must occur before concentrations can be reduced below current levels (Likens et al.,  
8 2001). Deposition is the key variable as sensitive ecosystems in the eastern North America have  
9 not yet shown improvement in response to decreased emissions of SO<sub>2</sub> (Driscoll et al., 1989;  
10 Likens et al., 1996). Clearly, additions of other chemicals, such as nitric acid and base cations,  
11 must be considered in addition to sulfur when attempting to resolve the acid rain problem  
12 (Likens et al., 1996, 1998). The effects of sulfur and nitrogen deposition on ecosystems are  
13 discussed in Section 4.2.2.2.

14 The long-term record indicates that a reduction in the deposition of basic cations (Ca<sup>+2</sup>,  
15 Mg<sup>2+</sup>, K<sup>+</sup>, Na<sup>+</sup>) in bulk precipitation was associated with significant declines in sulfate deposition  
16 cited above for the HBEF region (Driscoll et al., 1989). Decreases in streamwater  
17 concentrations of basic cations have decreased simultaneously, suggesting that streamwater  
18 concentrations of basic cations are relatively responsive to changes in atmospheric inputs.  
19 Regardless of the cause, the decline in atmospheric influx of basic cations could have important  
20 effects on nutrient availability as well as on the acid/base status of soil and drainage water  
21 (Driscoll et al., 1989).

## 22

### 23 **Trace Elements**

24 Deposition velocities for fine particles to forest surfaces have been reported in the range of  
25 1 to 15 cm s<sup>-1</sup> (Smith, 1990a). For example, total, annual heavy metal deposition amounts are  
26 highly variable depending on specific forest location and upwind source strength (Table 4-10).  
27 Lindberg et al. (1982) quantified the dry deposition of heavy metals to inert surfaces and to  
28 leaves of an upland oak forest. As noted for other chemical species, V<sub>d</sub> was highly dependent on  
29 particle size and chemical species (Table 4-11) with the larger particles depositing more  
30 efficiently.

**TABLE 4-10. MEAN ( $\pm$ SE) PARTICLE SIZE, DEPOSITION RATES, AND DERIVED DEPOSITION VELOCITIES ( $V_d$ ) FOR HEAVY METAL DEPOSITION TO THE UPPER CANOPY (INERT PLATES OR LEAVES) OF AN UPLAND OAK FOREST**

Metal	Particle Size ( $\mu\text{m}$ )	Deposition Rate	$V_d$
		( $\text{pg cm}^{-2} \text{h}^{-1}$ )	( $\text{cm s}^{-1}$ )
Manganese	$3.4 \pm 0.7$	$91 \pm 23$	$6.4 \pm 3.6$
Cadmium	$1.5 \pm 0.7$	$0.3 \pm 0.1$	$0.37 \pm 0.18$
Zinc	$0.9 \pm 0.2$	$6 \pm 1$	$0.38 \pm 0.1$
Lead	0.5	$23 \pm 8$	$0.06 \pm 0.01$

**TABLE 4-11. TOTAL HEAVY METAL DEPOSITION TO TEMPERATE LATITUDE FORESTS**

Heavy Metal	Forest Deposition $\text{kg ha}^{-1} \text{ year}^{-1}$ (Range)
Cadmium	0.002 - 0.02
Copper	0.016 - 0.24
Lead	0.099 - 1000
Nickel	0.014 - 0.15
Zinc	0.012 - 0.178

Source: Smith (1990c).

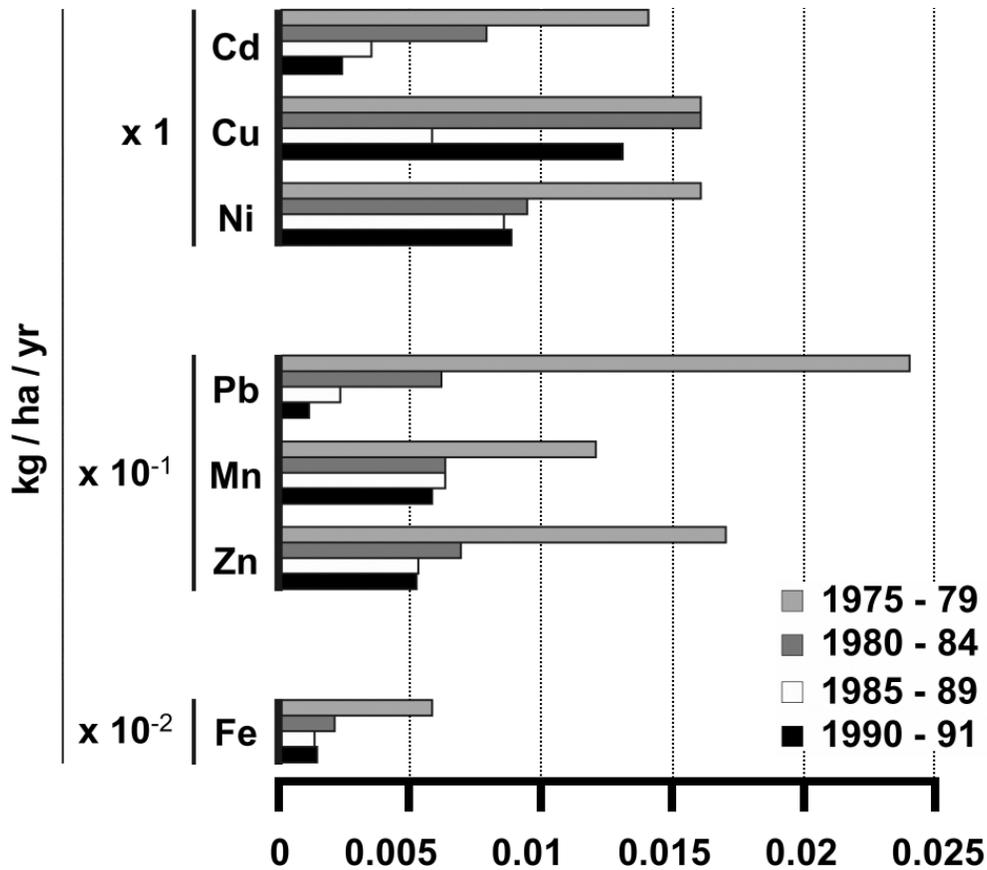

1 Preferential association of heavy metals with fine particles results in reduced control in  
2 emission control systems. Metal removal efficiencies for baghouse filters are typically 95 to  
3 99% for all but mercury, but fine particle capture is much less efficient. Wet scrubber efficiency  
4 varies with design and pressure drop, typically 50 to 90% (McGowan et al., 1993). Fine  
5 particles also have the longest atmospheric residence times and, therefore, can be carried long  
6 distances. Depending on climate conditions and topography, fine particles may remain airborne  
7 for days to months and may be transported 1,000 to 10,000 km or more from their source. This  
8 long-distance transport and subsequent deposition qualify heavy metals as regional- and global-

1 scale air pollutants. Ecosystems immediately downwind of major emissions sources (such as  
2 power generating, industrial, or urban complexes) may receive locally heavy inputs. Mass  
3 balance budgets (inputs and outputs) of seven heavy metals (cadmium, copper, iron, lead,  
4 manganese, nickel, and zinc) have been determined at the Hubbard Brook Experimental Forest  
5 (White Mountain National Forest) in New Hampshire. This forest is about 120 km northwest of  
6 Boston and relatively distant from major sources of heavy metal emissions. However,  
7 continental air masses that have passed over centers of industrial and urban activity also  
8 frequently follow storm tracks over northern New England. Resulting annual inputs for the  
9 seven heavy metals at Hubbard Brook for 1975 to 1991 are presented in Figure 4-11. Note that  
10 the 44-fold decrease in lead deposition is correlated with removal of lead from motor vehicle  
11 fuels.

12 Trace element investigations conducted in roadside, industrial, and urban environments  
13 have shown that impressive burdens of particulate heavy metals accumulate on vegetative  
14 surfaces. Lead deposition to roadside vegetation (prior to its removal from fuel) was 5 to 20,  
15 50 to 200, and 100 to 200 times lead deposition to agricultural crops, grasses, and trees,  
16 respectively, in non-roadside environments. In an urban setting, it has been estimated that the  
17 leaves and twigs of a 30-cm (12-in.) diameter sugar maple remove 60, 140, 5800, and 820 mg of  
18 cadmium, chromium, lead, and nickel, respectively, during the course of a single growing season  
19 (Smith, 1973).

## 21 **Semivolatile Organics**

22 Organic compounds partition between gas and particle phases, and particulate deposition  
23 depends largely on the particle sizes available for adsorption (Pankow, 1987; Smith and Jones,  
24 2000). Dry deposition of organic materials (e.g., dioxins, dibenzofurans, polycyclic aromatics)  
25 is often dominated by the coarse fraction, even though mass loading in this size fraction may be  
26 small (Lin et al., 1993) relative to the fine PM fraction. For example, measurements in Bavaria  
27 in both summer and winter revealed that > 80% of organics were in the fine (< 1.35  $\mu\text{m}$ ) fraction  
28 (Kaupp and McLachlan, 1999). Nevertheless, in most cases, calculated values of dry deposition  
29 were dominated by the material adsorbed to coarse particles. Wet deposition, in contrast, was  
30 dominated by the much larger amount of material associated with fine particles. In this  
31 environment (where monthly precipitation is about 50 mm in winter and summer), wet

**Figure 4-11. Annual total deposition of heavy metals to Hubbard Brook Experimental Forest, NH (Smith, 1990a).**

1 deposition dominated, with dry deposition accounting for only 14 to 25% of total deposition  
 2 (Kaupp and McLachlan, 1999). Lower relative contents of more volatile species in summer than  
 3 winter (Kaupp and McLachlan, 1999) indicate the critical importance of gas-particle phase  
 4 interconversions in determining deposition.

5 Effective deposition of PM is required before biological effects on plants or ecosystems  
 6 can occur. It is clear that substantially improved techniques for monitoring and predicting  
 7 deposition will be required to characterize with certainty quantitative relationships between rates  
 8 and quantities of PM deposition associated with such effects.

 10

### 4.2.3 Assessment of Atmospheric PM Deposition Effects

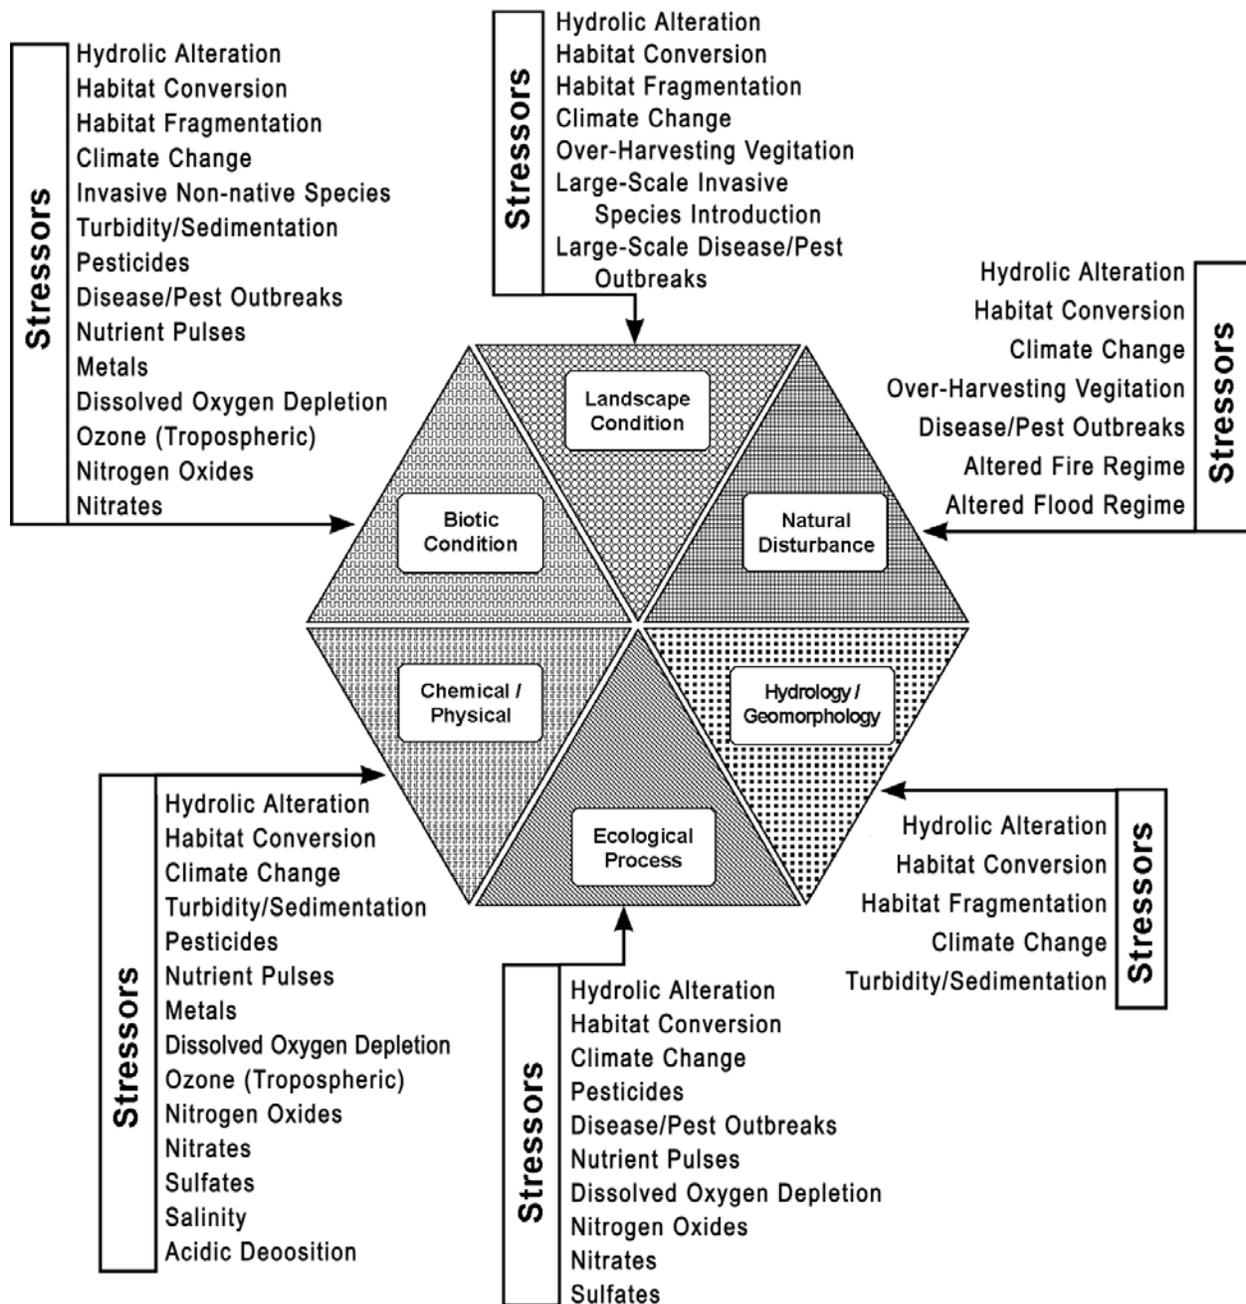

#### Introduction

The discussion in the pages that follow assesses and characterizes the overall ecological condition or integrity of the ecosystems within the United States affected by the deposition of the anthropogenic stressors associated with PM and indicates their status. The six Essential Ecological Attributes (EEAs) – the Landscape Condition, Biotic Condition, and Chemical/Physical Characteristics, Ecological Processes, Hydrology/Geomorphology, and Natural Disturbance Regimes (Table 4-1) provide a hierarchical framework for determining ecosystem status. Measurable characteristics related to structure, composition, or functioning of ecological systems may be determined by the use of endpoints or ecological indicators of condition that are significant either ecologically or to society (Harwell et al., 1999).

The relationships among the EEAs are complex because all are interrelated (i.e., changes in one EEA may affect, directly or indirectly, every other EEA). The ecological processes create and maintain patterns, which consist of elements in the system and the way they are arranged; whereas the patterns in turn affect how the processes are expressed (Science Advisory Board, 2002). Changes in patterns or processes result in changes in the status and functioning of an ecosystem. The information in the sections that follow discusses changes in Landscape and Biotic patterns and in Ecological and Chemical/Physical Processes resulting from the stressors in PM deposition (Figure 4-12).

The elements of Biotic Condition are organized as nested hierarchy with several levels. These include the structural and composition aspects (patterns) of the biota within landscape, ecosystem or ecological community, species/population, organism and genetic/molecular level (Science Advisory Board, 2002). Within these biological levels of organization, changes in the biodiversity, composition, and structural elements relate directly to functional integrity (such as trophic status or structural integrity within habitats). Changes in biodiversity are of particular significance in altering the functioning of ecosystems.

As previously stated, ecosystems are dynamic, self-adjusting, self-maintaining, complex, adaptive systems, in which patterns at the higher levels of biotic organization emerge from interactions and selection processes at localized levels (Levin, 1998). Ecosystems components must have an adequate supply of energy, mineral nutrients, and water to maintain themselves and function properly. During the ecological processes of energy and material flow, the energy

**Figure 4-12. Sample stressors and the essential ecological attributes they affect (after Science Advisory Board, 2002).**

- 1 obtained by plants (the producers) from sunlight during photosynthesis (primary production) and
- 2 chemical nutrients (e.g., nitrogen, phosphorus, sulfur cycling) taken up from the soil are
- 3 transferred to other species (the consumers) within the ecosystem through food webs. The

1 movement of chemical nutrients (materials) through an ecosystem is cyclic, as the nutrients are  
2 used or stored and eventually returned to the soil by decomposer organisms. Energy, on the  
3 other hand, is transferred from organism to organism through an ecosystem in food webs and,  
4 finally, is dissipated into the environment as heat (Odum, 1993).

5 Ecosystem and community patterns are characterized by the interaction of their component  
6 species, the ecosystems processes of energy flow, nutrient flux, water and material flow and by  
7 the effect their activities have on the physical and chemical environment. The flows of energy  
8 and nutrient cycling provide the interconnectedness among the elements of the biotic hierarchy  
9 and transform the community from random collection of species into an integrated whole,  
10 an ecosystem. Elucidating these interactions across scales is fundamental to understanding the  
11 relationships between biodiversity and ecosystem functioning (Levin, 1998).

12 Human existence on this planet depends on the life-support services provided by the  
13 interaction of the different EEAs. Both ecosystem structure (biotic condition) and functions  
14 (ecological processes) play an essential role in providing ecosystem goods (products) and  
15 services (Table 4-12; Daily, 1997). Ecosystem processes maintain clean water, clean air, a  
16 vegetated Earth, and a balance of organisms, the functions that enable humans to survive. The  
17 benefits they impart include absorption and breakdown of pollutants, cycling of nutrients,  
18 binding of soil, degradation of organic waste, maintenance of a balance of gases in the air,  
19 regulation of radiation balance and climate, and the fixation of solar energy (World Resources,  
20 2000-2001; Westman, 1977; Daily, 1997). Economic benefits and values associated with  
21 ecosystem functions, goods and services, and the need to preserve them because of their value to  
22 human life are discussed by Costanza et al. (1997) and (Pimentel et al., 1997). Goods have  
23 market value; whereas services usually are not considered to have market value.

24 Attempts have been made to calculate the value of biodiversity and the world's ecosystem  
25 services and natural capital (Goulder and Kennedy, 1997; Pimentel et al., 1997; Costanza et al.,  
26 1997). The majority of these have been controversial because of a lack of agreement on the  
27 philosophical basis for placing a value on ecosystem services. Costanza et al. (1997) state that it  
28 may never be possible to make a precise estimate of the services provided by ecosystems;  
29 however, their estimates indicate the relative importance of ecosystem services, not their true  
30 value considering that the loss of ecosystem services can affect human existence. One problem  
31 with traditional economic analysis is that following consumption, the material and energy

**TABLE 4-12. PRIMARY GOODS AND SERVICES PROVIDED BY ECOSYSTEMS**

<b>Ecosystem</b>	<b>Goods</b>	<b>Services</b>
<u>Agroecosystems</u>	Food crops Fiber crops Crop genetic resources	Maintain limited watershed functions (infiltration, flow control, and partial soil protection) Provide habitat for birds, pollinators, and soil organisms important to agriculture Sequester atmospheric carbon Provide employment
<u>Coastal ecosystems</u>	Fish and shellfish Fishmeal (animal feed) Seaweeds (for food and industrial use) Salt Genetic resources	Moderate storm impacts (mangroves, barrier islands) Provide wildlife (marine and terrestrial) habitat and breeding areas/hatcheries/nurseries Maintain biodiversity Dilute and treat wastes Provide harbors and transportation routes Provide human and wildlife habitat Provide employment Contribute aesthetic beauty and provide recreation
<u>Forest ecosystems</u>	Timber Fuelwood Drinking and irrigation water Fodder Nontimber products (vines, bamboos, leaves, etc.) Food (honey, mushrooms fruit, and other edible plants; game) Genetic resources	Remove air pollutants, emit oxygen Cycle nutrients Maintain array of watershed functions (infiltration, purification, flow control, soil stabilization) Maintain biodiversity Sequester atmospheric carbon Moderate weather extremes and impacts Generate soil Provide employment Provide human and wildlife habitat Contribute aesthetic beauty and provide recreation
<u>Freshwater</u>	Drinking and irrigation water Fish Hydroelectricity Genetic resources	Buffer water flow (control timing and volume) Dilute and carry away wastes Cycle nutrients Maintain biodiversity Provide aquatic habitat Provide transportation corridor Provide employment Contribute aesthetic beauty and provide recreation
<u>Grassland ecosystems</u>	Livestock (food, game, hides, and fiber) Drinking and irrigation water Genetic resources	Maintain array of watershed functions (infiltration, purification, flow control, and soil stabilization) Cycle nutrients Remove air pollutants and emit oxygen Maintain biodiversity Generate soil Sequester atmospheric carbon Provide human and wildlife habitat Provide employment Contribute aesthetic beauty and provide recreation

Source: World Resources (2000-2001).

1 embedded in economic goods disappear from the universe of economic analysis although the  
2 laws of thermodynamics conservation guarantee their persistence (Moomaw, 2002).

3 An industrial ecology approach considers the full life cycle of materials and energy and  
4 recognizes that economic wastes still need to be accounted for following consumption of goods.  
5 For example, nitrogen incorporated in fertilizer does not disappear after fuel is burned to produce  
6 smog; it continues to cascade through the biosphere. The degraded ecosystem continues to  
7 provide fewer ecosystem services for the indefinite future. Some nitrogen in the form of nitric  
8 acid may rain down on crops and forests, providing nutrients in degraded form. This diluted  
9 nitrogen has the economic equivalent of “scrap value,” even if humans do not find it expedient to  
10 recover it, given present techniques (Moomaw, 2002).

11 Heal (2000), on the other hand, feels that attempts to value ecosystems and their services  
12 are misplaced: “Economics cannot estimate the importance of natural environments to society:  
13 only biology can do that” (Heal, 2000). The role of economics is to help design institutions that  
14 will provide incentives to the public and policy makers for the conservation of important natural  
15 systems and for mediating human impacts on the biologically diverse ecosystems and the  
16 biosphere so that they are sustainable. The approach of Harwell et al. (1999) and the report by  
17 the Ecological Processes and Effects Committee of the SAB (Science Advisory Board, 2002)  
18 also deals with the need to understand human effects on ecosystems so that ecosystem  
19 management can define what ecological conditions are desired. Further, they state that the  
20 establishment of ecological goals involves a close linkage between scientists and decision  
21 makers in which science informs decision makers and the public by characterizing the ecological  
22 conditions that are achievable under particular management regimes. Decision makers then can  
23 make choices that reflect societal values including issues of economics, politics, and culture.  
24 For management to achieve their goals, the general public, scientific community, resource  
25 managers, and decision makers need to be routinely apprised of the condition or integrity of  
26 ecosystems so that ecological goals may be established (Harwell et al., 1999).

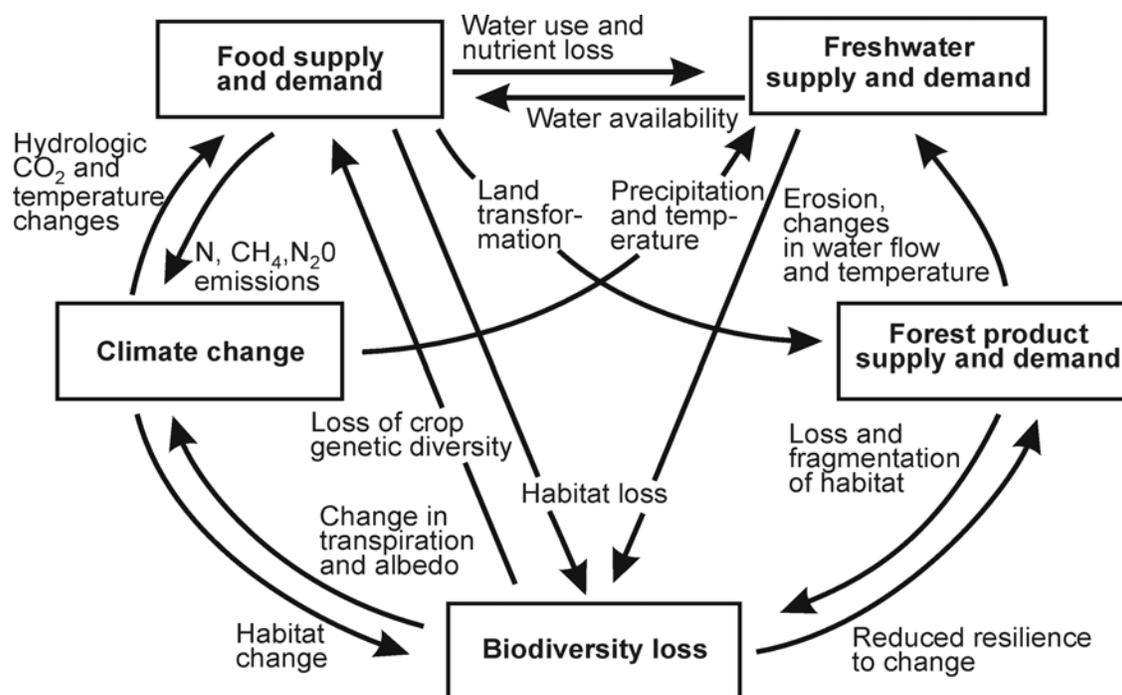

27 Biodiversity, the variety of life, encompasses all levels of biological organization,  
28 including species individuals, populations, and ecosystems (Figure 4-1; Wilson, 1997).  
29 Human-induced changes in biotic diversity and alterations in the structure and functioning of  
30 ecosystems are the two most dramatic ecological trends in the past century (Vitousek et al.,  
31 1997). There are few ecosystems on Earth today that are not influenced by humans

1 (Freudenburg and Alario, 1999; Vitousek et al., 1997; Matson et al., 1997; Noble and Dirzo,  
2 1997). The scientific literature is filled with publications discussing the importance of  
3 ecosystem structure (patterns) and function (processes). The deposition of particulate matter  
4 from the atmosphere has the potential to alter ecosystem structure and function by altering  
5 nutrient cycling and changing biodiversity. There is a need, therefore, to understand how  
6 ecosystems respond to both natural and anthropogenic stresses in order to determine whether or  
7 not anthropogenic stresses are affecting ecosystem services and products (Table 4-12).

8 Concern has risen in recent years regarding the consequences of changing the biological  
9 diversity of ecosystems (Tilman, 2000; Ayensu et al., 1999; Wall, 1999; Hooper and Vitousek,  
10 1997; Chapin et al., 1998). The concerns arise because human activities are creating  
11 disturbances that are decreasing biodiversity; altering the complexity and stability of  
12 ecosystems; and producing changes in ecological processes and the structure, composition and  
13 function of ecosystems (Figure 4-13; Pimm, 1984; Levin, 1998; Chapin et al., 1998; Peterson  
14 et al., 1998; Tilman, 1996; Tilman and Downing, 1994; Wall, 1999; Daily and Ehrlich, 1999).  
15 The above changes can affect the ecosystem services vital to human life.

#### 17 **4.2.3.1 Effects on Vegetation and Ecosystems**

18 Exposure to a given mass concentration of airborne PM may lead to widely differing  
19 phytotoxic responses, depending on the particular mix of deposited particles. Effects of  
20 particulate deposition on individual plants or ecosystems are difficult to characterize because of  
21 the complex interactions among biological, physicochemical, and climatic factors. Most direct  
22 effects, other than regional effects associated with global changes, occur in the severely polluted  
23 areas surrounding industrial point sources, such as limestone quarries, cement kilns, and metal  
24 smelting facilities. Fine particles are more widely distributed from their source. Experimental  
25 applications of PM constituents to foliage typically elicit little response at the more common  
26 ambient concentrations. The diverse chemistry and size characteristics of ambient PM and the  
27 lack of clear distinction between effects attributed to phytotoxic particles and to other air  
28 pollutants further confound understanding of the direct effects on foliar surfaces. The majority  
29 of documented toxic effect of particles on vegetation reflect their chemical content (acid/base,  
30 trace metal, nutrient), surface properties, or salinity. Studies of direct effects of particles on  
31 vegetation have not yet advanced to the stage of reproducible exposure experiments. Difficulties

**Figure 4-13. Linkages among various ecosystem goods and services (food, water, biodiversity, forest products) and other driving forces (climate change) (modified from Ayensu et al., 1999).**

1 in experimental application of ambient particles to vegetation have been discussed by Olszyk  
 2 et al. (1989). It is now clear that many phytotoxic gases are deposited more readily, assimilated  
 3 more rapidly, and lead to greater direct injury to vegetation than do most common particulate  
 4 materials (Guderian, 1986). The dose-specific responses (dose-response curves) obtained in  
 5 early experiments following the exposure of plants to phytotoxic gases generally have not been  
 6 observed following the application of particles.

7 Unlike gaseous dry deposition, neither the solubility of the particles nor the physiological  
 8 activity of the surface is likely to be of first order of importance in determining deposition  
 9 velocity ( $V_d$ ). Factors that contribute to surface wetness and stickiness may be critical  
 10 determinants of sticking efficiency. Available tabulation of deposition velocities are highly  
 11 variable and suspect. High-elevation forests receive larger particle deposition loadings than  
 12 equivalent lower elevations sites because of higher wind speeds and enhanced rates of aerosol

1     impaction; orographic effects on rainfall intensity and composition; increased duration of occult  
2     deposition; and, in many areas, the dominance of coniferous species with needle-shaped leaves  
3     (Section 4.2.2.3; Lovett, 1984). Recent evidence indicates that all three modes of deposition  
4     (wet, occult, and dry) must be considered in determining inputs to ecosystems or watersheds,  
5     because each may dominate over specific intervals of space.

6             Atmospheric PM may affect vegetation directly following deposition on foliar surfaces or  
7     indirectly by changing the soil chemistry or through changes in the amount of radiation reaching  
8     the Earth's surface through PM-induced climate change processes. Indirect effects, however, are  
9     usually the most significant because they can alter nutrient cycling and inhibit plant nutrient  
10    uptake.

### 12     **Direct Effects of PM Deposition**

13             Coarse and fine PM deposition affects both (a) patterns in the elements of EEA categories  
14    subsumed under Biotic Condition and (b) processes subsumed under Chemical/Physical and  
15    Ecological Processes in the EPEC framework described earlier. Measurable responses have  
16    been observed as reductions in photosynthesis and in salinity of the soil and foliar effects of  
17    nitrate, sulfate, and acidic and heavy metal deposition.

18             Particles transferred from the atmosphere to foliar surfaces may reside on the leaf, twig, or  
19    bark surface for extended periods; be taken up through the leaf surface; or be removed from the  
20    plant via resuspension to the atmosphere, washing by rainfall, or litter-fall with subsequent  
21    transfer to the soil. Any PM deposited on above-ground plant parts may exert physical or  
22    chemical effects. The effects of "inert" PM are mainly physical; whereas those of toxic particles  
23    are both chemical and physical. The effects of dust deposited on plant surfaces or soil are more  
24    likely to be associated with their chemistry than simply with the mass of deposited particles and  
25    may be more important than any physical effects (Farmer, 1993). Nevertheless, vegetative  
26    surfaces represent filtration and reaction/exchange sites (Tong, 1991; Youngs et al., 1993).

### 28     **Direct Effects of Coarse Particles**

29             Coarse particles, ranging in size from 2.5 to 100  $\mu\text{m}$ , are chemically diverse, dominated by  
30    local sources, and typically deposited near their source because of their sedimentation velocities.  
31    Airborne coarse particles are derived from the following sources: road, cement kiln, and

1 foundry dust; fly ash; tire particles and brake linings; soot and cooking oil droplets; biogenic  
2 materials (e.g, plant pollen, fungal spores, bacteria and viruses); abraded plant fragments; sea  
3 salt; and hydrated deliquescent particles of otherwise fine aerosol. In many rural areas and some  
4 urban areas, the majority of mass in the coarse particle mode is in the elements silicon,  
5 aluminum, calcium, and iron, suggesting a crustal origin as fugitive dust from disturbed land,  
6 roadways, agriculture tillage, or construction activities. Rapid sedimentation of coarse particles  
7 tends to restrict their direct effects on vegetation largely to roadsides and forest edges.  
8

9 ***Physical Effects — Radiation.*** Dust can cause physical and chemical effects. Deposition  
10 of inert PM on above-ground plant organs sufficient to coat them with a layer of dust may result  
11 in changes in radiation received, a rise in leaf temperature, and the blockage of stomata.  
12 Increased leaf temperature and heat stress; reduced net photosynthesis; and leaf chlorosis,  
13 necrosis, and abscission were reported by Guderian (1986). Road dust decreased the leaf  
14 temperature on *Rhododendron catawbiense* by ca., 4 °C (Eller, 1977); whereas foundry dust  
15 caused an 8.7 °C increase in leaf temperature of black poplar (*Populus nigra*) under the  
16 conditions of the experiment (Guderian, 1986). Deciduous (broad) leaves exhibited larger  
17 temperature increases because of particle loading than did conifer (needle) leaves, a function of  
18 poorer coupling to the atmosphere. Inert road dust caused a three- to four-fold increase in the  
19 absorption coefficient of leaves of English ivy (Eller, 1977; Guderian, 1986) for near infrared  
20 radiation (NIR; 750 to 1350 nm). Little change in absorption occurred for photosynthetically  
21 active radiation (PAR; 400 to 700 nm). The increase in NIR absorption was equally at the  
22 expense of reflectance and transmission in these wavelengths. The amount of energy entering  
23 the leaf increased by ca., 30% in the dust-affected leaves. Deposition of coarse particles  
24 increased leaf temperature and contributed to heat stress; reduced net photosynthesis; and caused  
25 leaf chlorosis, necrosis, and abscission (Dässler et al., 1972; Parish, 1910; Guderian, 1986;  
26 Spinka, 1971).

27 Starch storage in dust-affected leaves increased with dust loading under high (possibly  
28 excessive) radiation, but decreased following dust deposition when radiation was limiting.  
29 These modifications of the radiation environment had a large effect on single-leaf utilization of  
30 light. The boundary layer properties, determined by leaf morphology and environmental  
31 conditions, strongly influenced the direct effects of particle deposition on radiation heating

1 (Eller, 1977; Guderian, 1986) and on gas exchange. Brandt and Rhoades (1973) attributed the  
2 reduction in growth of trees to crust formation from limestone dust on the leaves. Crust  
3 formation reduced photosynthesis and the formation of carbohydrates needed for normal growth,  
4 induced premature leaf-fall, damaged leaf tissues, inhibited growth of new tissue, and reduced  
5 starch storage. Dust may decrease photosynthesis, respiration, and transpiration; and it may  
6 allow penetration of phytotoxic gaseous pollutants, thereby causing visible injury symptoms and  
7 decreased productivity. Permeability of leaves to ammonia increased with increasing dust  
8 concentrations and decreasing particle size (Farmer, 1993).

9 Dust also has been reported to physically block stomata (Krajíčková and Mejstřík, 1984).  
10 Stomatal clogging by particulate matter from automobiles, stone quarries, and cement plants was  
11 also studied by Abdullah and Iqbal (1991). The percentage of clogging was low in young leaves  
12 when compared with old and mature leaves and the amount of clogging varied with species and  
13 locality. The maximum clogging of stomata observed was about 25%. The authors cited no  
14 evidence that stomatal clogging inhibited plant functioning. The heaviest deposit of dust is  
15 usually on the upper surface of broad-leaved plants; whereas the majority of the stomata are on  
16 the lower surface where stomatal clogging would be less likely.

17  
18 ***Chemical Effects.*** The chemical composition of PM is usually the key phytotoxic factor  
19 leading to plant injury. Cement-kiln dust on hydration liberates calcium hydroxide that can  
20 penetrate the epidermis and enter the mesophyll; and, in some cases, this has caused the leaf  
21 surface alkalinity to reach a pH of 12. Lipid hydrolysis, coagulation of the protein compounds,  
22 and ultimately plasmolysis of the leaf tissue result in reduction in the growth and quality of  
23 plants (Guderian, 1986). In experimental studies, application of cement kiln dust of known  
24 composition for 2 to 3 days yielded dose-response curves between net photosynthetic inhibition  
25 or foliar injury and dust application rate (Darley, 1966). Lerman and Darley (1975) determined  
26 that leaves must be misted regularly to produce large effects. Alkalinity was probably the  
27 essential phytotoxic property of the applied dusts.

28  
29 ***Salinity.*** Particulate matter enters the atmosphere from oceans following the mixing of air  
30 into the water column and the subsequent bursting of bubbles at the surface. The effervescence  
31 of bubbles on the surface of the ocean forcefully ejects droplets of sea water into the air. These

1 droplets, concentrated by evaporation, are carried inland by wind and deposited on the seaward  
2 side of coastal plants (Boyce, 1954). This occurs largely in the surf line (i.e., near land and  
3 potentially sensitive terrestrial receptors). This process can be a significant source of sulfate,  
4 sodium, chloride, and trace elements (as well as living material) in the atmospheric aerosol  
5 impacting coastal vegetation. Sea-spray particles (Taback et al., 1979) are approximately 24%  
6 greater in size than 10  $\mu\text{m}$ , and 54% are between 3 and 10  $\mu\text{m}$ . Thus, only about 20% are fine  
7 (0 to 2.5  $\mu\text{m}$ ) particles; and deposition by sedimentation and impaction is concentrated near the  
8 coast, whereas particle size distribution shifts toward the fine fraction over longer inland  
9 transport distances. Airborne concentrations of this marine PM decrease quickly with distance  
10 inland from the surfline both by deposition and dilution within atmospheric mixed layer (McKay  
11 et al., 1994; Nelis et al., 1994). Near-shore sediments with associated pollutants present in  
12 coastal runoff may be suspended in the surf and reentrained into the air. This can be a  
13 substantial source of microorganisms and of radionuclides to coastal vegetation (Nelis et al,  
14 1994; McKay et al., 1994).

15 Sea-salt particles can serve as nuclei for the absorption and subsequent reaction of other  
16 gaseous and particulate air pollutants. Both nitrate and sulfate from the atmosphere have been  
17 found to associate with coarse and fine sea-salt particles (Wu and Okada, 1994). Direct effects  
18 on vegetation reflect these inputs, as well as classical salt injury caused by the sodium and  
19 chloride that constitute the bulk of these particles. Foliar accumulation of airborne salt particles  
20 may lead to foliar injury, thusly affecting the species composition in coastal environments  
21 (Smith, 1984).

22 The effects of winds and sea spray on coastal vegetation has been reported in the literature  
23 since the early 1800s (Boyce, 1954). However, there has been a difference of opinion as to  
24 whether the injury to coastal vegetation resulted from windblown aerial salts or from mechanical  
25 injury (i.e., sand blasting) due to wind alone. Though the significance of sea water dashed on  
26 fore dunes and rocky coasts had been recognized by several authors, Wells and Shunk (1937,  
27 1938) and Wells (1939) were the first to recognize the importance of salt spray in coastal  
28 ecology. Wells and Shunk (1937) reported that salt spray carried over dunes was the most  
29 important factor influencing growth form, zonation, and succession in coastal dunes. Salt spray  
30 injury was recorded 1.25 miles inland on the North Carolina coast. On the basis of observations  
31 in the Cape Fear area, they determined that the shape of coastal “wind form” shrubs were the

1 result of sea spray carried by high winds. They found injury on shrubs only near the coast while  
2 those at a greater distances inland showed no injury whatsoever after a strong southeast wind  
3 that persisted for a period of nineteen hours during cloudy weather and abundant soil moisture.

4 To determine the cause of injury, injured and uninjured shoots were titrated for chlorides.  
5 A marked difference was observed between the injured and uninjured shoots (Wells and Shunk,  
6 1937, 1938). Experimental spraying of shoots of woody plants with seawater resulted in a  
7 pattern of injury similar to the injury observed on seaside shrubs. The absence of the more  
8 inland species, such as persimmon (*Diosporos virginiana* L.), turkey oak (*Quercus laevis* Walt.),  
9 longleaf pine (*Pinus palustris* Mill., *P. australis* Michx.), and wire grass (*Aristida stricta*  
10 Michx.), was explained on the basis of intolerance of these species to salt spray. The dominance  
11 of live oak (*Quercus virginiana* Mill.), as a practically pure stand on Smith Island (also known  
12 as Bald Head Island), NC, and along the eastern and southern NC coast, was determined by  
13 Wells (1939) to be due to the tree's tolerance to salt spray. He termed the long term stabilization  
14 of the live oak stand as a new type of climax, the "salt spray climax." The later work of Oosting  
15 and Billings (1942) near Beaufort, NC, corroborated the findings of Wells and Shunk, 1937,  
16 1938).

17 The report by Boyce (1954) is probably the most extensive on salt-spray communities.  
18 Dune sands in many coastal areas have been shown to have extremely low concentrations of  
19 dissolved salts. Studies have indicated that the salt content of the coastal dunes of Virginia,  
20 Massachusetts, and California did not exceed the maximum occurring in ordinary cultivated  
21 soils. Oosting and Billings (1942) found no correlation between soil salinity and plant  
22 distribution on the North Carolina coast. Surface crusts of sand dunes have been shown to have  
23 high concentrations of chlorides which could be attributed to sea spray, while concentrations of  
24 chlorides in underlying layers was low. The surface layer, however, varied with exposure of the  
25 dunes to oceanic winds (Boyce, 1954).

26 Boyce (1954), Wells (1939), and Wells and Shunk (1938) concluded on the basis of their  
27 studies that necrosis and death of plant tissues results from the high deposition of salt spray and  
28 high accumulation of the chloride ion in the plant tissues. Very little salt is taken up by plant  
29 roots; most enters through the aerial organs. Leaves of plants exposed to salt spray show  
30 a distinct pattern of injury (Wells and Shunk, 1938). Necrotic areas first appear at the leaf tips  
31 and upper margins and then progress slowly in an inverted "V" toward the petiole. This leaf

1 injury pattern was verified experimentally. Mechanical injury resulting from leaves and twigs  
2 beating against each another in the wind causes the formation of small lesions through which salt  
3 can enter. After entry into the plant, the chloride ion is rapidly translocated to the apices of the  
4 leaves and twigs where it accumulates to injurious concentrations and results in the death of only  
5 a portion of the plant. The differential deposition and translocation of the chloride ion results in  
6 the death of the seaward leaves and twigs. The result is the continued growth of the uninjured  
7 branches in an inland direction. As a result, the canopy angle varies with the intensity of the  
8 spray (Boyce, 1954).

9 Little or no mineral ions are available in the silicate sands of the of coastal dunes.  
10 Consequently, plants obtain mineral ions needed for growth from the salt spray. Seawater  
11 contains all of the mineral ions required for growth except nitrogen and phosphorus. The  
12 amount of nitrogen and phosphorus in seawater varies over a wide range (Boyce, 1954).  
13 Experiments indicated that available nitrogen in sea spray was a conditioning factor. Low  
14 nitrogen availability increased the tolerance of dune species to salt spray. Increasing the  
15 availability of nitrogen resulted in a different pattern of plant zonation and distribution.  
16 Dicotyledonous species were restricted to areas of lower spray intensity. The severity of  
17 chloride injury was associated more with the amount of available potassium than with the  
18 concentration of chlorides within the limits of 280-360 mg Cl/liter (Boyce, 1954).

19 Other sources of phytotoxic saline PM include aerosols from cooling towers and roadway  
20 deicing salt. Cooling towers used to dissipate waste heat from steam-electric power generating  
21 facilities may emit salt if brackish water or saltwater is used as a coolant (McCune et al., 1977;  
22 Talbot, 1979). Foliar injury is related to salt droplets deposited by sedimentation or impaction  
23 from cooling tower drift. The distance of the salt drift determines the amount of deposition and  
24 location of injury. Environmental conditions most conducive to injury were absence of  
25 precipitation, which can wash salt off leaves, and high relative humidity (RH; Talbot, 1979).  
26 Increased injury is associated with wind speed and salt concentrations. Typical toxicity  
27 symptoms from acute exposures include marginal foliar necrosis and lesions; shoot-tip dieback;  
28 leaf curl; and interveinal necrosis (McCune et al., 1977). Based on experimental data, Grattan  
29 et al. (1981) observed that, to cause injury, salt deposited on leaf surfaces must dissolve and be  
30 absorbed into leaf tissue. Their work also indicated the importance of RH in foliar uptake.

1 If RH remained below 70%, even heavy deposition of salt did not induce injury in peppers,  
2 soybeans, and tomatoes.

3 Injury to vegetation from the application of deicing salt was related to salt spray blown or  
4 drifting from the highways by Hofstra and Hall (1971) and Viskari and Kärenlampi (2000). The  
5 most severe injury was observed nearest to the highways. The results presented in these studies  
6 agrees with that of Wyttenbach et al. (1989), who observed that conifers planted near roadway  
7 margins in the eastern United States often exhibit foliar injury due to toxic levels of saline  
8 aerosols deposited from deicing solutions. Piatt and Krause (1974) demonstrated that road and  
9 site factors influence the spread of deicing salt into forested areas. The slope away from the road  
10 influenced the distance from the road where injury was observed and the percent slope was  
11 correlated with distance.

### 13 **Effects of Fine Particles**

14 Fine PM in rural areas is generally secondary in nature, having condensed from the vapor  
15 phase or been formed by chemical reaction from gaseous precursors in the atmosphere, and is  
16 generally smaller than 1 to 2.5  $\mu\text{m}$ . Nitrogen and sulfur oxides, volatile organic gases,  
17 condensates of volatilized metals, and products of incomplete combustion are common  
18 precursors for fine PM. Reactions of many of these materials with an oxidizing atmosphere  
19 contribute to high secondary PM concentrations during summer months in many U.S. areas or  
20 during late fall and winter in areas with high nitrate concentrations. The conclusion that  
21 sufficient data were not available for adequate quantification of dose-response functions for  
22 direct effects of fine aerosols on vegetation, reached in the 1982 PM/SO<sub>x</sub> AQCD (U.S.  
23 Environmental Protection Agency, 1982), continues to be true today. Only a few studies on the  
24 direct effects of acid aerosols have been completed (U.S. Environmental Protection Agency,  
25 1982). The major effects are indirect and occur through the soil (Section 4.2.3.2).

26  
27 **Nitrogen.** Nitrate is observed in both fine and coarse particles. Nitrates from atmospheric  
28 deposition represent a substantial fraction of total nitrogen inputs to southeastern forests (Lovett  
29 and Lindberg, 1986). However, much of this is contributed by gaseous nitric acid vapor; and a  
30 considerable amount of the particulate nitrate is taken up indirectly through the soil. Garner  
31 et al. (1989) estimated deposition of nitrogen to forested landscapes in eastern North America at

1 10 to 55 kg/ha/year for nitrate and 2 to 10 kg/ha/year for ammonium. About half of these values  
2 were ascribed to dry deposition.

3 Driscoll et al. (2003) estimated anthropogenic nitrogen inputs to eight large watersheds in  
4 the Northeastern United States for the year 1997. Inputs of total nitrogen deposition ranged from  
5 14 kg/ha/year in the Casco Bay watershed, ME, to 68 kg/ha/year in the Massachusetts Bay  
6 watershed. Atmospheric deposition of nitrogen was the second largest source ranging in  
7 amounts from 5 to 10 kg/ha/year (11-36% of the total; Driscoll et al., 2003). Nitrogen deposition  
8 in the western United States ranges from 1 to 4 kg/ha/year over much of the region to as high as  
9 30 kg/year downwind of major urban and agricultural areas. An unknown amount of nitrogen  
10 deposited to the West Coast originates in Asia (Fenn et al., 2003a).

11 Atmospheric additions of particulate nitrogen in excess of vegetation needs are lost from  
12 the system, mostly as leachate from the soil as nitrate. Managed agricultural ecosystems may be  
13 able to utilize deposited particulate nitrogen more efficiently than native ecosystems although  
14 many cultivated systems also lose considerable nitrogen as nitrate in runoff, deep drainage, or  
15 soil water. It has proven difficult to quantify direct foliar fertilization by uptake of nitrogen from  
16 ambient particles.

17 There is no doubt that foliar uptake of nitrate can occur, as clearly shown by the efficacy of  
18 foliar fertilization in horticultural systems. Potassium nitrate was taken up by leaves of  
19 deciduous fruit trees (Weinbaum and Neumann, 1977) and resulted in increased foliar nitrogen  
20 concentrations. Not all forms of nitrogen are absorbed equally, nor are all equally benign.  
21 Following foliar application of 2600 ppm of nitrogen as  $\text{Ca}(\text{NO}_3)_2$ ,  $(\text{NH}_4)_2\text{SO}_4$ , or  $(\text{NH}_2)_2\text{CO}$  to  
22 apple canopies (Rodney, 1952; Norton and Childers, 1954), leaf nitrogen levels were observed to  
23 increase to similar levels; but calcium nitrate and ammonium sulfate caused visible foliar injury;  
24 whereas urea did not. Urea is generally the recommended horticultural foliar fertilizer.

25 The mechanism of uptake of foliarly deposited nitrate is not well established. Nitrate  
26 reductase is generally a root-localized enzyme: it is generally not present in leaves, but is  
27 inducible there. Induction typically occurs when the soil is heavily enriched in  $\text{NO}_3^-$ . As the  
28 root complement of nitrate reductase becomes overloaded, unreduced nitrate reaches the leaves  
29 through the transpiration stream. Nitrate metabolism has been demonstrated in leaf tissue  
30 (Weinbaum and Neumann, 1977) following foliar fertilization. Residual nitrate reductase  
31 activity in leaves may be adequate to assimilate typical rates of particulate nitrate deposition.

1 Uptake of nitrate may be facilitated by codeposited sulfur (Karmoker et al., 1991; Turner and  
2 Lambert, 1980).

3 Nitrate reductase is feedback-inhibited by its reaction product  $\text{NH}_4^+$ . The common  
4 atmospheric aerosol,  $\text{NH}_4\text{NO}_3$ , therefore may be metabolized in two distinct biochemical steps:  
5 first the ammonium (probably leaving nitric acid) and then the nitrate. Losses of nitric acid by  
6 volatilization during this process, if they occur, have not been quantified.

7 Direct foliar effects of particulate nitrogen have not been documented. Application of a  
8 variety of fine nitrogenous aerosol particles ( $0.25\ \mu\text{m}$ ) ranging from  $109$  to  $244\ \mu\text{g}/\text{m}^3$  nitrogen  
9 with or without  $637\ \mu\text{g}/\text{m}^3$  sulfur caused no consistent short-term (2- to 5-h) effect on gas  
10 exchange in oak, maize, or soybean leaves (Martin et al., 1992).

11 Although no evidence exists for the direct transfer of nutrient particulate aerosols into  
12 foliage, a few studies give insights into the potential for ammonium and nitrate transfer into  
13 leaves. Fluxes of both  $\text{NO}_3^-$  and  $\text{NH}_4^+$ , measured in wet deposition and in throughfall plus  
14 stemflow in forests, commonly indicate higher fluxes of nitrogen above the canopy (Parker,  
15 1983; Lindberg et al., 1987; Sievering et al., 1996), and imply net foliar uptake. Lovett and  
16 Lindberg (1993) reported a linear relationship between inorganic nitrogen fluxes in deposition  
17 and throughfall, suggesting that uptake may be considered passive to some extent.

18 Garten and Hanson (1990) studied the movement of  $^{15}\text{N}$ -labeled nitrate and ammonium  
19 across the cuticles of red maple (*Acer rubrum*) and white oak (*Quercus alba*) leaves when  
20 applied as an artificial rain mixture. Brumme et al. (1992), Bowden et al. (1989), and Vose and  
21 Swank (1990) have published similar data for conifers. These studies show the potential for  
22 nitrate and ammonium to move into leaves, where it may contribute to normal physiological  
23 processes (e.g., amino acid production; Wellburn, 1990). Garten (1988) showed that internally  
24 translocated  $^{35}\text{S}$  was not leached readily from tree leaves of yellow poplar (*Liriodendron*  
25 *tulipifera*) and red maple (*Acer rubrum*), suggesting that  $\text{SO}_4^{2-}$  would not be as mobile as the  
26 nitrogen-containing ions discussed by Garten and Hanson (1990). Further, when the foliar  
27 extraction method is used, it is not possible to distinguish sources of chemicals deposited as  
28 gases or particles (e.g., nitric acid [ $\text{HNO}_3$ ], nitrogen dioxides [ $\text{NO}_2$ ], nitrate [ $\text{NO}_3^-$ ]), or sources of  
29 ammonium (deposited as ammonia [ $\text{NH}_3$ ] or ammonium ion [ $\text{NH}_4^+$ ]; Garten and Hanson, 1990).

30 Particle deposition contributes only a portion of the total atmospheric nitrogen deposition  
31 reaching vegetation; but, when combined with gaseous and precipitation-derived sources, total

1 nitrogen deposition to ecosystems has been identified as a possible causal factor leading to  
2 changes in natural ecosystems (See Section 4.2.2).

3  
4 **Sulfur.** Anthropogenic sulfur emissions are > 90% SO<sub>2</sub>. Most of the remaining emission  
5 of sulfur is directly as sulfate (U.S. Environmental Protection Agency, 1996a). Sulfur dioxide is  
6 hydrophilic and is rapidly hydrated and oxidized to sulfite and bisulfite and then to sulfate,  
7 which is approximately 30-fold less phytotoxic. The ratio of SO<sub>4</sub><sup>-2</sup>/SO<sub>2</sub> increases with aging of  
8 the air mass and, therefore, with distance from the source. Sulfate is sufficiently hygroscopic in  
9 humid air that it may exist significantly in the coarse particulate fraction. Because dilution of  
10 both SO<sub>2</sub> and particulate SO<sub>4</sub><sup>-2</sup> occurs with distance from the source, it is unusual for damaging  
11 levels of particulate sulfate to be deposited. Gas to particle conversion in this case is of benefit  
12 to vegetation.

13 Sulfur is an essential plant nutrient. Low dosages of sulfur serve as a fertilizer, particularly  
14 for plants growing in sulfur-deficient soil (Hogan et al., 1998). However, current levels of  
15 sulfate deposition reportedly exceed the capacity of most vegetative canopies to immobilize the  
16 sulfur (Johnson, 1984). Nitrogen uptake in forests may be regulated loosely by sulfur  
17 availability, but sulfate additions in excess of needs do not typically lead to injury unless  
18 deposited in acidic precipitation (Turner and Lambert, 1980).

19 There are few field demonstrations of foliar sulfate uptake (Krupa and Legge, 1986, 1998).  
20 Sulfate in throughfall is often enriched above levels in precipitation. The relative importance of  
21 foliar leachate and prior dry-deposited sulfate particles remains difficult to quantify (Cape et al.,  
22 1992). Leaching rates are not constant and may respond to levels of other pollutants, including  
23 acids. Uptake and foliar retention of gaseous and particulate sulfur are confounded by variable  
24 rates of translocation and accessibility of deposited materials to removal and quantification by  
25 leaf washing. Following soil enrichment with <sup>35</sup>SO<sub>4</sub><sup>-2</sup> in a Scots pine forest, the apparent  
26 contribution of leachate to throughfall was only a few percent following an initial burst of over  
27 90% because of extreme disequilibrium in labeling of tissue sulfate pools (Cape et al., 1992).

28 Olszyk et al. (1989) provide information on the effects of multiple pollutant exposures  
29 including particles (NO<sub>3</sub><sup>-</sup>, 142 µg/m<sup>3</sup>; NH<sub>4</sub><sup>+</sup>, 101 µg/m<sup>3</sup>; SO<sub>4</sub><sup>-2</sup>, 107 µg/m<sup>3</sup>). They found that only  
30 gaseous pollutants produced direct (harmful) effects on vegetation for the concentrations  
31 documented, but the authors hypothesized that long-term accumulation of the nitrogen and sulfur

1 compounds contributed from particle deposition might have effects on plant nutrition over long  
2 periods of time. Martin et al. (1992) exposed oak (*Quercus macrocarpa*), soybean (*Glycine*  
3 *max*), and maize (*Zea mays*) plants to acute exposures (2 to 5 h) of aerosols (0.25  $\mu\text{m}$ ) containing  
4 only nitrate (109  $\mu\text{g}/\text{m}^3$ ), ammonium and nitrate (244 and 199  $\mu\text{g}/\text{m}^3$ ), or ammonium and sulfate  
5 (179 and 637  $\mu\text{g}/\text{m}^3$ ). They found that these exposures, which exceeded the range of naturally  
6 occurring aerosol concentrations, had little effect on foliar photosynthesis and conductance.  
7 Martin et al. (1992) concluded that future investigations should focus on the effects of particles  
8 on physiological characteristics of plants following chronic exposures.

9 ***Acidic Deposition.*** The effects of acidic deposition have been accorded wide attention in  
10 the media and elsewhere (Altshuller and Linthurst, 1984; Hogan et al., 1998). Probably the most  
11 extensive assessment of acidic deposition processes and effects is the NAPAP Biennial Report to  
12 Congress: An Integrated Assessment (National Science and Technology Council, 1998).  
13 Concern regarding the effects of acidic deposition on crops and forest trees has resulted in  
14 extensive monitoring and research. Exposures to acidic rain or clouds can be divided into  
15 “acute” exposures to higher ionic concentrations (several  $\mu\text{mol}/\text{L}$ ) and “chronic” long-term  
16 repeated exposures to lower concentrations (Cape, 1993). Pollutant concentrations in rainfall  
17 have been shown to have little capacity for producing direct effects on vegetation (Altshuller and  
18 Linthurst, 1984; Hogan et al., 1998); however, fog and clouds, which may contain solute  
19 concentrations up to 10 times those found in rain, have the potential to cause direct effects.  
20 More than 80% of the ionic composition of most cloud water is made up of four major pollutant  
21 ions:  $\text{H}^+$ ,  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and  $\text{SO}_4^{2-}$ . Ratios of hydrogen to ammonium and sulfate to nitrate vary  
22 from site to site with all four ions usually present in approximately equal concentrations.  
23 Available data from plant effect studies suggest that hydrogen and sulfate ions are more likely to  
24 cause injury than ions containing nitrogen (Cape, 1993).

25 The possible direct effects of acidic precipitation on forest trees have been evaluated by  
26 experiments on seedlings and young trees. The size of mature trees makes experimental  
27 exposure difficult, therefore necessitating extrapolations from experiments on seedlings and  
28 saplings; however, such extrapolations must be used with caution (Cape, 1993). Both conifers  
29 and deciduous species have shown significant effects on leaf surface structures after exposure to  
30 simulated acid rain or acid mist at pH 3.5. Some species have shown subtle effects at pH 4 and  
31 above. Visible lesions have been observed on many species at pH 3 and on sensitive species at

1 pH 3.5 (Cape, 1993). The relative sensitivities of forest vegetation to acidic precipitation based  
2 on macroscopic injury have been ranked as follows: herbaceous dicots > woody dicots >  
3 monocots > conifers (Percy, 1991).

4 Huttunen (1994) described the direct effects of acid rain or acidic mist on epicuticular  
5 waxes whose ultrastructure is affected by plant genotype and phenotype. The effects of air  
6 pollutants on epicuticular waxes of conifers have received greater study than the waxes of other  
7 species. Leaf age and the shorter life span of broad-leaved trees make them less indicative of the  
8 effects of acid precipitation. Many experimental studies indicate that epicuticular waxes that  
9 function to prevent water loss from plant leaves can be destroyed by acid rain in a few weeks  
10 (Huttunen, 1994). This function is crucial in conifers because of their longevity and evergreen  
11 foliage. Microscopic observations of epicuticular wax structures have, for a long time,  
12 suggested links between acidic deposition and aging. In Norway spruce (*Picea abies*), acid rain  
13 causes not only the aging of needles (which in northern conditions normally last from  
14 11 to 14 years) to be shortened, but also accelerates the erosion rate of the waxes as the needles  
15 age.

16 The effects of acidic precipitation and fog on red spruce (*Picea rubens*) have been studied  
17 extensively (Schier and Jensen, 1992). Visible foliar injury of the needles in the form of a  
18 reddish-brown discoloration has been observed on red spruce seedlings experimentally exposed  
19 to acidic mist, but this visible symptom has not been observed in the field. Ultrastructural  
20 changes in the epicuticular wax were observed both experimentally and on spruce growing at  
21 high elevations. Laboratory studies indicate that visible injury usually does not occur unless the  
22 pH is 3 or less (Schier and Jensen, 1992). Cape (1993) reported that, when compared with other  
23 species, red spruce seedlings appeared to be more sensitive to acid mist. From studies of  
24 conifers and a review of the literature, Huttunen (1994) concluded that acidic precipitation  
25 causes direct injury to tree foliage and indirect effects through the soil. The indirect effects of  
26 acidic precipitation are discussed in Section 4.2.3.2.

27 Based on a review of the many studies in the literature involving field and controlled  
28 laboratory experiments on crops, Cape (1993) drew a number of conclusions concerning the  
29 direct effects of acidic precipitation on crops:

- 30 • foliar injury and growth reduction occur below pH 3;
- 31 • allocation of photosynthate is altered, with increased shoot to root ratios;

- 1 • expanded and recently expanded leaves are most susceptible, and injury occurs first to epidermal cells;
- 2 • leaf surface characteristics such as wettability, buffering capacity, and transport of material across the leaf surface contribute to susceptibility and differ among species;
- 3 • data obtained from experiments in greenhouses or controlled environmental chambers cannot be used to predict effects on plants grown in the field;
- 4 • quantitative data from experimental exposures cannot be extrapolated to field exposures because of differences and fluctuations in concentrations, durations, and frequency of exposure;
- 5 • there are large differences in response within species;
- 6 • timing of exposure in relation to phenology is of utmost importance;
- 7 • plants may be able to recover from or adapt to injurious exposures; and
- 8 • sequential exposure to acidic precipitation and gaseous pollutants is unlikely to be more injurious than exposure to individual pollutants.

9       Studies by Chevone et al. (1986), Krupa and Legge (1986), and Blaschke (1990) differ  
10 with the last conclusion of Cape listed above. Their studies indicate that interactions between  
11 acidic deposition and gaseous pollutants do occur. Acidity affects plant responses to both O<sub>3</sub> and  
12 SO<sub>2</sub>. Chevone et al. (1986) observed increased visible injury on soybean and pinto bean when  
13 acid aerosol exposure preceded O<sub>3</sub> exposure; whereas linear decreases in dry root weight of  
14 yellow poplar occurred as acidity increased with simultaneous exposures to O<sub>3</sub> and simulated  
15 acid rain. Krupa and Legge (1986) also noted increased visible injury to pinto bean plants when  
16 aerosol exposure preceded O<sub>3</sub> exposure. In none of the studies cited above did acid rain per se  
17 produce significant growth changes. In contrast, Blaschke (1990) observed a decrease in  
18 ectomycorrhizal frequency and short root distribution caused by acid rain exposure in  
19 combination with either SO<sub>2</sub> or O<sub>3</sub>.

20  
21       ***Trace Elements.*** All but 10 of the 90 elements that comprise the inorganic fraction of the  
22 soil occur at concentrations of less than 0.1% (1000 µg/g) and are termed “trace” elements.  
23 Trace elements with a density greater than 6 g cm<sup>-3</sup>, referred to as “heavy metals,” are of  
24 particular interest because of their potential toxicity for plant and animals. Although some trace

1 metals are essential for vegetative growth or animal health, they are all toxic in large quantities.  
2 Combustion processes produce metal chlorides that tend to be volatile and metal oxides that tend  
3 to be nonvolatile in the vapor phase (McGowan et al., 1993). Most trace elements exist in the  
4 atmosphere in particulate form as metal oxides (Ormrod, 1984). Aerosols containing trace  
5 elements derive predominantly from industrial activities (Ormrod, 1984). Generally, only the  
6 heavy metals cadmium, chromium, nickel, and mercury are released from stacks in the vapor  
7 phase (McGowan et al., 1993). Concentrations of heavy metals in incinerator fly ash increase  
8 with decreasing particle size.

9 Vegetational surfaces, especially the foliage, present a major reaction and filtration surface  
10 to the atmosphere and act to accumulate particles deposited via wet and dry processes described  
11 in Section 4.2.2 (Tong, 1991; Youngs et al., 1993). The chemical constituents of particles  
12 deposited on foliar surfaces may be taken up through the leaf surface. The greatest particle  
13 loading is usually on the adaxial (upper) leaf surface where particles accumulate in the mid-vein,  
14 center portion of the leaves. Additionally, the mycelium of fungi becomes particularly abundant  
15 on leaf surfaces as the growing season progresses and is in intimate association with deposited  
16 particles (Smith, 1990c).

17 Investigations of trace elements present along roadsides and in industrial and urban  
18 environments indicate that impressive burdens of particulate heavy metals can accumulate on  
19 vegetative surfaces. Foliar uptake of available metals could result in metabolic effects in above-  
20 ground tissues. Only a few metals, however, have been documented to cause direct  
21 phytotoxicity in field conditions. Copper, zinc, and nickel toxicities have been observed most  
22 frequently. Low solubility, however, limits foliar uptake and direct heavy metal toxicity  
23 because trace metals must be brought into solution before they can enter into leaves or bark of  
24 vascular plants. In those instances when trace metals are absorbed, they are frequently bound in  
25 leaf tissue and are lost when the leaf drops off (Hughes, 1981). Trace metals in mixtures may  
26 interact to cause a different plant response when compared with a single element; however, there  
27 has been little research on this aspect (Ormrod, 1984). In experiments using chambers,  
28 Marchwinska and Kucharski (1987) studied the effects of SO<sub>2</sub> alone and in combination with  
29 PM components (Pb, Cd, Zn, Fe, Cu, and Mn) obtained from a zinc smelter bag filter. The  
30 combined effects of SO<sub>2</sub> and PM further increased the reduction in yield of beans caused by SO<sub>2</sub>;

1 whereas the combination, though severely injuring the foliage, produced little effect on carrots  
2 and parsley roots except after long-term exposures (when there was a decrease in root weight).

3 Trace metal toxicity of lichens has been demonstrated in relatively few cases. Nash (1975)  
4 documented zinc toxicity in the vicinity of a zinc smelter near Palmerton, PA. Lichen species  
5 richness and abundance were reduced by approximately 90% in lichen communities at Lehigh  
6 Water Gap near the zinc smelter when compared with those at Delaware Water Gap. Zinc,  
7 cadmium, and SO<sub>2</sub> were present in concentrations toxic to some species near the smelter;  
8 however, toxic zinc concentrations were detected farther away than the detectable limits of SO<sub>2</sub>  
9 (Nash, 1975). Experimental data suggest that lichen tolerance to Zn and Cd falls between  
10 200 and 600 ppm (Nash, 1975).

11 Though there has been no direct evidence of a physiological association between tree  
12 injury and exposure to metals, heavy metals have been implicated because their deposition  
13 pattern is correlated with forest decline. The role of heavy metals has been indicated by  
14 phytochelatin measurements. Phytochelatins are intracellular metal-binding peptides that act as  
15 specific indicators of metal stress. Because they are produced by plants as a response to  
16 sublethal concentrations of heavy metals, they can indicate that heavy metals play a role in forest  
17 decline (Gawel et al., 1996). Concentrations of heavy metals increased with altitude, as did  
18 forest decline, and increased concentrations across the study region that show increased levels of  
19 forest injury, as well.

20 Phytochelatin concentrations were measured in red spruce and balsam fir (*Abies balsamea*)  
21 needles throughout the 1993 growing season at 1000 m on Whiteface Mountain in New York.  
22 Mean foliar concentrations in red spruce were consistently higher than in balsam fir from June  
23 until August, with the greatest and most significant difference occurring at the peak of the  
24 growing season in mid-July. In July, the phytochelatin concentrations were significantly higher  
25 than at any other time measured. Balsam fir did exhibit this peak, but maintained a consistently  
26 low level throughout the season. Both the number of dead red spruce trees and phytochelatin  
27 concentrations increased sharply with elevation (Gawel et al., 1996). The relationship between  
28 heavy metals and the decline of forests in northeastern United States was further tested by  
29 sampling red spruce stands showing varying degrees of decline at 1000 m on nine mountains  
30 spanning New Hampshire, Vermont, and New York. The collected samples indicated a  
31 systematic and significant increase in phytochelatin concentrations associated with the extent of

1 tree injury. The highest phytochelatin concentrations were measured during 1994 from sites  
2 most severely affected by forest decline in the Green Mountains, VT, and the Adirondack  
3 Mountains, NY. These data strongly imply that metal stress causes tree injury and contributes to  
4 forest decline in the northeastern United States (Gawel et al., 1996).

5 One potential direct effect of heavy metals is on the activity of microorganisms and  
6 arthropods resident on and in the leaf surface ecosystem. The fungi and bacteria living on and in  
7 the surfaces of leaves play an important role in the microbial succession that prepares leaves for  
8 decay and litter decomposition after their fall (U.S. Environmental Protection Agency, 1996b).  
9 Numerous fungi were consistently isolated from foliar surfaces at various crown positions from  
10 London plane trees growing in roadside environments in New Haven, CT. Those existing  
11 primarily as saprophytes included *Aureobasidium pullulans*, *Chaetomium sp.*, *Cladosporium sp.*,  
12 *Epicoccum sp.*, and *Philaphora verrucosa*. Those existing primarily as parasites included  
13 *Gnomonia platani*, *Pestalotiopsis sp.*, and *Pleurophomella sp.* The following cations were  
14 tested in vitro for their ability to influence the growth of these fungi: cadmium, copper,  
15 manganese, aluminum, chromium, nickel, iron, lead, sodium, and zinc. Results indicated  
16 variable fungal response with no correlation between saprophytic or parasitic activity and  
17 sensitivity to heavy metals. Both linear extension and dry weight data indicated that the  
18 saprophytic *Chaetomium sp.* was very sensitive to numerous metals. *Aureobasidium pullulans*,  
19 *Epicoccum sp.*, and especially *P. verrucosa*, on the other hand, appeared to be much more  
20 tolerant. Of the parasites, *G. platani* appeared to be more tolerant than *Pestalotiopsis sp.* and  
21 *Pleurophomella sp.* Metals exhibiting the broadest spectrum growth suppression were iron,  
22 aluminum, nickel, zinc, manganese, and lead (Smith and Staskawicz, 1977; Smith, 1990c).  
23 These in vitro studies employed soluble compounds containing heavy metals. Trace metals  
24 probably occur naturally on leaf surfaces as low-solubility oxides, halides, sulfates, sulfides, or  
25 phosphates (Clevenger et al., 1991; Koslow et al., 1977). In the event of sufficient solubility and  
26 dose, however, changes in microbial community structure on leaf surfaces because of heavy  
27 metal accumulation are possible.

28  
29 **Organic Compounds.** Volatile organic compounds in the atmosphere are partitioned  
30 between the gas and particle phases, depending on the liquid phase vapor pressure at the ambient  
31 atmospheric temperature, the surface area of the particles per unit volume of air, the nature of the

1 particles and of the chemical being adsorbed; and they can be removed by wet and dry  
2 deposition (McLachlan, 1996a). Materials as diverse as DDT, polychlorinated biphenyls  
3 (PCBs), and polynuclear aromatic hydrocarbons (PAHs) are being deposited from the  
4 atmosphere on rural as well as urban landscapes (Kylin et al., 1994). Motor vehicles emit  
5 particles to the atmosphere from several sources in addition to the tailpipe. Rogge et al. (1993b)  
6 inventoried the organic contaminants associated with fine particles (diameter  $\leq 2.0 \mu\text{m}$ ) in road  
7 dust, brake-lining-wear particles, and tire tread debris. More than 100 organic compounds were  
8 identified in these samples, including n-alkanols, benzoic acids, benzaldehydes, polyalkylene  
9 glycol ethers, PAHs, oxy-PAH, steranes, hopanes, natural resins, and other compound classes.  
10 A large number of PAHs, ranging from naphthalene ( $\text{C}_{10}\text{H}_8$ ) to 5- and 6-ring and higher PAHs,  
11 their alkyl-substituted analogues, and their oxygen- and nitrogen-containing derivatives are  
12 emitted from motor vehicle sources (Seinfeld, 1989).

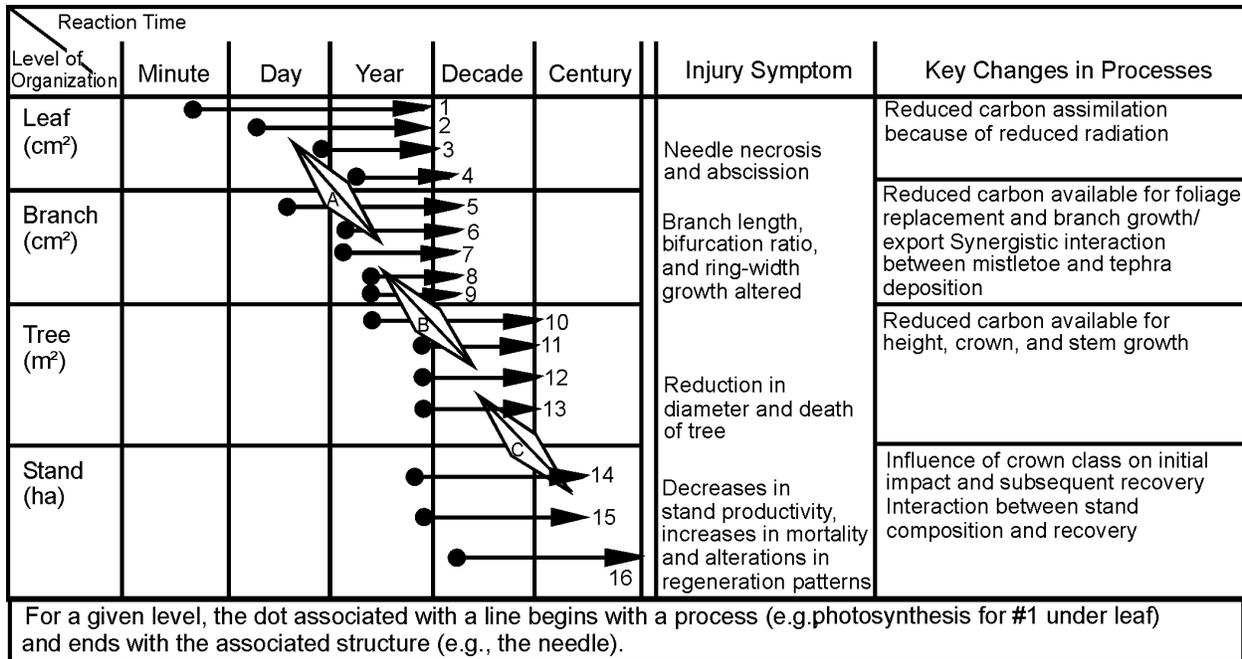

13 Plants may be used as environmental monitors to compare the deposition of PAH,  
14 persistent organic pollutants (POPs), or semivolatile organic components (SOCs) between sites  
15 (e.g., urban versus rural; Wagrowski and Hites, 1997; Ockenden et al., 1998; McLachlan, 1999).  
16 Vegetation can be used qualitatively to indicate organic pollutant levels as long as the  
17 mechanism of accumulation is considered. The substance may enter the plant via the roots or, as  
18 mentioned above, be deposited as a particle onto the waxy cuticle of leaves or be taken up  
19 through the stomata. The pathways are a function of the chemical and physical properties of the  
20 pollutant such as its lipophilicity, water solubility, vapor pressure (which controls the  
21 vapro-particle partitioning) and Henry's law constant; environmental conditions such as ambient  
22 temperature and the organic content of the soil; and the plant species, which controls the surface  
23 area and lipids available for accumulation (Simonich and Hites, 1995). Ockenden et al. (1998)  
24 have observed that, for lipophilic POPs, atmospheric transfer to plant has been the main avenue  
25 of accumulation. Plants can differentially accumulate POPs. Results have shown differences  
26 between species with higher concentrations in the lichen (*Hypogymnia physiodes*) than in Scots  
27 pine needles (*Pinus sylvestris*). Even plants of the same species, because they have different  
28 growth rates and different lipid contents (depending on the habitat in which they are growing),  
29 have different rates of sequestering pollutants. These facts confound data interpretations and  
30 must be taken into account when considering their use as passive samplers.

1 Vegetation itself is an important source of hydrocarbon aerosols. Terpenes, particularly  
2  $\alpha$ -pinene,  $\beta$ -pinene, and limonene, released from tree foliage may react in the atmosphere to  
3 form submicron particles. These naturally generated organic particles contribute significantly to  
4 the blue haze aerosols formed naturally over forested areas (Geron et al., 2000).

5 The low water solubility with high lipoaffinity of many of these organic xenobiotics  
6 strongly control their interaction with the vegetative components of natural ecosystems. The  
7 cuticles of foliar surfaces are covered with a wax layer that helps protect plants from moisture  
8 and short-wave radiation stress. This epicuticular wax, consisting mainly of long-chain esters,  
9 polyesters, and paraffins, has been demonstrated to accumulate lipophilic compounds. Organic  
10 air contaminants in the particulate or vapor phase are absorbed to and accumulate in the  
11 epicuticular wax of vegetative surfaces (Gaggi et al., 1985; Kylin et al., 1994). Direct uptake of  
12 organic contaminants through the cuticle or the vapor-phase uptake through the stomates are  
13 characterized poorly for most trace organics. The phytotoxicity and toxicity of organic  
14 contaminants to soil microorganisms is not well studied (Foster, 1991).

#### 15 16 **4.2.3.2 Ecosystem Response to Stresses**

17 Ecosystem response to stress begins within the Biotic Condition Attribute at the population  
18 level with changes in patterns resulting from the response of sensitive individual plants or  
19 animals. Ecosystem response to pollutant deposition is a direct function of the ecosystem's  
20 ability to ameliorate resulting change (Strickland et al., 1993). Plant responses, changes in both  
21 structural and compositional patterns, and functional ecological processes must be scaled in both  
22 time and space and be propagated from the individual to the more complex levels of community  
23 interaction to produce observable changes in an ecosystem (see Figure 4-14). Among ecosystem  
24 biota, at least three levels of biological interaction are involved: (1) the individual plant and its  
25 environment; (2) the population and its environment; and (3) the biological community  
26 composed of many species and its environment (Billings, 1978). Individual organisms within a  
27 population vary in their ability to withstand the stress of environmental change. The response of  
28 individual organisms within a population is based on their genetic constitution (genotype), stage  
29 of growth at time of exposure to stress, and the microhabitat in which they are growing (Levin,  
30 1998). The range within which these organisms can exist and function determines the ability of  
31 the population to survive. Those able to cope with the stresses survive and reproduce.

Evaluating Impacts Within a Level of Organization			
Leaf Level	Carbon exchange-1 Carbon pools-2 Needle number and size-3 Needle retention/abscission-4	Tree Level	Height and diameter growth-10 Crown shape and size-11 Tree vigor-12 Mortality-13
Branch Level	Carbon allocation-5 Branch growth-6 Branch morphology-7 Branch vigor-8 Branch retention-9	Stand Level	Productivity-14 Mortality-15 Species composition-16

Evaluating Interactions Between Different Levels of Organization	
	<p>The diagonal arrow indicates the interaction between any two levels of organization. The types of interaction are due to the properties of variability and compensation.</p> <p>A - Refers to the interaction between the leaf and branch levels, where, for example, variability at the branch level determines leaf quantity, and compensation at the leaf level in photosynthesis may compensate for the reduction in foliage amount.</p> <p>B - Refers to the interaction between the branch and the tree, where variability in branches determines initial interception, branch vigor, and branch location in the crown; compensation may be related to increased radiation reaching lower branches.</p> <p>C - Refers to the interaction between the tree and the stand. Both genetic and environmental variability, inter- and intraspecific compensations, and tree historical and competitive synergisms are involved.</p>

**Figure 4-14. Effects of environmental stress on forest trees are presented on a hierarchical scale for the leaf, branch, tree, and stand levels of organization. The evaluation of effects within a level of organization are indicated by horizontal arrows. The evaluation of interactions between different levels of organization are indicated by diagonal arrows.**

Source: Hinckley et al. (1992).

1 Competition among the different species results in succession (community change over time)  
2 and, ultimately, produces ecosystems composed of populations of plant species that have the  
3 capability to tolerate the stresses (Rapport and Whitford, 1999; Guderian, 1985).

4 The number of species in a community usually increases during succession in unpolluted  
5 atmospheres. Productivity, biomass, community height, and structural complexity increase.  
6 Severe stresses, on the other hand, divert energy from growth and reproduction to maintenance  
7 and return succession to an earlier stage (Waring and Schlesinger, 1985). Ecosystems are  
8 subject to natural periodic stresses, such as drought, flooding, fire, and attacks by biotic  
9 pathogens (e.g., fungi, insects). Extremely severe natural perturbations return succession to an  
10 earlier stage; reduce ecosystem structure and functions (i.e., produce a scarcity of life forms and  
11 extinguish symbiotic interactions); disrupt the plant processes of photosynthesis and nutrient  
12 uptake, carbon allocation, and transformation that are directly related to energy flow and nutrient  
13 cycling; shorten food chains; and reduce the total nutrient inventory (Odum, 1993). This  
14 transformation, however, sets the stage for recovery that permits the perturbed ecosystem to  
15 adapt to changing environments (Holling, 1986). Therefore, these perturbations are seldom  
16 more than a temporary setback, and recovery can be rapid (Odum, 1969).

17 In contrast, anthropogenic stresses usually are severe, debilitating stresses. Severely  
18 stressed ecosystems do not recover readily, but may be further degraded (Odum, 1969; Rapport  
19 and Whitford, 1999). Anthropogenic stresses can be classified into four main groups:  
20 (1) physical restructuring (e.g., changes resulting from land use); (2) introduction of exotic  
21 species; (3) over harvesting; and (4) discharge of toxic substances into the atmosphere, onto  
22 land, and into water. Ecosystems usually lack the capacity to adapt to the above stresses and  
23 maintain their normal structure and functions unless the stress is removed (Rapport and  
24 Whitford, 1999). These stresses result in a process of degradation marked by a decrease in  
25 biodiversity, reduced primary and secondary production, and a lower capacity to recover and  
26 return to its original state. In addition, there is an increased prevalence of disease, reduced  
27 nutrient cycling, increased dominance of exotic species, and increased dominance by smaller,  
28 short-lived opportunistic species (Odum, 1985; Rapport and Whitford, 1999). Discharge of toxic  
29 substances into the atmosphere, onto land, and into water can cause acute and chronic stresses;  
30 and, once the stress is removed, a process of succession begins that can ultimately return the  
31 ecosystem to a semblance of its former structure. Air pollution stresses, if acute, are usually

1 short-term and the effects soon visible. Chronic stresses, on the other hand, are long-term  
2 stresses whose effects occur at different levels of ecosystem organization and appear only after  
3 long-term exposures, as in the case of acidic deposition in the northeast or ozone in California  
4 (Shortle and Bondiotti, 1992; U.S. Environmental Protection Agency, 1996b).

5 The possible effects of air pollutants on ecosystems have been categorized by Guderian  
6 (1977) as follows:

- 7 (1) accumulation of pollutants in the plant and other ecosystem components (such as soil  
and surface- and groundwater),
- 8 (2) damage to consumers as a result of pollutant accumulation,
- 9 (3) changes in species diversity because of shifts in competition,
- 10 (4) disruption of biogeochemical cycles,
- 11 (5) disruption of stability and reduction in the ability of self-regulation,
- 12 (6) breakdown of stands and associations, and
- 13 (7) expansion of denuded zones.

14 How changes in these functions can result from PM deposition and influence ecosystems is  
15 discussed in the following text. It should be remembered that, although the effects of PM are  
16 being emphasized, the vegetational components of ecosystems also are responding to multiple  
17 stresses from multiple sources.

### 18 19 **Response to Direct Effects of PM**

20 In the previous section, it was noted that PM affects patterns in the EEA Biotic Condition  
21 and processes in the Chemical/Physical and Ecological Processes categories. The presence of  
22 PM in the atmosphere may affect vegetation directly, following physical contact with the foliar  
23 surface (Section 4.2), but in most cases, the more significant effects are indirect. These effects  
24 may be mediated by suspended PM (i.e., through effects on radiation and climate) and by  
25 particles that pass through the vegetative canopies to the soil.

26 The majority of studies dealing with direct effects of particulate dust and trace metals on  
27 vegetation have focused on responses of individual plant species and were conducted in the  
28 laboratory or in controlled environments (Saunders and Godzik, 1986). A few have considered  
29 the effects of particles on populations, communities, and ecosystems. Most of these focused on

1 ecosystems in industrialized areas heavily polluted by deposits of both chemically inert and  
2 active dusts. Effects can result from direct deposition or indirectly by deposition onto the soil.  
3 Reductions in growth, yield, flowering, and reproductive processes of plants from particulate  
4 deposition have been reported (Saunders and Godzik, 1986). Sensitivities of individual species  
5 have been associated with changes in composition and structural patterns of natural ecosystems.

6 Evidence from studies of effects of PM deposition, specifically chemically inert and active  
7 dusts indicates that, within a population, plants exhibit a wide range of sensitivity, which is the  
8 basis for the natural selection of tolerant individuals. Rapid evolution of certain populations of  
9 tolerant species at sites with heavy trace element and nitrate deposition has been observed  
10 (Saunders and Godzik, 1986). Tolerant individuals present in low frequencies in populations  
11 when growing in unpolluted areas have been selected for tolerance at both the seedling and adult  
12 stages when exposed to trace metal or nitrate deposition (Ormrod, 1984; U.S. Environmental  
13 Protection Agency, 1993). Chronic pollutant injury to a forest community may result in the loss  
14 of sensitive species, loss of tree canopy, and maintenance of a residual cover of pollutant-  
15 tolerant herbs or shrubs that are recognized as successional species (Table 4-13; Smith, 1974).  
16 These changes in forest patterns result from altered ecological processes.

17 Responses of ecosystems to stresses (unless severe or catastrophic) are difficult to  
18 determine because the changes are subtle (Garner, 1991). This is particularly true of responses  
19 to particles. Changes in the soil may not be observed until accumulation of the pollutant has  
20 occurred for 10 or more years, except in the severely polluted areas around heavily industrialized  
21 point sources (Saunders and Godzik, 1986). In addition, the presence of other co-occurring  
22 pollutants makes it difficult to attribute the effects to PM alone. In other words, the potential for  
23 alteration of ecosystem function and structure exists but is difficult to quantify, especially when  
24 there are other pollutants present in the ambient air that may produce additive or synergistic  
25 responses even though PM concentrations may not be elevated.

### 26 27 ***Physical Effects***

28 The direct effects of limestone dust on plants and ecosystems has been known for many  
29 years. Changes have been observed in both ecosystem patterns and processes. Long-term  
30 changes in the structure and composition of the seedling-shrub and sapling strata of an  
31 experimental site near limestone quarries and processing plants in Giles County in southwestern

**TABLE 4-13. ECOSYSTEM FUNCTIONS IMPACTED BY AIR POLLUTION  
EFFECTS ON TEMPERATE FOREST ECOSYSTEMS**

Forest Soil and Vegetation: Activity and Response	Ecosystem Consequence and Impact
(1) Forest tree reproduction, alteration, or inhibition	(1) Altered species composition

Microbial pathogens, increased or decreased activity</li> <li>c. Foliar damage increased by direct air pollution influence</li> </ul>	(4) Altered ecosystem stress: increased or decreased insect infestations; increased or decreased disease epidemics; and reduced growth, less biomass, and altered species composition

Source: Smith (1974).

1 Virginia were reported by Brandt and Rhoades (1972, 1973). Dominant trees in the control area,  
 2 a part of the oak-chestnut association of the eastern deciduous forests of eastern North America,  
 3 were chestnut oak (*Quercus prinus*), red oak (*Q. rubra*), and red maple (*Acer rubrum*). An  
 4 abundance of uniformly distributed saplings and seedlings were visible under the tree canopy,  
 5 and herbs appeared in localized areas in canopy openings. Chestnut oak dominated the area, and  
 6 the larger trees were 60 to 80 years old. The dusty site was dominated by white oak (*Q. alba*);  
 7 whereas red oak and tulip poplar (*Liriodendron tulipifera*) were subcodominants. The largest  
 8 trees were 100 years old and had necrotic leaves, peeling bark, and appeared to be in generally  
 9 poor condition except for tulip poplar (which thrived in localized areas). The site contained a  
 10 tangled growth of seedlings and shrubs, a few saplings, and a prevalence of green briar (*Smilax*  
 11 *spp.*) and grape (*Vitis spp.*). The sapling strata in the area was represented by red maple, hickory  
 12 (*Carya spp.*), dogwood (*Cornus florida*), and hop-hornbeam (*Ostrya virginiana*). Saplings of  
 13 none of the leading dominant trees were of importance in this stratum. The most obvious form

1 of vegetation in the seedling-shrub stratum, because of their tangled appearance, were dogwood,  
2 hop-hornbeam, redbud (*Cercis canadensis*), and sugar maple (*Acer saccharum*).

3 Crust formation reduced photosynthesis, induced premature leaf fall and destruction of leaf  
4 tissues, inhibited growth of new tissue, and reduced the formation of carbohydrate needed for  
5 normal growth and storage (Brandt and Rhoades, 1973). The authors (Brandt and Rhoades,  
6 1972), citing Odum (1969), also stated that one result of the accumulation of toxic pollutants in  
7 the biosphere (as the result of human activities) is the simplification of both plant and animal  
8 communities. In plant communities, structure is determined by sampling various strata within  
9 the community. Each stratum comprises a particular life form (e.g., herbs, seedlings, saplings,  
10 trees). Dust accumulation favored growth of some species and limited others. For example,  
11 sugar maple was more abundant in all strata of the dusty site when compared with the control  
12 site where it was present only as a seedling. The growth of tulip poplar, dogwood, hop-  
13 hornbeam, black haw (*Viburnum prunifolium*), and redbud (*C. canadensis*) appeared to be  
14 favored by the dust. Growth of conifers and acidophiles such as rhododendron (*Rhododendron*  
15 *maximum*), however, was limited. Although dust accumulation began in 1945, the heaviest  
16 accumulation occurred between 1967 and 1972 during the time of the study.

17 Changes in community composition were associated closely with changes in the growth of  
18 the dominant trees. Decrease in density of seedlings and saplings and in mean basal area, as well  
19 as lateral growth of red maple, chestnut oak, and red oak, occurred in all strata. On the other  
20 hand, all of these characteristics increased in tulip poplar, which was a subordinate species  
21 before dust accumulation began but had assumed dominance at the time of the study. Reduction  
22 in growth of the dominant trees had apparently given tulip poplar competitive advantage because  
23 of its ability to tolerate dust. Changes in soil alkalinity occurred because of the heavy deposition  
24 of limestone dust; however, the facilities necessary for critical analysis of the soils were not  
25 available. From the foregoing, it is obvious that PM physical effects in the vicinity of limestone  
26 quarries and processing plants can affect ecosystems.

27 Changes in ecosystem structure resulting from exposures to sea salt were cited previously  
28 (Section 4.3.1.1). The dominance of live oak (*Quercus virginiana*) as a practically pure stand on  
29 Smith Island (Bald Head), NC and along the eastern and southern coast of North Carolina has  
30 been explained as due to its tolerance to salt spray. The absence of more inland species is

1 attributed to their intolerance to salt spray. Wells (1939) termed the long-term stabilization of  
2 live oak as “salt spray climax,” a new type of climax.

### 3 4 ***Acidic Deposition***

5 The effects of acidic deposition have been discussed in several previous reports. The 1982  
6 EPA document, *Air Quality Criteria for Particulate Matter and Sulfur Oxides*, devoted a chapter  
7 to the effects of acidic deposition (U.S. Environmental Protection Agency, 1982). In 1984, EPA  
8 published *The Acidic Deposition Phenomenon and Its Effects* (Altshuller and Linthurst, 1984),  
9 and, in 1991, NAPAP published the result of its extensive study, *Acidic Deposition: State of*  
10 *Science and Technology* (Irving, 1991). The major effects of acidic deposition occur through the  
11 soil and are discussed under indirect effects. However, included among the direct responses of  
12 forest trees to acidic deposition are increased leaching of nutrients from foliage; accelerated  
13 weathering of leaf cuticular surfaces; increased permeability of leaf surfaces to toxic materials,  
14 water, and disease agents; and altered reproductive processes (Altshuller and Linthurst, 1984).

### 15 16 ***Trace Elements***

17 Possible direct responses of trace elements on vegetation result from their deposition and  
18 residence on the phyllosphere (i.e., leaf surfaces). Fungi and other microorganisms living on the  
19 leaves of trees and other vegetation play an important role in leaf decomposition after litterfall  
20 (Miller and McBride, 1999; Jensen, 1974; Millar, 1974). Possible effects of heavy metals on  
21 nutrient cycling and their effects on leaf microflora appear not to have been studied.

22 A trace metal must be brought into solution before it can enter into the leaves or bark of  
23 vascular plants. Low solubility limits entry. In those instances when trace metals are absorbed,  
24 they frequently are bound in the leaf tissue and then are lost from the plant when the leaf drops  
25 off (Hughes, 1981) are transferred to the litter layer where they can affect litter decomposition,  
26 an important source of soil nutrients. Changes in litter decomposition processes influence  
27 nutrient cycling in the soil and limit the supply of essential nutrients. Both Cotrufo et al. (1995)  
28 and Niklińska et al. (1998) point out that heavy metals affect forest litter decomposition.  
29 Cotrufo et al. (1995) observed that decomposition of oak leaves containing Fe, Zn, Cu, Cr, Ni,  
30 and Pb was influenced strongly during the early stages by metal contamination. Fungal  
31 mycelium was significantly less abundant in litter and soil in contaminated sites when compared

1 with control sites. Niklińska et al. (1998) stated that toxic effects of heavy metals on soil  
2 respiration rate have been reported by many scientists, and that, in polluted environments, this  
3 results in accumulation of undecomposed organic matter. However, they state that results of  
4 experiments should identify the most important “natural” factors affecting soil/litter sensitivity  
5 because the effects of heavy metals on respiration rates depend on the dose of heavy metals, the  
6 type of litter, types of metals deposited, and the storage time before respiration tests are made.

7 Trace metals, particularly heavy metals (e.g., cadmium, copper, lead, chromium, mercury,  
8 nickel, zinc) have the greatest potential for influencing forest growth (Smith, 1991).

9 Experimental data indicate that the broadest spectrum of growth suppression of foliar microflora  
10 resulted from iron, aluminum, and zinc. These three metals also inhibited spore formation, as  
11 did cadmium, chromium, manganese, and nickel (see Smith, 1990c). In the field, the greatest  
12 injury occurs from pollution near mining, smelting, and other industrial sources (Ormrod, 1984).  
13 Direct metal phytotoxicity can occur only if the metal can move from the surface into the leaf or  
14 directly from the soil into the root.

### 16 ***Organic Compounds***

17 Primary and secondary organic compounds formed in the atmosphere, the effects of some  
18 of which are discussed below, have been referred to under the following terms: toxic substances,  
19 pesticides, hazardous air pollutants (HAPS), air toxics, semivolatile organic compounds (SOCs),  
20 and persistent organic pollutants (POPS). Again, it should be remembered that chemical  
21 substances denoted by such headings are not criteria air pollutants controlled by the National  
22 Ambient Air Quality Standards under Section 109 of the Clean Air Act (CAA), but rather are  
23 controlled under Sect. 112, Hazardous Air Pollutants (U.S. Code, 1991). Their possible effects  
24 on humans and ecosystems are discussed in a number of government documents and in many  
25 other publications. They are mentioned here because many of the chemical compounds are  
26 partitioned between gas and particle phases in the atmosphere. As particles, they can become  
27 airborne, be distributed over a wide area, and affect remote ecosystems. Some of the chemical  
28 compounds are of concern because they may reach toxic levels in food chains of both animals  
29 and humans; whereas others tend to decrease or maintain the same toxicity as they move through  
30 the food chain. Some examples of movement through food chains are provided below.

1 Many chemical compounds from a variety of anthropogenic sources are released into the  
2 ambient air (see Section 4.2.1). In the atmosphere, the emitted compounds initially go through a  
3 mixing process, and the airborne particles then are distributed over a wide area and ultimately  
4 deposited on ecosystem components. Atmospheric deposition of polychlorinated dibenzo-*p*-  
5 dioxins and dibenzofurans (PCDD/Fs), as an example, can be divided into three different forms:  
6 (1) dry gaseous, (2) dry particle-bound, and (3) wet deposition. Dry particle-bound deposition  
7 occurs when the PM containing the pollutant is deposited on the plant surface; whereas wet  
8 deposition ranges from hail to rain to fog and dew fall (McLachlan, 1996b).

9 Human exposure to PCDD/Fs has been demonstrated to be caused almost exclusively by  
10 the ingestion of animal fat from fish, meat, and dairy products. Almost half of human exposure  
11 to PCDD/Fs is caused by consumption of beef and dairy products (McLachlan, 1996b). Cattle  
12 obtain most of their PCDD/Fs through grass. Therefore, the grass → cattle → milk/beef pathway is  
13 critical for human exposure. It has been shown that root uptake/translocation is an insignificant  
14 pathway of PCDD/Fs to aerial plant parts. Wet and dry particle deposition are the most  
15 important for the accumulation of the higher chlorinated congeners in vegetation. The persistence  
16 of PCDD/Fs in plants has not been investigated extensively; however, biodegradation probably  
17 does not occur in that these compounds are found primarily in the lipophilic cuticle and are very  
18 resistant to microbial degradation (McLachlan, 1996b). Feed contaminated with soil containing  
19 the pollutant can be another source of exposure of beef and dairy cattle, as well as chickens. The  
20 PCDD/Fs are near a steady state in milk cows and laying hens; however, animals raised for meat  
21 production (such as beef cattle and pigs) may accumulate them. The beef cattle and pigs cannot  
22 excrete the contaminants in a lipid-rich matrix such as milk or eggs. Thus, all of the PCDD/Fs,  
23 ingested are stored in the body. In agricultural food chains, there is a biodilution of PCDD/Fs,  
24 with the fugacity decreasing by up to three orders of magnitude between the air and cows milk  
25 (McLachlan, 1996b). Fürst et al. (1993), based on surveys to determine the factors that influence  
26 the presence of PCDD/PCDF in cows milk, earlier concluded that regardless of which pathway,  
27 soil → grass → cow or air → grass → cow, it was the congener of the chemical that was most  
28 important.

29 Chlorinated persistent organic pollutants (POPS), such as PCBs, PCDFs, and PCDDs, can  
30 be transported as particles through the atmosphere from industrial and agricultural sources; be  
31 brought down via wet and dry deposition in remote regions, such as the Arctic; and have been

1 detected in all levels of the Arctic food chain (Oehme et al., 1995). High concentrations of PCB  
2 (1 to 10 ppm) were found in seals, but the concentrations increased to 10 to 100 ppm in polar  
3 bears. The polar bear is the top predator in the Arctic and feeds preferentially on ringed seals  
4 and, to a lesser extent, on other seal species. Bioconcentration factors of organochlorines in the  
5 Arctic food web, reaching  $10^7$  for fish and seals, are biomagnified in polar bears (Oehme et al.,  
6 1995). Polychlorinated dibenzo-*p*-dioxins and polychlorinated dibenzofurans have also been  
7 found in seals (Oehme et al., 1995). Milk taken from anaesthetized polar bears was also found  
8 to contain PCDD/PCDF. Very little is known regarding the intake of milk by polar bear cubs.  
9 However, estimates of the intake of milk containing detectable levels of PCDD/PCDF and PCB  
10 and the additional consumption of seal blubber confirm that these pollutants are passed on to the  
11 next generation (Oehme et al., 1995).

12 Section 112 of the CAA provides the legislative basis for U.S. hazardous air pollutant  
13 (HAP) programs. In response to mounting evidence that air pollution contributes to water  
14 pollution, Congress included Section 112m (*Atmospheric Deposition to Great Lakes and Coastal*  
15 *Waters*) in the 1990 CAA Amendments that direct the EPA to establish a research program on  
16 atmospheric deposition of HAPS to the “Great Waters.”

17 Actions taken by EPA and others to evaluate and control sources of Great Waters  
18 pollutants of concern appear to have positively affected trends in pollutant concentrations  
19 measured in air, sediment, and biota. Details concerning these effects may be found in  
20 “Deposition of Air Pollutants to the Great Waters,” Third Report to Congress (U.S.  
21 Environmental Protection Agency, 2000a). The Third Report (EPA-453/R-00-005, June 2000),  
22 like the First and Second Reports to Congress, focuses on 15 pollutants of concern, including  
23 pesticides, metal compounds, chlorinated organic compounds, and nitrogen compounds. The  
24 new scientific information in the Third Report supports and builds on three broad conclusions  
25 presented in the previous two EPA Reports to Congress:

- 26 (1) Atmospheric deposition from human activities can be a significant contributor of toxic  
chemicals and nitrogen compounds to the Great Waters. The relative importance of  
atmospheric loading for a particular chemical in a water body depends on many factors  
(e.g., characteristics of the water body, properties of the chemical, and the kind and  
amount of atmospheric deposition versus water discharges).

- 1 (2) A plausible link exists between emissions of toxic pollutants of concern into the air  
above the Great Waters; the deposition of these pollutants (and their transformation  
products); and the concentrations of these pollutants found in the water, sediments, and  
biota, especially fish and shellfish. For mercury, fate and transport modeling and  
exposure assessments predict that the anthropogenic contribution to the total amount of  
methylmercury in fish is, in part, the result of anthropogenic mercury releases from  
industrial and combustion sources increasing mercury body burdens (i.e.,  
concentrations) in fish. Also, the consumption of fish is the dominant pathway of  
exposure to methylmercury for fish-consuming humans and wildlife. However, what is  
known about each stage of this process varies with each pollutant (for instance, the  
chemical species of the emissions and its transformation in the atmosphere).
- 2 (3) Airborne emissions from local as well as distant sources, from both within and outside  
the United States, contribute pollutant loadings to waters through atmospheric  
deposition. Determining the relative roles of particular sources — local, regional,  
national, and possibly global, as well as anthropogenic, natural, and reemission of  
pollutants — contributing to specific water bodies is complex, requiring careful  
monitoring, atmospheric modeling, and other analytical techniques.

#### 3 4 **Response to Indirect Effects of PM**

5 The presence of PM in the atmosphere directly affects vegetation following physical  
6 contact with foliar surfaces (as discussed above), but in many cases the more significant effects  
7 are indirect. These effects may be mediated by suspended PM (i.e., through effects on radiation  
8 and climate) and by particles that pass through vegetative canopies to reach the soil. Effects  
9 mediated through the atmosphere are considered briefly below and in greater detail later, under  
10 Section 4.5.

11 The major indirect plant responses are chiefly soil-mediated and depend primarily on the  
12 chemical composition of the individual stressors deposited in PM. The chemical stressors must  
13 be bioavailable in order to produce an effect. The effects of exposures may result in changes in  
14 biota patterns and in chemical/physical soil conditions that affect ecological processes, such as  
15 nutrient cycling and uptake by plants.

1 The soil environment, composed of mineral and organic matter, water, air, and a vast array  
2 of bacteria, fungi, algae, actinomycetes, protozoa, nematodes, and arthropods, is one of the most  
3 dynamic sites of biological interactions in nature (Wall and Moore, 1999; Alexander, 1977).  
4 The quantity of organisms in soils varies by locality. Bacteria and fungi are usually most  
5 abundant in the rhizosphere, the soil around plant roots that all mineral nutrients must pass  
6 through. Bacteria and fungi benefit from the nutrients in the root exudates (chiefly sugars) in the  
7 soil and, in turn, they play an essential role by making mineral nutrients available for plant  
8 uptake (Wall and Moore, 1999; Rovira and Davey, 1974). Their activities create chemical and  
9 biological changes in the rhizosphere by decomposing organic matter and making inorganic  
10 minerals available for plant uptake. Bacteria are essential in the nitrogen and sulfur cycles and  
11 make these elements available for plant uptake and growth (see Section 4.3.3). Fungi are  
12 directly essential to plant growth. Attracted to the roots by the exudates, they develop  
13 mycorrhizae, a mutualistic, symbiotic relationship, that is integral in the uptake of the mineral  
14 nutrients (Allen, 1991). The impact in ecosystems of PM, particularly nitrates, sulfates, and  
15 metals, is determined by their effects on the growth of the bacteria involved in nutrient cycling  
16 and the mycorrhizal fungi involved in plant nutrient uptake.

17  
18 ***Atmospheric Turbidity: Effects on Direct Beam and Photosynthetically Active***  
19 ***Radiation.*** Photosynthetic processes underlie the contribution of vegetative surfaces to nutrient  
20 and energy cycling. The characteristics and net receipts of environmental radiation determine  
21 the rates of both photosynthesis and the heat-driven process of water cycling. Atmospheric  
22 turbidity due to particulate loading can substantially alter the characteristics and net receipts of  
23 solar radiation. One measure of atmospheric turbidity, Linke's turbidity factor, T, can be  
24 derived as a direct function of light extinction by solid particles. It is defined as the ratio of the  
25 total extinction coefficient and the extinction due exclusively to gases:

$$T = \sigma/\sigma_g = 1 + w\sigma_w/\sigma_g + s\sigma_s/\sigma_g \quad (4-6)$$

26  
27  
28  
29 where s and w are the relative concentrations of dust and water vapor in the atmosphere, and  $\sigma_s$   
30 and  $\sigma_w$  are the wavelength-dependent scattering coefficients for solid, dry particles and water  
31 vapor. The scattering coefficients are in units of inverse distance, such as  $\text{km}^{-1}$  (Rosenberg,

1 1974). According to this expression, a clean atmosphere would have a turbidity value of 1.  
2 Given that turbidity and visibility are both functions of light scattering, the trends in and physical  
3 processes underlying reduced visibility discussed in Section 4.3 are directly relevant to the  
4 discussion of radiative effects on vegetation due to particulate matter.

5 Turbidity, as defined above, describes the degree of scattering occurring in the atmosphere  
6 due to particles and gases. Total, particle-based extinction, however, is the sum of both  
7 scattering and absorption. Absorption of short-wavelength solar radiation reduces the amount of  
8 radiation reaching the Earth's surface and leads to atmospheric heating. If the absorbing  
9 particles re-radiate in the infrared range, some of this energy is lost as long-wave re-radiation to  
10 space. The balance of this energy is captured at the surface as down-welling infrared radiation.  
11 Canopy temperature and transpirational water use by vegetation are particularly sensitive to  
12 long-wave, infrared radiation. Atmospheric heating by particles reduces vertical temperature  
13 gradients, potentially reducing the intensity of atmospheric turbulent mixing. The magnitude of  
14 such potential effects on turbulent transport within canopies remains unknown although the  
15 damping of eddy transport might inhibit canopy gas exchange. Suppressed tropospheric mixing  
16 could also intensify local temperature inversions and increase the severity of pollution episodes  
17 (Pueschel, 1993) with direct inhibitory effects on photosynthetic processes.

18 Atmospheric turbidity increases the intensity of diffuse (sky) radiation (Hoyt, 1978). In a  
19 clear atmosphere, diffuse radiation may be on the order of 10% of total solar radiation  
20 (Choudhury, 1987). However, in highly turbid, humid conditions, this fraction may increase, to  
21 as much as 100% of the incident solar intensity in extreme cases. The direct-to-diffuse-radiation  
22 ratio is highest at solar noon and lowest near dawn or dusk when the path length through the  
23 atmosphere is longest. The wavelength dependence of particle scattering induces an enrichment  
24 of PAR with respect to total or direct beam radiation.

25 Aerosols produced by incomplete combustion, from forest fires to specifically  
26 anthropogenic processes such as diesel fuel combustion, contain significant fractions of black  
27 carbon which absorbs across the solar and terrestrial radiation spectra. The presence of  
28 absorbing aerosols reduces the ratio of photosynthetically active radiation to total radiation  
29 received at the surface, potentially reducing photosynthetic water uptake efficiency. The net  
30 effect of aerosol absorption on the surface depends on the relative magnitudes of the particulate  
31 absorption coefficients in the visible and infrared area and on the albedo of the Earth's surface.

1           The greater effect of particulate loading on visibility and turbidity is due to scattering.  
2 Non-absorbing, scattering aerosols raise the overall albedo of the atmosphere and reduce the  
3 amount of radiation reaching the surface by the amount reflected or scattered back into space.  
4 Analysis of data collected by a global network of thermopile pyranometers operated by the  
5 World Meteorological Organization show a 50-year global trend of a 2.7% per decade reduction  
6 in the amount of solar radiation reaching the Earth's surface. This has been associated with an  
7 increasing global albedo caused by an increasing abundance of atmospheric particles.  
8 By evaluating the WMO data set with four different approaches to the statistical analyses,  
9 Stanhill and Cohen (2001) have estimated that average global solar radiation receipts have  
10 declined by 20 Wm<sup>-2</sup> since 1958. Examples of individual measurement sites include Barrow,  
11 Alaska (71 °N), where the average solar irradiance from 1963 – 1993 was 100.9 W m<sup>-2</sup> and the  
12 estimated linear trend was -0.23% per year; and Jerusalem, Israel (32 °N), where the average  
13 solar irradiance from 1954 – 1994 was 244.2 W m<sup>-2</sup> and the estimated linear trend was -0.37%  
14 per year.

15  
16           ***Increased Turbidity and Altered Radiative Flux: Effects on Vegetative Processes.*** In a  
17 detailed canopy-response model (e.g., Choudhury, 1987), radiation is considered in its direct and  
18 diffuse components. Foliar interception by canopy elements is considered for both up- and  
19 down-welling radiation (a two-stream approximation). In this case, the effect of atmospheric  
20 PM on turbidity influences canopy processes both by radiation attenuation and by influencing  
21 the efficiency of radiation interception throughout the canopy through conversion of direct to  
22 diffuse radiation (Hoyt, 1978). Diffuse radiation is more uniformly distributed throughout the  
23 canopy and increases canopy photosynthetic productivity by distributing radiation to lower  
24 leaves. The treatment of downwelling direct-beam radiation in the two-stream approach remains  
25 an elaboration of the simplified Beer's Law analogy with solar angle, leaf area distribution, and  
26 orientation individually parameterized (Choudhury, 1987). Diffuse downwelling radiation is a  
27 function of diffuse and direct radiation at the top of the canopy and penetration within the  
28 canopy according to cumulative leaf area density and foliage orientation. Diffuse upwelling  
29 radiation results from scattering and reflectance of both direct and diffuse downwelling radiation  
30 within the canopy and by the soil.

1           Rochette et al. (1996) conducted simultaneous measurements of radiation and water use  
2 efficiencies by maize and found that, in the absence of water stress and with adequate  
3 fertilization, 90% of all variation in crop net photosynthesis (P-n) could be explained by  
4 variations in PAR. Alternatively, an evaluation of the available experimental literature and  
5 statistics on crop yields by Stanhill and Cohen (2001) indicate that plant productivity is more  
6 affected by changes in evapo-transpiration induced by changes in the amount of solar radiation  
7 plants receive than by changes in the amount of PAR plants receive.

8           The enrichment in PAR present in diffuse radiation appears, however, to offset a portion of  
9 the effect of an increased atmospheric albedo due to atmospheric particles. An observational and  
10 theoretical study by Bange et al. (1997) of the level of radiation use efficiency (RUE) of  
11 sunflowers indicated a degree of compensation for reduced incident radiation by a proportional  
12 increase in diffuse radiation. Variables measured by Bange et al. (1997) included biomass,  
13 phenology, leaf area, canopy light extinction, grain size, and harvest index. Crops subject to  
14 reduced direct beam/increased diffuse radiation produced biomass, phenology, leaf area and  
15 canopy light extinction at leaves similar to unshaded crops, but yielded smaller grains and a  
16 lower harvest index. RUE was also seen to improve for soybeans and maize with a proportional  
17 increase in diffuse radiation with respect to direct beam (Sinclair et al., 1992; Healey et al.,  
18 1998) although the effect on harvest index was not indicated. Following a comparison of the  
19 relative efficiencies of canopy photosynthesis to diffuse and direct PAR for a Scots pine forest,  
20 an aspen forest, a mixed deciduous forest, a tall grass prairie and a winter wheat crop, Gu et al.  
21 (2002) concluded (1) diffuse radiation over direct radiation results in higher light use efficiencies  
22 by plant canopies; (2) diffuse radiation has much less tendency to cause canopy photosynthetic  
23 saturation; (3) the advantages of diffuse radiation over direct radiation increase with radiation  
24 level; (4) temperature as well as vapor pressure deficit can cause different responses in diffuse  
25 and direct canopy photosynthesis, indicating that their effects on terrestrial ecosystem carbon  
26 assimilation may depend upon radiation regimes, thus sky conditions.

27           The potentially significant effect of regional haze on the yield of crops because of  
28 reduction in solar radiation has been examined by Chameides et al. (1999). Using a case study  
29 approach, Chameides et al. (1999), studied the effects of regional haze on crop production in  
30 China where regional haze is especially severe. A rudimentary assessment of the direct effect of  
31 atmospheric aerosols on agriculture suggests that yields of approximately 70% of crops are being

1 depressed by at least 3 to 5% by regional scale air pollution and its associated haze (Chameides  
2 et al., 1999).

3  
4 ***Effects of Nitrogen Deposition.*** Nitrogen is required by all organisms. It is a major  
5 constituent of the nucleic acids that determine the genetic character of all living things and the  
6 enzyme proteins that drive the metabolic machinery of every living cell (Galloway, 1998;  
7 Galloway and Cowling, 2002). Though nitrogen composes 80% of the total mass of the Earth's  
8 atmosphere, it is not biologically available. Nitrogen fixation is accomplished in nature by  
9 certain unique organisms that have developed the capability of converting  $N_2$  to biologically  
10 active reduced forms of nitrogen such as ammonia, amines, and amino acids which are the  
11 structural constituents of proteins and nucleic acids (Galloway and Cowling, 2002).

12 Nitrogen has long been recognized as the nutrient most important for plant growth. It is of  
13 overriding importance in plant metabolism and, to a large extent, governs the utilization of  
14 phosphorus, potassium, and other nutrients. Most of the nitrogen in soils is associated with  
15 organic matter. Typically, the availability of nitrogen via the nitrogen cycle controls net primary  
16 productivity, and possibly, the decomposition rate of plant litter. Photosynthesis is influenced by  
17 nitrogen uptake in that ca., 75% of the nitrogen in a plant leaf is used during the process of  
18 photosynthesis. The nitrogen-photosynthesis relationship is, therefore, critical to the growth of  
19 trees and other plants (Chapin et al., 1987). Plants usually obtain nitrogen directly from the soil  
20 through their roots by absorbing  $NH_4^+$  or  $NO_3^-$ , or it is formed by symbiotic organisms (bacteria,  
21 blue-green algae) in the roots.

22 Because nitrogen is not readily available and is usually in short supply, it is the chief  
23 element in agricultural fertilizers. The realization of the importance of nitrogen in crop  
24 production resulted in a search for natural nitrogen such as guano and nitrate deposits. The  
25 invention of the Haber-Bosch process in 1913 made reactive nitrogen (Nr) available for use in  
26 food production, and more than half of the food eaten by peoples of the world today is produced  
27 using fertilizer produced by this process (Galloway and Cowling, 2002).

28 Nitrogen in nature may be divided into two groups: nonreactive ( $N_2$ ) and reactive (Nr).  
29 Reactive Nr includes all biologically, photochemically, and radioactively active nitrogen  
30 compounds in the Earth's atmosphere and biosphere (Galloway et al., 2003). Among those  
31 included are: the inorganic reduced forms of nitrogen (e.g., ammonia [ $NH_3$ ] and ammonium

1 [NH<sub>4</sub><sup>+</sup>]), inorganic oxidized forms (e.g., nitrogen oxide [NO<sub>x</sub>], nitric acid [HNO<sub>3</sub>], nitrous oxide  
2 [N<sub>2</sub>O], and nitrate [NO<sub>3</sub><sup>-</sup>]), and organic compounds (e.g., urea, amine, proteins, and nucleic  
3 acids)).

4 Food production continues to account for most of the newly Nr created. However, since  
5 approximately 1965 the magnitude of Nr created by humans began to exceed natural terrestrial  
6 creation of Nr and its conversion back to N<sub>2</sub> by denitrification. The overall increase in global Nr  
7 is the result of three main causes: (1) widespread cultivation of legumes, rice and other crops  
8 that promote conversion of N<sub>2</sub> to organic nitrogen through biological nitrogen fixation;  
9 (2) combustion of fossil fuels, which converts both atmospheric N<sub>2</sub> and fossil nitrogen to  
10 reactive NO<sub>x</sub>; and (3) the Haber-Bosch process, which converts nonreactive NH<sub>3</sub> to sustain food  
11 production and some industrial activities (Galloway and Cowling, 2002; Galloway et al., 2003).

12 Reactive nitrogen is now accumulating in the environment on all spatial scales – local,  
13 regional and global (2002:Galloway and Cowling, 2002; Galloway et al. 2003). As a result, Nr  
14 is accumulating in various environmental reservoirs, e.g., the atmosphere, soils and waters  
15 (Galloway and Cowling, 2002). The accumulation of Nr in the environment has effects on  
16 humans and ecosystems Rabelais, 2002; van Egmond et al., 2002; Galloway, 1998).

17 Large uncertainties regarding the rates of Nr accumulation in the various reservoirs limits  
18 our ability to determine the temporal and spatial distribution of environmental effects. These  
19 uncertainties are of great significance because of the sequential nature of Nr on environmental  
20 processes. (Galloway and Cowling, 2002). The sequence of transfers, transformations, and  
21 environmental effects is referred to as the nitrogen cascade (Figure 4-15; Galloway and Cowling,  
22 2002; Galloway et al, 2003). A single atom of new NH<sub>x</sub> or NO<sub>x</sub> can alter a wide array of  
23 biogeochemical processes and exchanges among environmental reservoirs.

24 The results of the Nr cascade in the global system and the wide variety of changes in the  
25 nitrogen cycle are both beneficial and detrimental to humans and to ecosystems (Galloway and  
26 Cowling, 2002; Galloway et al., 2003). Though the synthetic fertilizers used in cultivation and  
27 the cultivation-induced bacterial nitrogen fertilization (BNF) sustain a large portion of the  
28 world's population, there are consequences: (1) the wide dispersal of Nr by hydrological and  
29 atmospheric transport; (2) the accumulation of Nr in the environment because the rates of its  
30 creation are greater than the rates of its removal through denitrification to nonreactive N<sub>2</sub>; (3) Nr  
31 creation and accumulation is projected to continue to increase in the future as per capita use of

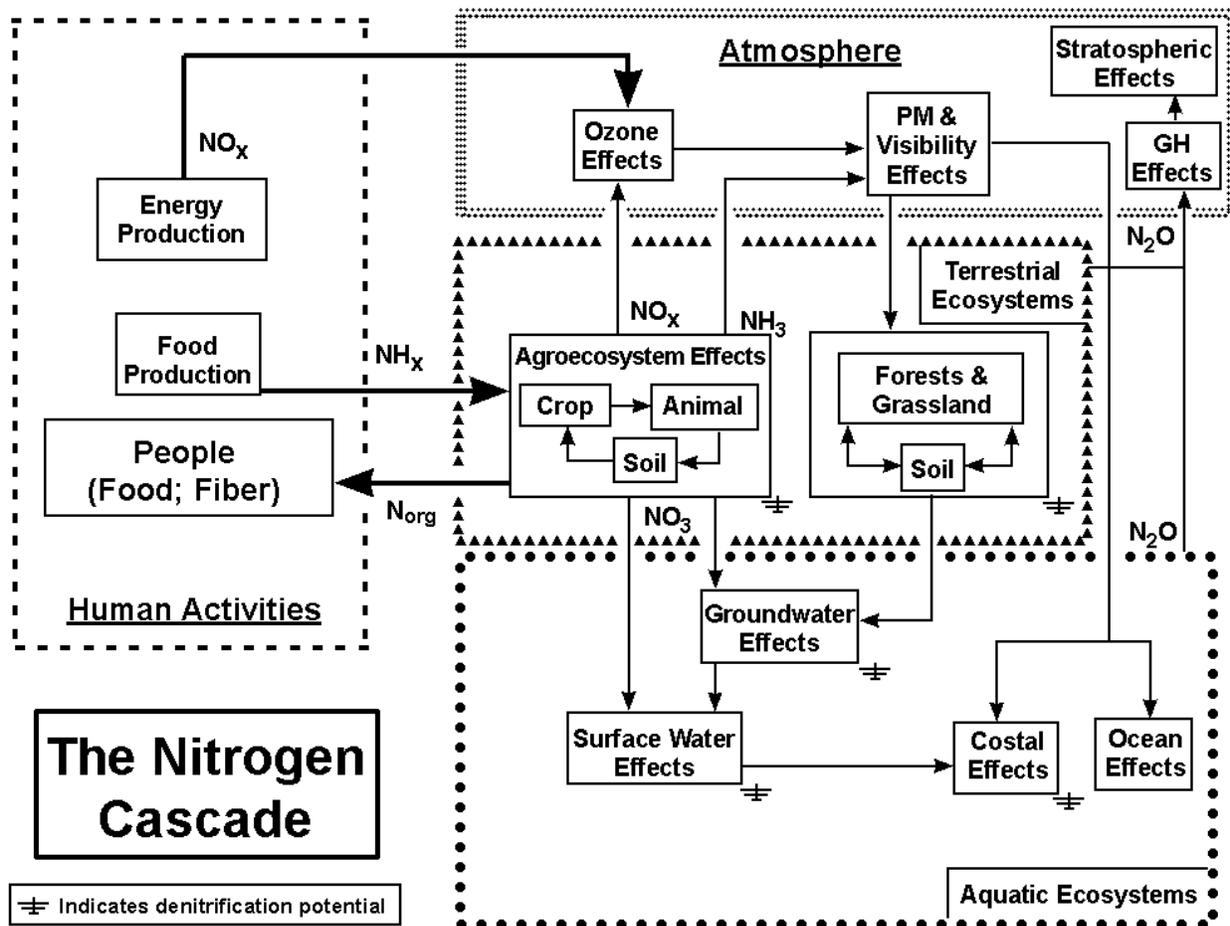

Figure 4-15. Illustration of the nitrogen cascade showing the movement of the human-produced reactive nitrogen (Nr) as it cycles through the various environmental reservoirs in the atmosphere, terrestrial ecosystems, and aquatic ecosystems.

Modified from Galloway and Cowling (2002).

- 1 resources by human populations increases; and (4) Nr accumulation contributes to many
- 2 contemporary environmental problems (Galloway et al., 2003)
- 3 Among the contemporary environmental problems are the following:
- 4
  - increases in Nr lead to production of tropospheric ozone and aerosols and the associated human health problems (Wolfe and Patz, 2002);

- 1 • productivity increases in forests and grasslands and then decreases wherever atmospheric  
Nr deposition increases significantly and critical thresholds are exceeded; Nr additions  
probably also decrease biodiversity in many natural habitats (Aber et al., 1995);
- 2 • reactive nitrogen in association with sulfur is responsible for acidification and loss of  
biodiversity in lakes and streams in many regions of the world (Vitousek et al., 1997);
- 3 • reactive nitrogen is responsible for eutrophication, hypoxia, loss of biodiversity, and habitat  
degradation in coastal ecosystems. It is now considered the biggest pollution problem in  
coastal waters (Rabelais, 2002);
- 4 • reactive nitrogen contributes to global climate change and stratospheric ozone depletion,  
both of which have an effect on the health of humans and ecosystems (Cowling et al.,  
1998).

5 The effect of increasing nitrogen inputs (e.g., NO<sub>x</sub>, nitrates, nitric acid) on the nitrogen  
6 cycle in forests, wetlands, and aquatic ecosystems is discussed in detail elsewhere (U.S.  
7 Environmental Protection Agency, 1993, 1997a; Garner, 1994; World Health Organization,  
8 1997).

9 The deposition of nitrogen in the United States from human activity has doubled between  
10 1961 and 1997 due mainly to the use of inorganic nitrogen fertilizers and the emissions of  
11 nitrogen oxides (NO<sub>x</sub>) from fossil fuel emissions with the largest increase occurring in the 1960s  
12 and 1970s (Howarth et al., 2002). Among the most important effects of chronic nitrogen  
13 deposition are changes in the composition of plant communities, disruptions in nutrient cycling,  
14 increased emissions from soil of nitrogenous greenhouse gases and accumulation of nitrogen  
15 compounds resulting in the enhanced availability of nitrate or ammonium, the soil-mediated  
16 effects of acidification, and increased susceptibility to stress factors (Fenn et al., 1998; Bobbink  
17 et al., 1998). A major concern is “nitrogen saturation,” the result of the atmospheric deposition  
18 of large amounts of particulate nitrates. Nitrogen saturation results when additions to soil  
19 background nitrogen (nitrogen loading) exceeds the capacity of plants and soil microorganisms  
20 to utilize and retain nitrogen (Aber et al., 1989, 1998; Garner, 1994; U.S. Environmental  
21 Protection Agency, 1993). Under these circumstances, disruptions of ecosystem functioning  
22 may result (Hornung and Langan, 1999).

23 Possible ecosystem responses to nitrate saturation, as postulated by Aber and coworkers  
24 (Aber et al., 1989), include (1) a permanent increase in foliar nitrogen and reduced foliar

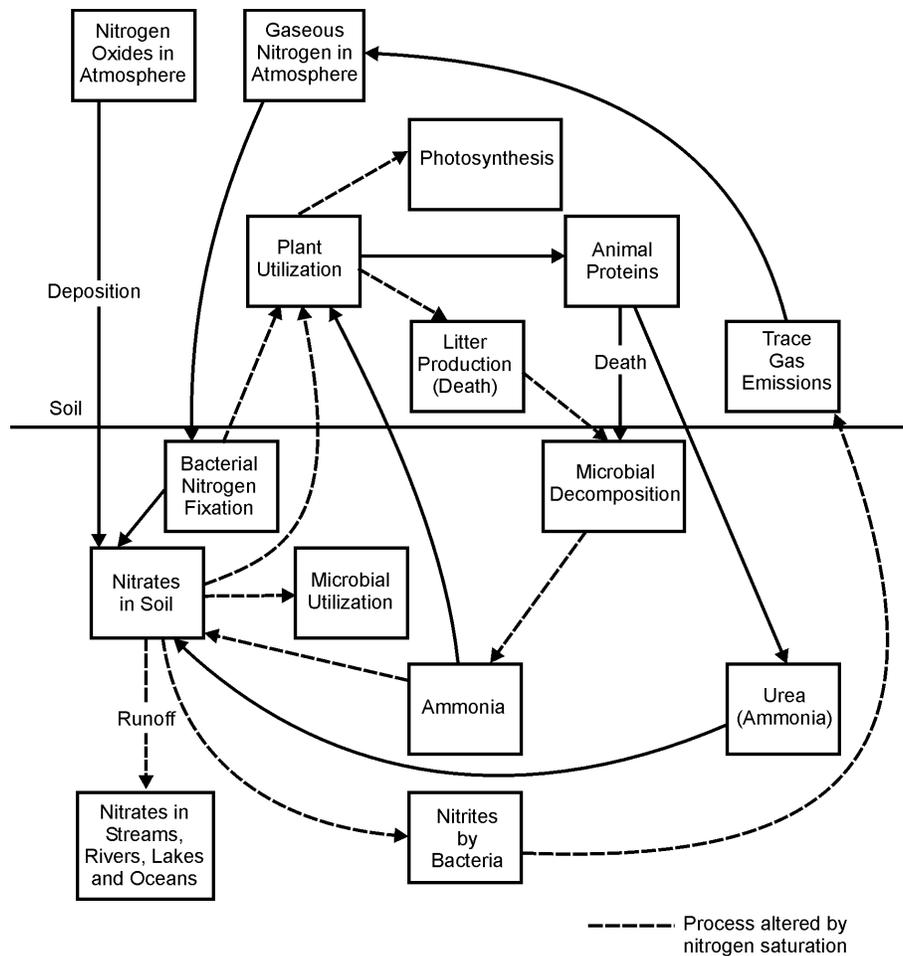

1 phosphorus and lignin caused by the lower availability of carbon, phosphorus, and water;  
2 (2) reduced productivity in conifer stands because of disruptions of physiological function;  
3 (3) decreased root biomass and increased nitrification and nitrate leaching; and (4) reduced soil  
4 fertility, resulting from increased cation leaching, increased nitrate and aluminum concentrations  
5 in streams, and decreased water quality. Saturation implies that some resource other than  
6 nitrogen is limiting biotic function.

7 Water and phosphorus for plants and carbon for microorganisms are the resources most  
8 likely to be the secondary limiting factors (Aber et al., 1989). The appearance of nitrogen in soil  
9 solution is an early symptom of excess nitrogen. In the final stage, disruption of forest structure  
10 becomes visible (Garner, 1994).

11 Changes in nitrogen supply can have a considerable effect on an ecosystem's nutrient  
12 balance (Waring, 1987). Large chronic additions of nitrogen influence normal nutrient cycling  
13 and alter many plant and soil processes involved in nitrogen cycling (Aber et al., 1989).  
14 Among the processes affected are (1) plant uptake and allocation, (2) litter production,  
15 (3) immobilization (includes ammonification [the release of ammonia] and nitrification  
16 [conversion of ammonia to nitrate during decay of litter and soil organic matter]), and (4) nitrate  
17 leaching and trace gas emissions (Figure 4-16; Aber et al., 1989; Garner 1994).

18 Subsequent studies have shown that, although there was an increase in nitrogen  
19 mineralization initially (i.e., the conversion of soil organic matter to nitrogen in available form  
20 [see item 3 above]), nitrogen mineralization rates were reduced under nitrogen-enriched  
21 conditions. Aber et al.(1998) hypothesize that mycorrhizal assimilation and exudation, using  
22 photosynthate from the host plant as the carbons source, is the dominant process involved in  
23 immobilization of nitrogen. In addition, studies suggested that soil microbial communities  
24 change from predominantly fungal (mycorrhizal) communities to those dominated by bacteria  
25 during saturation (Aber et al., 1998).

26 The growth of most forests in North America is limited by the nitrogen supply. Severe  
27 symptoms of nitrogen saturation, however, have been observed in high-elevation, nonaggrading  
28 spruce-fir ecosystems in the Appalachian Mountains, as well as in the eastern hardwood  
29 watersheds at Fernow Experimental Forest near Parsons, WV. Mixed conifer forests and  
30 chaparral watersheds with high smog exposure in the Los Angeles Air Basin also are nitrogen  
31 saturated and exhibit the highest stream water  $\text{NO}_3^-$  concentrations for wildlands in North

**Figure 4-16. Nitrogen cycle (dotted lines indicate processes altered by nitrogen saturation).**

Source: Garner (1994).

1 America (Bytnerowicz and Fenn, 1996; Fenn et al., 1998). Forests in southern California, the  
 2 southwestern Sierra Nevada in Central California, and the Front Range in northern Colorado  
 3 have all been exposed to highly elevated nitrogen deposition, and nitrogen saturated watersheds  
 4 have been reported in the above mentioned areas. Annual nitrogen additions through deposition  
 5 (6-11 kg ha<sup>-1</sup> y<sup>-1</sup> as through fall) in the southwestern Sierra Nevada are similar to nitrogen storage  
 6 (4 kg ha<sup>-1</sup> y<sup>-1</sup>) in vegetation growth increment of western forests suggesting that current nitrogen  
 7 deposition rates may be near the assimilation capacity of the overstory vegetation. Ongoing  
 8 urban expansion will increase the potential for nitrogen saturation of forests from urban sources

1 (e.g., Salt Lake City, Seattle, Tucson, Denver, central and southern California) unless there are  
2 improved emission controls (Fenn et al., 1998).

3       Atmospherically deposited nitrogen also can act as a fertilizer in soil low in nitrogen. Not  
4 all plants, however, are capable of utilizing extra nitrogen as plants vary in their ability to absorb  
5 ammonium and nitrate (Chapin, et al., 1987). Inputs of nitrogen to natural ecosystems that  
6 alleviate deficiencies and increase growth of some plants can alter competitive relationships and  
7 alter species composition and diversity (Ellenberg, 1987; Kenk and Fischer, 1988; U.S.  
8 Environmental Protection Agency, 1993).

9       Not all forest ecosystems react in the same manner to nitrogen deposition. High-elevation  
10 alpine watersheds in the Colorado Front Range (Bowman, 2000) and a deciduous forest in  
11 Ontario, Canada, also are naturally saturated even though nitrogen deposition has been moderate  
12 ( $\approx 8 \text{ kg ha}^{-1} \text{ y}^{-1}$ ). The nitrogen saturated forests in North America, including estimated inputs and  
13 outputs, are shown in Table 4-14 (Fenn et al., 1998). The Harvard Forest hardwood stand in  
14 Massachusetts, however, has absorbed  $> 900 \text{ kg N/ha}$  without significant  $\text{NO}_3^-$  leaching during a  
15 nitrogen amendment study of 8 years (Table 4-14; Fenn et al., 1998). Nitrate leaching losses  
16 were high, on the other hand, in the Harvard Forest pine sites suggesting that deciduous forest  
17 may have a greater capacity for nitrogen retention. During the 8-year experimental study  
18 (1988-96), nitrate leaching was observed in the pine stand after the first year (1989) in the high  
19 nitrogen plots. Further increase was observed in 1995 and 1996, while the hardwood stand  
20 showed no significant increases in nitrate leaching until 1996. The sharp contrast in response of  
21 pine and hardwood stands indicates that the mosaic of community types across the landscape  
22 must be considered when determining regional scale response to nitrogen deposition (Magill  
23 et al., 2002). Johnson et al. (1991a) reported that measurements showing the leaching of nitrates  
24 and aluminum ( $\text{Al}^{+3}$ ) from high elevation forests in the Great Smoky Mountains indicate that  
25 these forests have reached saturation.

26       Because the competitive equilibrium of plants in any community is finely balanced, the  
27 alteration of one of a number of environmental parameters, (e.g., continued nitrogen additions)  
28 can change the vegetation structure of an ecosystem (Bobbink, 1998; Skeffington and Wilson,  
29 1988). Increases in soil nitrogen play a selective role. When nitrogen becomes more readily  
30 available, plants adapted to living in an environment of low nitrogen availability will be replaced  
31 by plants capable of using increased nitrogen because they have a competitive advantage.

**TABLE 4-14. NITROGEN-SATURATED FORESTS IN NORTH AMERICA,  
INCLUDING ESTIMATED N INPUTS AND OUTPUTS**

Location	Forest Type	Elevation (m)	N Input (kg ha <sup>-1</sup> year <sup>-1</sup> )	N Output (kg ha <sup>-1</sup> year <sup>-1</sup> )	Reference
Adirondack Mts. northeastern New York	Northern hardwoods or hardwood/ conifer mix	396-661	9.3 <sup>a</sup>	Stage 1 N loss <sup>b</sup>	Driscoll and Van Dreason (1993)
Catskill Mts., southeastern New York	Mainly hardwood; some eastern hemlock	335-675	10.2 <sup>a</sup>	Stage 1 and 2 N loss <sup>b</sup>	Stoddard (1994)
Turkey Lakes Watershed, Ontario, Canada	Sugar maple and yellow birch	350-400	7.0-7.7 (as throughfall)	17.9-23.6	Foster et al. (1989); Johnson and Lindberg (1992a)
Whitetop Mt., southwestern Virginia	Red spruce	1650	32 <sup>c</sup>	47 <sup>c</sup>	Joslin and Wolfe (1992); Joslin et al. (1992)
Fernow, West Virginia	Mixed hardwood	735-870	15-20	6.1	Gilliam et al. (1996); Peterjohn et al. (1996)
Great Smoky Mts. National Park, Tennessee	American beech	1600	3.1 <sup>d</sup>	2.9	Johnson and Lindberg (1992b)
Great Smoky Mts. National Park, Becking Site, North Carolina	Red spruce	1800	10.3 <sup>d</sup>	19.2	Johnson et al. (1991a)
Great Smokey Mts. National Park, Tower Site, North Carolina	Red spruce	1740	26.6	20.3	Johnson et al. (1991a)
Front Range, Colorado	Alpine tundra, subalpine conifer	3000-4000	7.5-8.0	7.5	Williams et al. (1996)
San Dimas, San Gabriel Mts., southern California	Chapparral and grasslands	580-1080	23.3 <sup>e</sup>	0.04-19.4	Riggan et al. (1985)
Camp Paivika, San Bernadino Mts., southern California	Mixed conifer	1600	30	7-26 <sup>f</sup>	Fenn et al. (1996)
Klamath Mts, northern California	Western coniferous	NA	Mainly geologic <sup>g</sup>	NA <sup>g</sup>	Dahlgren (1994)
Thompson Forest, Cascade Mts., Washington	Red alder	220	4.7 plus > 100 as N <sub>2</sub> fixation	38.9	Johnson and Lindberg (1992b)

<sup>a</sup>Estimated total N deposition from wet deposition data is from Driscoll et al. (1991) for the Adirondacks, and from Stoddard and Murdoch (1991) for the Catskills. Total deposition was estimated based on the wet deposition/total N deposition ratio (0.56) at Huntington Forest in the Adirondacks (Johnson and Lindberg, 1992b). Nitrogen deposition can be higher in some areas, especially at high-elevation sites such as Whiteface Mountain (15.9 kg ha<sup>-1</sup> year<sup>-1</sup>; Johnson and Lindberg, 1992b).

<sup>b</sup>Stage 1 and 2 of N loss according to the watershed conceptual model of Stoddard (1994). Nitrogen discharge (kg ha<sup>-1</sup> year<sup>-1</sup>) data are not available; only stream water NO<sub>3</sub><sup>-</sup> concentration trend data were collected.

<sup>c</sup>Values appear high compared to other sites, especially N leaching losses. Joslin and Wolfe (1992) concede that "there is considerable uncertainty associated with the estimates of atmospheric deposition and leaching fluxes." However, elevated NO<sub>3</sub><sup>-</sup> concentrations in soil solution, and lack of a growth response to N fertilization (Joslin and Wolfe, 1994) support the hypothesis that the forest at Whitetop Mountain is N saturated.

<sup>d</sup>Estimated total N deposition from throughfall data. Total deposition was estimated based on the throughfall/total N deposition ration (0.56) from the nearby Smokies Tower site (Johnson and Lindberg, 1992b).

<sup>e</sup>Annual throughfall deposition to the chaparral ecosystem.

<sup>f</sup>Nitrogen output is from unpublished streamwater data (Fenn and Poth, 1999). The low value represents a year of average precipitation, and the high value is for 1995, when precipitation was nearly double the long-term average. Nitrogen output includes N export in streamwater and to groundwater.

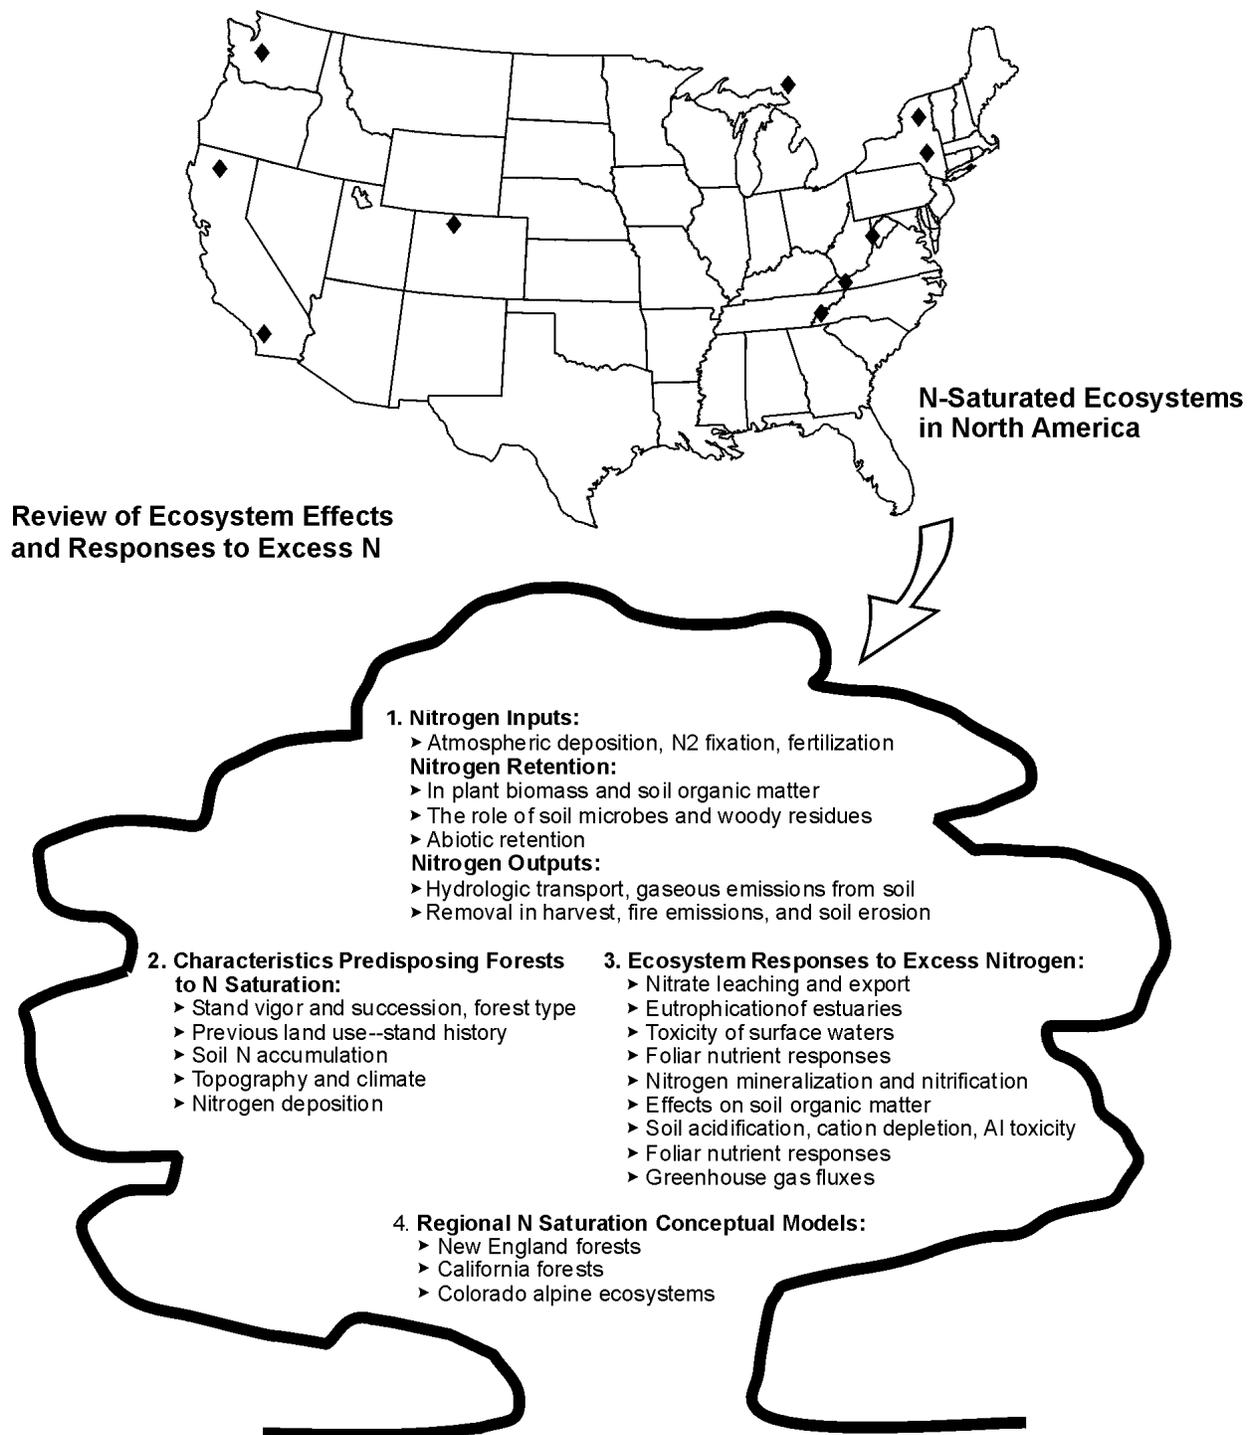

<sup>g</sup>Annual input and output data are not known, although N deposition in this forest is probably typical for much of the rural western United States (2-3 kg N ha<sup>-1</sup> year<sup>-1</sup> (Young et al., 1988). Excess N is from weathering of ammonium in mica schist bedrock. The ammonium was rapidly nitrified, leading to high NO<sub>3</sub><sup>-</sup> concentrations in soil solution (Dahlgren, 1994).

1 Plant succession patterns and biodiversity are affected significantly by chronic nitrogen  
2 additions in some North American ecosystems (Figure 4-17). The location of nitrogen saturated  
3 ecosystems in North America, and the steps leading to nitrogen saturation, are indicated on the  
4 map in Figure 4-16. Conceptual models of regional nitrogen saturation indicate saturation in  
5 New England, in the Colorado alpine ecosystems and in California forests. Fenn et al. (1998)  
6 reported that long-term nitrogen fertilization studies in both New England and Europe, as well,  
7 suggest that some forests receiving chronic inputs of nitrogen may decline in productivity and  
8 experience greater mortality. Long-term fertilization experiments at Mount Ascutney, VT,  
9 suggest that declining coniferous forest stands with slow nitrogen cycling may be replaced by  
10 deciduous fast-growing forests that cycle nitrogen rapidly (Fenn et al., 1998).

11 Atmospheric nitrogen deposition in the northeastern United States is largely a regional  
12 problem (Driscoll et al., 2001). In contrast, in the western United States, vast acres of land  
13 receive low levels of atmospheric nitrogen deposition that are interspersed with hot spots of  
14 elevated nitrogen deposition downwind of large expanding metropolitan centers or large  
15 agricultural operations (Fenn et al., 2003).

16 Fenn et al. (1998) have documented the major effects of Nr deposition in terrestrial and  
17 aquatic ecosystems in the western United States. Primarily these effects are in response to  
18 nitrogen enrichment of systems that are naturally nitrogen limited. Included in these effects are  
19 greenhouse gas emissions, higher nitrogen concentrations in plant tissues, and increased  
20 nitrification rates and nitrate ( $\text{NO}_3^-$ ) levels in soils, streams, and lakes (Fenn et al., 2003b). A  
21 result of chronic Nr enrichment has resulted in important community changes in vegetation,  
22 lichens, mycorrhizae, and phytoplankton, occasionally at relatively low levels of nitrogen  
23 deposition (3 to 8 kgN/ha/year; Baron et al., 2000).

24 Developments in recent decades in the Colorado Front range have resulted in increased  
25 nitrogen deposition since the 1980s at high-elevation sites. Total deposition values currently  
26 range from 4-8 kgN/ha/year (Baron et al., 2000). Competition among species resulting in  
27 changes in community composition is one of the most notable responses to environmental  
28 change (Bowman, 2000). Nitrogen saturation, the result of increased deposition in the alpine  
29 tundra of Niwot Ridge in the Front Range of the Southern Rockies in Colorado, has changed  
30 nitrogen cycling and provided the potential for replacement in plant species by more  
31 competitive, faster growing species (Bowman and Steltzer, 1998; Bowman, 2000; Baron et al.,

**Figure 4-17. Diagrammatic overview of excess nitrogen (N) in North America.**

Source: Fenn et al. (1998).

1 2000). Plants growing in an alpine tundra, as is true of other plants growing in low resource  
2 environments (e.g., infertile soil, shaded understory, deserts), have been observed to have certain  
3 similar characteristics: a slow grow rate, low photosynthetic rate, a low capacity for nutrient  
4 uptake and low soil microbial activity (Bowman and Steltzer, 1998; Bowman, 2000).

5 An important feature of such plants is that they continue to grow slowly and tend to respond  
6 even less when provided with an optimal supply and balance of resources (Pearcy et al., 1987;  
7 Chapin, 1991). Plants adapted to cold, moist environments grow more leaves than roots as the  
8 relative availability of nitrogen increases; however, other nutrients may soon become limiting.

9 These patterns of vegetative development affect their capacity to respond to variation in  
10 available resources and to environmental stresses such as frost, high winds, and drought.

11 Preformation of buds 3-4 years in advance of emergence, reduced cell numbers, and high  
12 biomass allocation to belowground organs also limits the ability of many alpine plants to  
13 respond to variations in their environment (Bowman, 2000). However, significant interspecific  
14 genetic variation influences the capacity of the alpine species to respond to changes in resource  
15 availability. The capacity of subalpine and boreal species in particular, and gymnosperms in  
16 general, to reduce nitrates in either roots or leaves appears to be limited. In addition, the ability  
17 of trees to use nitrogen varies with the age of the tree and the density of the stand (Waring,  
18 1987).

19 In experimental studies of nitrogen deposition conducted by Wedin and Tilman (1996)  
20 over a 12-year period on Minnesota grasslands, plots dominated by native warm-season grasses  
21 shifted to low-diversity mixtures dominated by cool-season grasses at all but the lowest rates of  
22 nitrogen addition. Grasslands with high nitrogen retention and carbon storage rates were the  
23 most vulnerable to loss of species and major shifts in nitrogen cycling. The shift to low-diversity  
24 mixtures was associated with the decrease in biomass carbon to nitrogen (C:N) ratios, increased  
25 nitrogen mineralization, increased soil nitrate, high nitrogen losses, and low carbon storage  
26 (Wedin and Tilman, 1996). Naeem et al. (1994) experimentally demonstrated under controlled  
27 environmental conditions that the loss of biodiversity, genetic resources, productivity, ecosystem  
28 buffering against ecological perturbation, and loss of aesthetic and commercially valuable  
29 resources also may alter or impair ecosystems services.

30 The long-term effects of increased nitrogen deposition have been studied in several  
31 western and central European plant communities these include lowland heaths, species-rich

1 grasslands, mesotrophic fens, ombrotrophic bogs, upland moors, forest-floor vegetation, and  
2 freshwater lakes (Bobbink, 1998). Large changes in species composition have been observed in  
3 regions with high nitrogen loadings or infield experiments after years of nitrogen addition  
4 (Bobbink et al., 1998). The increased input of nitrogen gradually increased the availability of  
5 nitrogen in the soil, and its retention because of low rates of leaching and denitrification resulted  
6 in faster litter decomposition and rate of mineralization. Faster growth and greater height of  
7 nitrophilic species enables these plants to shade out the slower growing species, particularly  
8 those in oligotrophic or mesotrophic conditions (Bobbink, 1998; Bobbink et al., 1998). Excess  
9 nitrogen inputs to unmanaged heathlands in the Netherlands has resulted in nitrophilous grass  
10 species replacing slower growing heath species (Roelofs et al., 1987; Garner, 1994).  
11 Van Breemen and Van Dijk (1988) noted that over the past several decades the composition of  
12 plants in the forest herb layers has been shifting toward species commonly found on nitrogen-  
13 rich areas. It also was observed that the fruiting bodies of mycorrhizal fungi had decreased in  
14 number.

15 Other studies in Europe point out the effects of excessive nitrogen deposition on mixed-oak  
16 forest vegetation along a deposition gradient largely controlled by soil acidity, nitrogen supply,  
17 canopy composition, and location of sample plots (Brunet et al., 1998; Falkengren-Grerup,  
18 1998). Results of the study, using multivariate methods, suggest that nitrogen deposition has  
19 affected the field-layer vegetation directly by increased nitrogen availability and, indirectly, by  
20 accelerating soil acidity. Time series studies indicate that 20 of the 30 field-layer species  
21 (nonwoody plants) that were associated most closely with high nitrogen deposition increased in  
22 frequency in areas with high nitrogen deposition during the past decades. Included in the field-  
23 layer species were many generally considered nitrophilous; however, there were several acid  
24 tolerant species (Brunet et al, 1998). In an experimental study involving 15 herbs and  
25 13 grasses, Falkengren-Grerup (1998), observed that species with a high nitrogen demand and a  
26 lesser demand for other nutrients were particularly competitive in areas with acidic soils and  
27 high nitrogen deposition. The grasses grew better than herbs with the addition of nitrogen. It  
28 was concluded that, at the highest nitrogen deposition, growth was limited for most species by  
29 the supply of other nutrients; and, at the intermediate nitrogen concentration, the grasses were  
30 more efficient than the herbs in utilizing nitrogen. Nihlgård (1985) suggested that excessive  
31 nitrogen deposition may contribute to forest decline in other specific regions of Europe.

1 Additionally, Schulze (1989), Heinsdorf (1993), and Lamersdorf and Meyer (1993) attribute  
2 magnesium deficiencies in German forests, in part, to excessive nitrogen deposition.

3 The carbon to nitrogen (C:N) ratio of the forest floor can also be changed by nitrogen  
4 deposition over time. This change appears to occur when the ecosystem becomes nitrogen  
5 saturated (Gundersen et al., 1998a). Long-term changes in C:N status have been documented in  
6 Central Europe and indicate that nitrogen deposition has changed the forest floor. In Europe,  
7 low C:N ratios coincide with high deposition regions (Gundersen et al., 1998a). A strong  
8 decrease in forest floor root biomass has been observed with increased nitrogen availability.  
9 Roots and the associated mycorrhizae appear to be an important factor in the accumulation of  
10 organic matter in the forest floor at nitrogen-limited sites. If root growth and mycorrhizal  
11 formation are impaired by nitrogen deposition, the stability of the forest floor may be affected by  
12 stimulating turnover and decreasing the root litter input to the forest floor and thus decrease the  
13 nitrogen that can be stored in the forest floor pool (Gundersen et al., 1998b). Nitrogen-limited  
14 forests have a high capacity for deposited nitrogen to be retained by plants and microorganisms  
15 competing for available nitrogen (Gundersen et al., 1998b). Nitrate leaching has been correlated  
16 significantly with nitrate status but not with nitrate depositions. Forest floor C:N ratio has been  
17 used as a rough indicator of ecosystem nitrogen status in mature coniferous forests and the risk  
18 of nitrate leaching; analyses of European databases indicated an empirical relationship between  
19 forest floor C:N ratio and nitrate leaching (Gundersen et al., 1998a). Nitrate leaching was  
20 observed when the deposition received was more than 10 kg N/ha. All of the data sets supported  
21 a threshold at which nitrate leaching seems to increase at a C:N ratio of 25. Therefore, to predict  
22 the rate of changes in nitrate leaching, it is necessary to be able to predict the rate of changes in  
23 the forest floor C:N ratio. Decreased foliar and soil nitrogen and soil C:N ratios, as well as  
24 changes in nitrogen mineralization rates, have been observed when comparing responses to  
25 nitrogen deposition in forest stands east and west of the Continental Divide in the Colorado  
26 Front Range (Baron et al., 2000; Rueth and Baron, 2002). Understanding the variability in forest  
27 ecosystem response to nitrogen input is essential in assessing pollution risks (Gundersen et al.,  
28 1998a).

29 The plant root is an important region of nutrient dynamics. The rhizosphere includes the  
30 soil that surrounds and is influenced by plant roots (Wall and Moore, 1999). The mutualistic  
31 relationship between plant roots, fungi, and microbes is critical for the growth of the organisms

1 involved. The plant provides shelter and carbon; whereas the symbiont provides access to  
2 limiting nutrients such as nitrogen and phosphorus. As indicated above, changes in soil nitrogen  
3 influence the mycorrhizal-plant relationship. Mycorrhizal fungal diversity is associated with  
4 above-ground plant biodiversity, ecosystem variability, and productivity (Wall and Moore,  
5 1999). Aber et al. (1998) showed a close relationship between mycorrhizal fungi and the  
6 conversion of dissolved inorganic nitrogen to soil nitrogen. During nitrogen saturation, soil  
7 microbial communities change from being fungal, and probably being dominated by  
8 mycorrhizae, to being dominated by bacteria. The loss of mycorrhizal function has been  
9 hypothesized as the key process leading to increased nitrification and nitrate mobility. Increased  
10 nitrate mobility leads to increased cation leaching and soil acidification (Aber et al., 1998).

11 The interrelationship of above- and below-ground flora is illustrated by the natural  
12 invasion of heathlands by oaks (*Quercus robur*). The soil-forming factors under the heath have  
13 been vegetation typed during the last 2000 years; whereas the invasion by oaks has been taking  
14 place for only a few decades. Clearly changes in the ground floor and soil morphology takes  
15 place when trees colonize heath (Nielsen et al., 1999). The distribution of roots also changed  
16 under the three different vegetation types. Under both heather and the Sitka spruce plantation,  
17 the majority of roots are confined to the uppermost horizons; whereas under oak, the roots are  
18 distributed more homogeneously. There was also a change in the C:N ratio when heather was  
19 replaced by oaks. Also, the spontaneous succession of the heath by oaks changed the biological  
20 nutrient cycle into a deeper vertical cycle when compared to the heath where the cycle is  
21 confined to the upper soil horizons. Soils similar to those described in this study (Jutland,  
22 Denmark) with mainly an organic buffer system seem to respond quickly to changes in  
23 vegetation (Nielsen et al., 1999).

24 The affects of changes in root to shoot relationships in plants were observed in studies of  
25 the coastal sage scrub (CSS) community in southern California which is composed of the  
26 drought-deciduous shrubs *Artemisia californica*, *Encelia farinosa*, and *Eriogonum fasciculatum*.  
27 The CSS in California has been declining in land area and in shrub density over the past 60 years  
28 and is being replaced in many areas by Mediterranean annual grasses (Allen et al., 1998; Padgett  
29 et al., 1999; Padgett and Allen, 1999). Nitrogen deposition was considered as a possible cause.  
30 Up to 45 kg/ha/yr are deposited in the Los Angeles Air Basin (Bytnerowicz and Fenn, 1996).  
31 Tracts of land set aside as reserves, which in many cases in southern California are surrounded

1 by urbanization, receive large amounts of nitrogenous compounds from polluted air. The CSS is  
2 of particular interest because some 200 sensitive plant species and several federally listed animal  
3 species are found in the area (Allen et al., 1998). Because changes in plant community structure  
4 often can be related to increases in the availability of a limiting soil nutrient or other resource,  
5 experiments were conducted to determine whether increased nitrogen availability was associated  
6 with the significant loss in native shrub cover. Studies indicated that the three native perennial  
7 shrubs (*Artemisia californica*, *Eriogonum fasciculatum*, and *Encelia farinosa*) tended to be more  
8 nitrophilous than the two exotic annual grasses (*Bromus rubens*, *Avena fatua*) and the weedy pod  
9 mustard (*Brassica geniculata*). These results contrast with most models dealing with the  
10 adaptation of perennial species to stressful environments (Padgett and Allen, 1999). If nitrogen  
11 were the only variable between the invasive annuals and native shrubs, neither shrubs nor  
12 grasses have a particular advantage. Although CSS shrubs are able to take up nitrogen at high  
13 rates, native grasses have a denser seedbank and earlier germination than native species. The  
14 native seedlings are not able to compete with dense stands of exotic grasses, and thus are  
15 gradually replaced by the grasses following disturbance such as frequent fire (Eliason and Allen,  
16 1997; Cione et al., 2002; Yoshida and Allen, 2001). In addition, nitrogen-induced changes in  
17 arbuscular mycorrhizal fungi may also affect the growth of native seedlings. Nitrogen  
18 enrichment of the soils induced a shift in the arbuscular mycorrhizal community composition.  
19 Larger-spored fungal species (*Scutellospora* and *Gigaspora*), due to a failure to sporulate,  
20 decreased in number with a concomitant proliferation of small-spored species of *Glomus*  
21 *aggregatum*, *G. leptotichum*, and *G. geosporum*, indicating a strong selective pressure for the  
22 smaller spores species of fungi (Edgerton-Warburton and Allen, 2000). These results  
23 demonstrate that nitrogen enrichment of the soil significantly alters the arbuscular mycorrhizal  
24 species composition and richness and markedly decreases the overall diversity of the arbuscular  
25 mycorrhizal community. The decline in coastal sage scrub species can, therefore, directly be  
26 linked to the decline of the arbuscular mycorrhizal community (Edgerton-Warburton and Allen,  
27 2000).

28 In addition to excess nitrogen deposition effects on terrestrial ecosystems of the types  
29 noted above (e.g., dominant species shifts and other biodiversity impacts), direct atmospheric  
30 nitrogen deposition and increased nitrogen inputs via runoff into streams, rivers, lakes, and  
31 oceans can noticeable affect aquatic ecosystems as well (Figure 4-15). Estuaries are among the

1 most intensely fertilized ecosystems on Earth, receiving far greater nutrient inputs than other  
2 systems. Chesapeake Bay is a prime example (Fenn et al., 1998). Another illustrative example  
3 is recently reported research (Paerl et al., 2001) characterizing the effects of nitrogen deposition  
4 on the Pamlico Sound, NC, estuarine complex, which serves as a key fisheries nursery  
5 supporting an estimated 80% of commercial and recreational finfish and shellfish catches in the  
6 southeastern U.S. Atlantic coastal region. Such direct atmospheric nitrogen deposition onto  
7 waterways feeding into the Pamlico Sound or onto the sound itself and indirect nitrogen inputs  
8 via runoff from upstream watersheds contribute to conditions of severe water oxygen depletion;  
9 formation of algae blooms in portions of the Pamlico Sound estuarine complex; altered fish  
10 distributions, catches, and physiological states; and increases in the incidence of disease. Under  
11 extreme conditions of especially high rainfall rate events (e.g., hurricanes) affecting watershed  
12 areas feeding into the sound, the effects of nitrogen runoff (in combination with excess loadings  
13 of metals or other nutrients) can be massive — e.g., creation of the widespread “dead-zone”  
14 affecting large areas of the Pamlico Sound for many months after hurricane Fran in 1996 and  
15 hurricanes Dennis, Floyd, and Irene in 1999 impacted eastern North Carolina.

16 The primary pathways of nitrogen loss from forest ecosystems are hydrological transport  
17 beyond the rooting zone into groundwater or stream water, or surface flows of organic nitrogen  
18 as nitrate and nitrogen loss associated with soil erosion (Fenn et al., 1998). Stream water nitrate  
19 concentrations have been related to forest successional stage in the eastern United States.  
20 Logging history and fire history of an area are major variables determining the capability of a  
21 forest stand to retain nitrogen. Nitrogen concentrations were high in manure ecosystems after  
22 disturbances such as clearcutting, but lower in mid-successional forests.

23 Nitrogen saturation of a high elevation watershed in the southern Appalachian Mountains  
24 was observed to affect stream water chemistry. High nitrate concentrations have been observed  
25 in streams draining undisturbed watersheds in the Great Smoky Mountains National Park in  
26 Tennessee and North Carolina. Nitrate concentrations were highest at higher elevations and in  
27 areas around old-growth forests that had never been logged (Fenn et al., 1998).

28 In the Northeast, nitrogen is the element most responsible for eutrophication in coastal  
29 waters of the region (Jaworski et al., 1997). There has been a 3 to 8-fold increase in nitrogen  
30 flux from 10 watersheds in the Northeastern United States since the early 1900s. These  
31 increases are associated with nitrogen oxide emissions from combustion which have increased

1 5-fold. Riverine nitrogen fluxes have been correlated with atmospheric deposition onto their  
2 landscapes and also with nitrogen oxides emissions into their airsheds. Data from 10 benchmark  
3 watersheds with good historical records, indicate that ca., 36-80% of the riverine total nitrogen  
4 export, with an average of 64%, was derived directly or indirectly from nitrogen oxide emissions  
5 (Jaworski et al., 1997).

6 Nitrogen saturation of a high elevation watershed in the southern Appalachian Mountains  
7 was observed to affect streamwater chemistry. The Great Smoky Mountains in the southeastern  
8 United States receive high total atmospheric deposition of sulfur and nitrogen (2,200 Eq/ha/yr of  
9 total sulfur and approximately 1,990 Eq/ha/yr of total nitrogen). A major portion of the  
10 atmospheric loading is from dry and cloud deposition. Extensive surveys conducted in October  
11 1993 and March 1994 indicated that stream pH values were near or below pH 5.5 and that the  
12 acid neutralizing capacity (ANC) was below 50  $\mu\text{eq/L}$  at high elevations. Analysis of  
13 streamwater indicated that nitrate was the dominant anion (Flum and Nodvin, 1995; Nodvin  
14 et al., 1995). The study was expanded to the watershed scale with monitoring of precipitation,  
15 thoughfall, stream hydrology, and stream chemistry. Nitrogen saturation of the watershed  
16 resulted in extremely high exports of nitrate and promoted both chronic and episodic stream  
17 acidification in which the nitrate was the dominant ion. Significant exports of base cation was  
18 also observed. Nitrification of the watershed soils resulted in elevations of soil solution  
19 aluminum concentrations to levels known to inhibit calcium uptake in red spruce (Nodvin et al.,  
20 1995).

21 Excessive nitrogen loss is a symptom of terrestrial ecosystem dysfunction and results in the  
22 degradation of water quality and potentially deleterious effects on terrestrial and aquatic  
23 ecosystems (Fenn and Poth, 1999). Data from a number of hydrologic, edaphic, and plant  
24 indicators indicate that the mixed conifer forests and chaparral systems directly exposed to air  
25 pollution from greater Los Angeles are nitrogen saturated. Preliminary data suggests that  
26 symptoms of nitrogen saturation are evident in mixed conifer or chaparral sites receiving  
27 atmospheric deposition of 20 to 25 kg/N/ha/y (Fenn et al, 1996). Available data clearly indicate  
28 that ecosystems with a Mediterranean climate have a limited capacity to retain nitrogen within  
29 the terrestrial system (Fenn and Poth, 1999). A 3-year study of streamwater  $\text{NO}_3^-$  concentrations  
30 along nitrogen deposition gradients in the San Bernardino Mountains in southern California  
31 evaluated streamwater quality and whether the streamwater concentrations covaried with

1 nitrogen deposition across pollution gradients in the San Bernardino Mountains. Streamwater  
2  $\text{NO}_3^-$  concentrations at Devil Canyon in the San Gabriel Mountains northeast of Los Angeles are  
3 the highest reported in North America for forested watersheds (Fenn and Poth, 1999). Five of  
4 the six streams monitored maintained elevated  $\text{NO}_3^-$  throughout the year. Peak nitrate  
5 concentrations ranged from 40 to 350  $\mu\text{mol/L}$ . In the San Gorgonio Wilderness, an area of low  
6 to moderate deposition where 12 streams were sampled, only the five that had the greatest air  
7 pollution exposure had high  $\text{NO}_3^-$  concentrations. The results of the study suggested a strong  
8 association between levels of  $\text{NO}_3^-$  export in streamwater and the severity of chronic nitrogen  
9 deposition to the terrestrial watersheds. However, nitrogen processing within terrestrial and  
10 aquatic systems, even in areas with high nitrogen deposition, determine streamwater  $\text{NO}_3^-$   
11 concentrations (Fenn and Poth, 1999). The Fernow Experimental Forest in West Virginia, the  
12 Great Smoky Mountains National park in Tennessee, and watersheds in southwestern  
13 Pennsylvania are the only undisturbed forested sites in North America known to have  
14 streamwater  $\text{NO}_3^-$  concentrations within the range of values found at Devil Canyon (Fenn and  
15 Poth, 1999).

16  
17 ***Effects of Sulfur Deposition.*** Sulfur is a major component of plant proteins and as such is  
18 an essential plant nutrient. The most important source of sulfur is sulfate taken up from the soil  
19 by plant roots even though plants can utilize atmospheric  $\text{SO}_2$  (Marschner, 1995). The  
20 availability of organically bound sulfur in soils depends largely on microbial decomposition, a  
21 relatively slow process. The major factor controlling the movement of sulfur from the soil into  
22 vegetation is the rate of release from the organic to the inorganic compartment (May et al., 1972;  
23 U.S. Environmental Protection Agency, 1982; Marschner, 1995). Sulfur plays a critical role in  
24 agriculture as an essential component of the balanced fertilizers needed to grow and increase  
25 worldwide food production (Ceccotti and Messick, 1997). Atmospheric deposition is an  
26 important component of the sulfur cycle. This is true not only in polluted areas where  
27 atmospheric deposition is very high, but also in areas of low sulfur input. Additions of sulfur  
28 into the soil in the form of  $\text{SO}_4^{2-}$  could alter the important organic-sulfur/organic-nitrogen  
29 relationship involved in protein formation in plants. The biochemical relationship between  
30 sulfur and nitrogen in plant proteins and the regulatory coupling of sulfur and nitrogen  
31 metabolism indicate that neither element can be assessed adequately without reference to the

1 other. Sulfur deficiency reduces nitrate reductase and, to a similar extent, also glutamine  
2 synthetase activity. Nitrogen uptake in forests, therefore, may be loosely regulated by sulfur  
3 availability, but sulfate additions in excess of needs do not necessarily lead to injury (Turner and  
4 Lambert, 1980; Hogan et al., 1998).

5 Only two decades ago, there was little information comparing sulfur cycling in forests with  
6 other nutrients, especially nitrogen. With the discovery of deficiencies in some unpolluted  
7 regions (Kelly and Lambert, 1972; Humphreys et al., 1975; Turner et al., 1977; Schnug, 1997)  
8 and excesses associated with acidic deposition in other regions of the world (Meiwes and  
9 Khanna, 1981; Shriner and Henderson, 1978; Johnson et al., 1982a,b), interest in sulfur nutrition  
10 and cycling in forests has heightened. General reviews of sulfur cycling in forests have been  
11 written by Turner and Lambert (1980), Johnson (1984), Mitchell et al. (1992a,b), and Hogan  
12 et al. (1998). The salient elements of the sulfur cycle as it may be affected by changing  
13 atmospheric deposition are summarized by Johnson and Mitchell (1998). Sulfur has become the  
14 most important limiting factor in European agriculture because of the desulfurization of  
15 industrial emissions (Schnug, 1997).

16 Most studies dealing with the effects of sulfur deposition on plant communities have been  
17 conducted in the vicinity of point sources and have investigated above-ground effects of SO<sub>2</sub> or  
18 acidifying effects of sulfate on soils (Krupa and Legge, 1998; Dreisinger and McGovern, 1970;  
19 Legge, 1980; Winner and Bewley, 1978a,b; Laurenroth and Michunas, 1985; U.S.  
20 Environmental Protection Agency, 1982). Krupa and Legge (1986), however, observed a  
21 pronounced increase in foliar sulfur concentrations in all age classes of needles of the hybrid  
22 pine lodgepole x jack pine (*Pinus contorta* x *P. banksiana*). This vegetation had been exposed to  
23 chronic low concentrations of sulfur dioxide (SO<sub>2</sub>) and hydrogen sulfide (H<sub>2</sub>S) for more than 20  
24 years and, then, to fugitive sulfur aerosol. Observations under the microscope showed no sulfur  
25 deposits on the needle surfaces and led to the conclusion that the sulfur in the needles was  
26 derived from the soil. The oxidation of elemental sulfur and the generation of protons is well  
27 known for the soils of Alberta, Canada. This process is mediated by bacteria of the *Thiobacillus*  
28 sp. As elemental sulfur gradually is converted to protonated SO<sub>4</sub>, it can be leached downward  
29 and readily taken up by plant roots. The activity of *Thiobacillus* sp. is stimulated by elemental  
30 sulfur additions (Krupa and Legge, 1986).

31

1            *Effects of Acidic Deposition on Forest Soils.* Acidic deposition over the past quarter of a  
2 century has emerged as a critical environmental stress that affects forested landscapes and  
3 aquatic ecosystems in North America, Europe, and Asia (Driscoll et al., 2001). Acidic  
4 deposition can originate from transboundary air pollution and affect large geographic areas. It is  
5 composed of ions, gases, particles derived from gaseous emissions of sulfur dioxide (SO<sub>2</sub>),  
6 nitrogen oxides (NO<sub>x</sub>), ammonia (NH<sub>3</sub>), and particulate emissions of acidifying and neutralizing  
7 compounds and is highly variable across space and time. It links air pollution to diverse  
8 terrestrial and aquatic ecosystems and alters the interactions of the hydrogen ion (H<sup>+</sup>) and many  
9 elements (e.g., sulfur, nitrogen, calcium, magnesium, aluminum, and mercury). Acidic  
10 deposition contributes directly and indirectly to biological stress and the degradation of  
11 ecosystems and has played a major role in recent acidification of soil in some areas of Europe  
12 and, to a more limited extent, eastern North America (Driscoll et al., 2001).

13            Substantial and previously unsuspected changes in soils have been observed in polluted  
14 areas of eastern North America, the United Kingdom, Sweden, and Central Europe and in less  
15 polluted regions of Australia and western North American (reviewed by Johnson et al., 1999 and  
16 by Huntington, 2000). In some cases, trends were toward more acidic soils (e.g., Markewitz  
17 et al., 1998), and, in others, there were no consistent trends, with some soils showing increases  
18 and some showing decreases at different sampling times, and some showing no change (e.g.,  
19 Johnson and Todd, 1998; Trettin et al., 1999; Yanai et al., 1999).

20            Significant changes in soil chemistry have occurred at many sites in the eastern United  
21 States during recent decades. Patterns of change in tree ring chemistry, principally at high  
22 elevations sites in the eastern United States, reflect the changing inputs of regional pollutants to  
23 forests. A temporal sequence of changes in uptake patterns, and possibly in tree growth, would  
24 be expected if significant base cation mobilization and depletion of base cations from eastern  
25 forest soils has occurred. Temporal changes in the chemistry of tree rings of red spruce were  
26 examined as indicators of historical changes in the chemical environment of red spruce.

27            Analysis of changes in wood chemistry from samples across several sites indicated that  
28 there have been substantial departures from the expected linear decreases in calcium  
29 accumulation patterns in wood. A region-wide calcium increase above expected levels followed  
30 by decreasing changes in wood calcium suggest that calcium mobilization began possibly 30 to  
31 40 years ago and has been followed by reduced accumulation rates in wood, presumably

1 associated with decreasing calcium availability in soil (Bondiotti and McLaughlin, 1992). The  
2 period of calcium mobilization coincides with a region-wide increase in growth rate of red  
3 spruce; whereas the period of decreasing levels of calcium in wood corresponds temporally with  
4 patterns of decreasing radial growth at high elevation sites throughout the region during the past  
5 20 to 30 years. The decline in wood calcium suggests that calcium loss may have increased to  
6 the point at which base saturation of soils has been reduced. Increases in aluminum and iron  
7 typically occur as base cations are removed from the soils by tree uptake (Bondiotti and  
8 McLaughlin, 1992). The changes are spatially and temporally consistent with changes in the  
9 emissions of SO<sub>2</sub> and NO<sub>2</sub> across the region and suggest that increased acidification of soils has  
10 occurred.

11 Studies by Shortle and Bondiotti (1992) support the view that changes in soil chemistry in  
12 eastern North America forest sites occurred many decades ago, “before anybody was looking.”  
13 Sulfur and nitrogen emissions began increasing in eastern North America in the 1920s and  
14 continued to increase into the 1980s when sulfur began to decrease but nitrogen emissions did  
15 not (Garner et al., 1989). Shortle and Bondiotti (1992) present evidence that, from the late 1940s  
16 into the 1960s, the mor humus (organic) layer of acid-sensitive forest sites in eastern North  
17 America underwent a significant change that resulted in the loss of exchangeable essential base  
18 cations and interrupted the critical base nutrient cycles between mature trees and the root-humus  
19 complex. The timing of the effect appears to have coincided with the period when the SO<sub>x</sub> and  
20 NO<sub>x</sub> emissions in eastern North America subject to long-range transport were increasing the  
21 most rapidly (see above; Shortle and Bondiotti, 1992). Although forest ecosystems other than  
22 the high-elevation spruce-fir forests are not currently manifesting symptoms of injury directly  
23 attributable to acid deposition, less sensitive forests throughout the United States are  
24 experiencing gradual losses of base cation nutrients, which in many cases will reduce the quality  
25 of forest nutrition over the long term (National Science and Technology Council, 1998).  
26 In some cases it may not even take decades because these forests already have been receiving  
27 sulfur and nitrogen deposition for many years. The current status of forest ecosystems in  
28 different U.S. geographic regions varies, as does their sensitivity to nitrogen and sulfur  
29 deposition. Variation in potential future forest responses or sensitivity are caused, in part, by  
30 differences in deposition of sulfur and nitrogen, ecosystem sensitivities to sulfur and nitrogen

1 additions, and responses of soils to sulfur and nitrogen inputs (National Science and Technology  
2 Council, 1998).

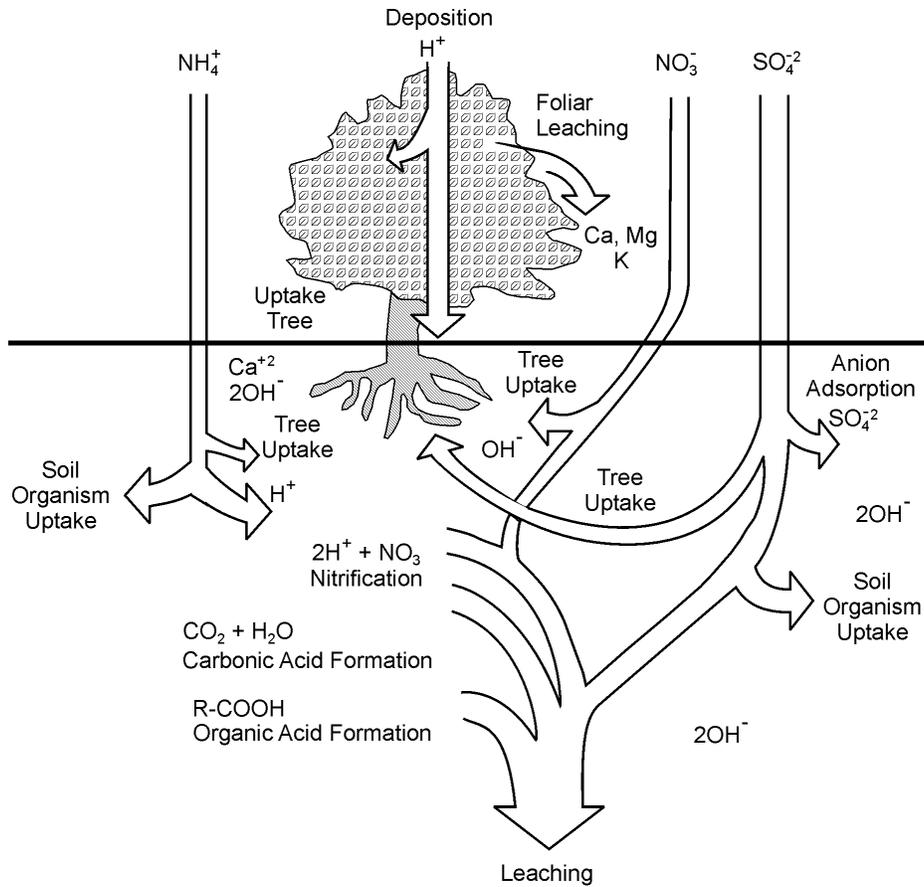

3 Acidic deposition has played a major role in recent soil acidification in some areas of  
4 Europe and, to a more limited extent, eastern North America. Examples include the study by  
5 Hauhs (1989) at Lange Bramke, Germany, which indicated that leaching was of major  
6 importance in causing substantial reduction in soil-exchangeable base cations over a 10-year  
7 period (1974-1984). Soil acidification and its effects result from the deposition of nitrate ( $\text{NO}_3^-$ )  
8 and sulfate ( $\text{SO}_4^{2-}$ ) and the associated hydrogen ( $\text{H}^+$ ) ion. The effects of excessive nitrogen  
9 deposition on soil acidification and nutrient imbalances have been well established in Dutch  
10 forests (Van Breemen et al., 1982; Roelofs et al., 1985; Van Dijk and Roelofs, 1988).  
11 For example, Roelofs et al. (1987) proposed that  $\text{NH}_3/\text{NH}_4^+$  deposition leads to heathland  
12 changes via two modes: acidification of the soil and the loss of cations  $\text{K}^+$ ,  $\text{Ca}^{+2}$ , and  $\text{Mg}^{+2}$ ; and  
13 nitrogen enrichment that results in “abnormal” plant growth rates and altered competitive  
14 relationships. Nihlgård (1985) suggested that excessive nitrogen deposition may contribute to  
15 forest decline in other specific regions of Europe. Falkengren-Grerup (1987) noted that, during  
16 about 50 years, unexpectedly large increases in growth of beech (*Fagus sylvatica* L.) were  
17 associated with decreases in pH and exchangeable cations in some sites in southernmost Sweden.

18 Likens et al. (1996, 1998) suggested that soils are changing at the Hubbard Brook  
19 Watershed, NH, because of a combination of acidic deposition and reduced base cation  
20 deposition. They surmised, based on long-term trends in streamwater data, that large amounts of  
21 calcium and magnesium have been lost from the soil-exchange complex over a 30-year period  
22 from approximately 1960 to 1990. The authors speculate that the declines in base cations in  
23 soils may be the cause of recent slowdowns in forest growth at Hubbard Brook. In a follow-up  
24 study, however, Yanai et al. (1999) found no significant decline in calcium and magnesium  
25 concentrations in forest floors at Hubbard Brook over the period 1976 to 1997. They also found  
26 both gains and losses in forest floor calcium and magnesium between 1980 and 1990 in a  
27 regional survey. Thus, they concluded that “forest floors in the region are not currently  
28 experiencing rapid losses of base cations, although losses may have preceded the onset of these  
29 three studies.” The biogeochemistry of calcium at Hubbard Brook is discussed in detail by  
30 Likens et al. (1998).

1 Hydrogen ions entering a forest ecosystem first encounter the forest canopy, where they  
2 are often exchanged for base cations that then appear in throughfall (Figure 4-18 depicts a model  
3 of  $H^+$  sources and sinks). Base cations leached from the foliage must be replaced through uptake  
4 from the soil, or foliage cations will be reduced by the amounts leached. In the former case, the  
5 acidification effect is transferred to the soil where  $H^+$  is exchanged for a base cation at the  
6 root-soil interface. Uptake of base cations or  $NH_4^+$  by vegetation or soil microorganisms causes  
7 the release of  $H^+$  in order to maintain charge balance; uptake of nutrients in anionic form ( $NO_3^-$ ,  
8  $SO_4^{2-}$ ,  $PO_4^{3-}$ ) causes the release of  $OH^-$  in order to maintain charge balance. Thus, the net  
9 acidifying effect of uptake is the difference between cation and anion uptake. The form of ions  
10 taken up is known for all nutrients but nitrogen because either  $NH_4^+$  or  $NO_3^-$  can be utilized.  
11 In that nitrogen is a nutrient taken up in greatest quantities, the uncertainty in the ionic form of  
12 nitrogen utilized creates great uncertainty in the overall  $H^+$  budget for soils (Johnson 1992).

13 The cycles of base cations differ from those of N, P, and S in several respects. The fact  
14 that calcium, potassium, and magnesium exist primarily as cations in solution, whereas N, P, and  
15 S exist primarily as anions, has major implications for the cycling of the nutrients and the effects  
16 of acid deposition on these cycles. The most commonly accepted model of base cation cycling  
17 in soils is one in which base cations are released by weathering of primary minerals to cation  
18 exchange sites where they are available for either plant uptake or leaching (Figure 4-18). The  
19 introduction of  $H^+$  by atmospheric deposition or by internal processes will affect the fluxes of  
20 Ca, K, and Mg via cation exchange or weathering processes. Therefore, soil leaching is often of  
21 major importance in cation cycles, and many forest ecosystems show a net loss of base cations  
22 (Johnson, 1992).

23 Two basic types of soil change are involved: (1) a short-term intensity type change  
24 resulting from the concentrations of chemicals in soil water and (2) a long-term capacity change  
25 based on the total content of bases, aluminum, and iron stored in the soil (Reuss and Johnson,  
26 1986; Van Breemen et al., 1983). Changes in intensity factors can have a rapid affect on the  
27 chemistry of soil solutions. Increases in the amounts of sulfur and nitrogen in acidic deposition  
28 can cause immediate increases in acidity and mobilization of aluminum in soil solutions.  
29 Increased aluminum concentrations and an increase in the Ca/Al ratio in soil solution have been  
30 linked to a significant reduction in the availability of essential base cations to plants, an increase  
31

**Figure 4-18. Schematic of sources and sinks of hydrogen ions in a forest (from Taylor et al., 1994).**

1 in plant respiration, and increased biochemical stress (National Science and Technology Council,  
 2 1998).

3 Rapid changes in intensity resulting from the addition of increased amounts of nitrogen or  
 4 sulfur in acidic deposition can have a rapid effect on the chemistry of soil solutions by increasing  
 5 the acidity and mobilizing aluminum. Increased concentrations of aluminum and an increase in  
 6 the ratio of calcium to aluminum in soil solution have been linked to a significantly reduced  
 7 availability of essential cations to plants.

8 Capacity changes are the result of many factors acting over long time periods. The content  
 9 of base cations (calcium, magnesium, sodium, and potassium) in soils results from additions  
 10 from the atmospheric deposition, decomposition of vegetation, and geologic weathering. Loss of

1 base cations may occur through plant uptake and leaching. Increased leaching of base cations  
2 may result in nutrient deficiencies in soils as has been happening in some sensitive forest  
3 ecosystems (National Science and Technology Council, 1998).

4 Aluminum toxicity is a possibility in acidified soils. Atmospheric deposition (or any other  
5 source of mineral anions) can increase the concentration of Al, especially  $Al^{3+}$ , in soil solution  
6 without causing significant soil acidification (Johnson and Taylor, 1989). Aluminum can be  
7 brought into soil solution in two ways: (1) by acidification of the soil and (2) by an increase in  
8 the total anion and cation concentration of the soil solution. The introduction of mobile, mineral  
9 acid anions to an acid soil will cause increases in the concentration of aluminum in the soil  
10 solution, but extremely acid soils in the absence of mineral acid anions will not produce a  
11 solution high in aluminum. An excellent review of the relationships among the most widely  
12 used cation-exchange equations and their implications for the mobilization of aluminum into soil  
13 solution is provided by Reuss (1983).

14 A major concern has been that soil acidity would lead to nutrient deficiency. Calcium is  
15 essential for root development and the formation of wood, and it plays a major role in cell  
16 membrane integrity and cell wall structure. Aluminum concentrations in the soil can influence  
17 forest tree growth in regions where acidic deposition and natural acidifying processes increase  
18 soil acidity. Acidic deposition mobilizes calcium and magnesium, which are essential for root  
19 development and stem growth. Mobilized aluminum can also bind to fine root tips of red spruce,  
20 further limiting calcium and magnesium uptake (Shortle and Smith, 1988; Shortle et al., 1997).

21 There is abundant evidence that aluminum is toxic to plants. Upon entering tree roots, it  
22 accumulates in root tissues (Thornton et al., 1987; Vogt et al., 1987a, b). Reductions in calcium  
23 uptake have been associated with increases in aluminum uptake (Clarkson and Sanderson, 1971).  
24 A number of studies suggest that the toxic effect of aluminum on forest trees could be caused by  
25  $Ca^{+2}$  deficiency (Shortle and Smith, 1988; Smith, 1990a). Mature trees have a high calcium  
26 requirement relative to agriculture crops (Rennie, 1955). Shortle and Smith (1988) attributed the  
27 decline of red spruce in eight stands across northern New England from Vermont to Maine to an  
28 imbalance of  $Al^{3+}$  and  $Ca^{+2}$  in fine root development.

29 To be taken up from the soil by roots, calcium must be dissolved in soil water (Lawrence  
30 and Huntington, 1999). Aluminum in soil solution reduces calcium uptake by competing for  
31 binding sites in the cortex of fine roots. Tree species may be adversely affected if high

1 aluminum to nutrient ratios create a nutrient deficiency by limiting uptake of calcium and  
2 magnesium (Shortle and Smith, 1988; Garner, 1994). Acid deposition, by lowering the pH of  
3 aluminum-rich soil, can increase aluminum concentrations in soil water through dissolution and  
4 ion exchange processes. Aluminum is more readily taken up than is calcium because of its  
5 greater affinity for negatively charged surfaces. When present in the forest floor, aluminum  
6 tends to displace adsorbed calcium and causes it to be more readily leached. The continued  
7 buildup of aluminum in the forest floor layer, where nutrient uptake is greatest, can lower  
8 efficiency of calcium uptake when the ratio of calcium to aluminum in soil water is less than one  
9 (Lawrence and Huntington, 1999). Reduction in calcium uptake suppresses cambial growth and  
10 reduces the rate of wood (annual ring) formation, decreases the amount of functional sapwood  
11 and live crown, and predisposes trees to disease and injury from stress agents when the  
12 functional sapwood becomes less than 25% of cross-sectional stem area (Smith, 1990a). A 1968  
13 Swedish report to the United Nations postulated a decrease in forest growth of ca., 1.5% per year  
14 when the ratio of calcium to aluminum in soil water is less than one (Lawrence and Huntington,  
15 1999). The concern that acidification and nutrient deficiency may result in forest decline  
16 remains today.

17       Acidic deposition has been firmly implicated as a causal factor in the northeastern high-  
18 elevation decline of red spruce (DeHayes et al., 1999). The frequency of freezing injury of red  
19 spruce has increased over the past 40 years, a period that coincides with increase emissions of  
20 sulfur and nitrogen oxides and acidic deposition (DeHayes et al., 1999). Studies indicate that  
21 there is a significant positive association between cold tolerance and foliar calcium in trees  
22 exhibiting deficiency in foliar calcium. Most of the calcium in conifer needles is insoluble  
23 calcium oxalate and pectate crystals, which are of little physiological importance. It is the labile  
24 calcium ions in equilibrium within the plasma membrane that are of major physiological  
25 importance (DeHayes et al., 1999). The membrane-associated pool of calcium (mCa), although  
26 a relatively small fraction of total foliar ion pools, strongly influences the response of cells to  
27 changing environmental conditions. The plant plasma membrane plays a critical role in  
28 mediating cold acclimation and low-temperature injury. Leaching of calcium associated with  
29 acidic deposition is considered to be the result of cation exchange due to exposure to the H<sup>+</sup> ion.  
30 The studies of DeHayes et al. (1999) demonstrate that the direct deposition of acidic deposition  
31 on needles represents a unique environmental stress, in that it preferentially removes mCa which

1 is not readily replaced in autumn. They propose that direct deposition on red spruce foliage  
2 preferentially displaces calcium ions specifically associated with plasma membranes of  
3 mesophyll cells resulting in the reduction of mCa and the destabilizing of plasma membranes  
4 and depletion of messenger calcium. Further, DeHayes et al. (1999) state that their studies raise  
5 the strong possibility that acid rain alteration of the mCa and membrane integrity is not unique to  
6 red spruce but has been demonstrated in many other northern temperate forest tree species  
7 including yellow birch (*Betula alleghaniensis*), white spruce (*Picea glaucus*), red maple (*Acer*  
8 *rubrum*) eastern white pine (*Pinus strobus*), and sugar maple (*Acer saccharum*). Assessments of  
9 mCa, membrane integrity, and the effects of other secondary stresses have not yet been made for  
10 these species.

11 Seasonal and episodic acidification of surface waters have been observed in the eastern  
12 United States, Canada and Europe (Hyer et al., 1995). In the Northeast, the Shenandoah  
13 National Park in Virginia, and the Great Smoky Mountains, episodic acidification has been  
14 associated with the nitrate ion (Driscoll et al., 2001; Hyer et al., 1995 ; Eshleman et al., 1995).  
15 The short-term acid episodes occur during spring snowmelts and large precipitation events  
16 (Driscoll et al., 2001). Episodic acidification of surface waters has usually been considered to be  
17 a transient loss of acid neutralizing capacity associated with snowmelt/rainfall runoff and, as  
18 such, represents short-term (hours to weeks) effects considered to be distinguishable from  
19 chronic long-term (years to centuries) changes in acidity. Studies of both episodic and chronic  
20 acidification of surface waters indicate that acidification can have long-term adverse effects on  
21 fish populations, declines of species richness, abundance of zooplankton, and macroinvertebrates  
22 (Driscoll et al., 2001; Eshleman et al., 1995). Nitrogen saturation of soils and the slow release of  
23 nitrates inhibited the recovery of acid sensitive systems (Driscoll et al., 2001). The acidification  
24 of aquatic ecosystems and effects on aquatic biota are discussed in more detail in the EPA  
25 document Air Quality Criteria for Nitrogen Oxides (U.S. Environmental Protection Agency,  
26 1993).

27 Air pollution is not the sole cause of soil change. High rates of acidification are occurring  
28 in less polluted regions of the western United States and Australia because of internal soil  
29 processes, such as tree uptake of nitrate and nitrification associated with excessive nitrogen  
30 fixation (Johnson et al., 1991b). Many studies have shown that acidic deposition is not a  
31 necessary condition for the presence of extremely acidic soils, as evidenced by their presence in

1 unpolluted, even pristine, forests of the northwestern United States and Alaska (Johnson et al.,  
2 1991b). Soil can become acidic when  $H^+$  ions attached to  $NH_4^+$  or  $HNO_3$  remain in the soil after  
3 nitrogen is taken up by plants. For example, Johnson et al. (1982b) found significant reductions  
4 in exchangeable  $K^+$  over a period of only 14 years in a relatively unpolluted Douglas fir  
5 Integrated Forest Study (IFS) site in the Washington Cascades. The effects of acid deposition at  
6 this site were negligible relative to the effects of natural leaching (primarily carbonic acid) and  
7 nitrogen tree uptake (Cole and Johnson, 1977). Even in polluted regions, numerous studies have  
8 shown the importance of tree uptake of  $NH_4^+$  and  $NO_3^-$  in soil acidification. Binkley et al. (1989)  
9 attributed the marked acidification (pH decline of 0.3 to 0.8 units and base saturation declines of  
10 30 to 80%) of abandoned agricultural soil in South Carolina over a 20-year period to  $NH_4^+$  and  
11  $NO_3^-$  uptake by a loblolly pine plantation.

12 An interesting example of uptake effects on soil acidification is that of Al uptake and  
13 cycling (Johnson et al., 1991b). Aluminum accumulation in the leaves of coachwood  
14 (*Ceratopetalum apetalum*) in Australia has been found to have a major effect on the distribution  
15 and cycling of base cations (Turner and Kelly, 1981). The presence of *C. apetalum* as a  
16 secondary tree layer beneath brush box (*Lophostemon confertus*) was found to lead to increased  
17 soil exchangeable  $Al^{3+}$  and decreased soil exchangeable  $Ca^{2+}$  (Turner and Kelly, 1981). The  
18 constant addition of aluminum-rich litter fall obviously has had a substantial effect on soil  
19 acidification, even if base cation uptake is not involved directly.

20 Given the potential importance of particulate deposition for base cation status of forest  
21 ecosystems, the findings of Driscoll et al. (1989, 2001) and Hedin et al. (1994) are especially  
22 relevant. Driscoll et al. (1989, 2001) noted a decline in both  $SO_4^{-2}$  and base cations in both  
23 atmospheric deposition and stream water over the past two decades at Hubbard Brook  
24 Watershed, NH. The decline in  $SO_4^{-2}$  deposition was attributed to a decline in emissions, and the  
25 decline in stream water  $SO_4^{-2}$  was attributed to the decline in sulfur deposition. Hedin et al.  
26 (1994) reported a steep decline in atmospheric base cation concentrations in both Europe and  
27 North America over the past 10 to 20 years. The reductions in  $SO_2$  emissions in Europe and  
28 North America in recent years have not been accompanied by equivalent declines in net acidity  
29 related to sulfate in precipitation. These current declines in sulfur deposition have, to varying  
30 degrees, been offset by declines in base cations and may be contributing “to the increased  
31 sensitivity of poorly buffered systems.” Analysis of the data from the IFS supports the authors’

1 contention that atmospheric base cation inputs may seriously affect ecosystem processes.  
2 Johnson et al. (1994) analyzed base cation cycles at the Whiteface Mountain IFS site in detail  
3 and concluded that Ca losses from the forest floor were much greater than historical losses,  
4 based on historical changes in forest floor Ca observed in an earlier study. Further, the authors  
5 suggested that the difference between historical and current net loss rates of forest floor Ca may  
6 be caused by sharply reduced atmospheric inputs of calcium after about 1970 and may be  
7 exacerbated by sulfate leaching (Johnson et al., 1994b).

8 The calcium/aluminum molar ratio has been suggested as a valuable ecological indicator of  
9 an approximate threshold beyond which the risk of forest injury from Al stress and nutrient  
10 imbalances increases (Cronan and Grigal, 1995). The Ca/Al ratio also can be used as an  
11 indicator to assess forest ecosystem changes over time in response to acidic deposition, forest  
12 harvesting, or other process that contribute to acid soil infertility. This ratio, however, may not  
13 be a reliable indicator of stress in areas with both high atmospheric deposition of ammonium and  
14 magnesium deficiency via antagonism involving ammonium rather than aluminum and in areas  
15 with soil solutions with calcium concentrations greater than 500 micromoles per liter (National  
16 Science and Technology Council, 1998). Cronan and Grigal (1995), based on a review of the  
17 literature, have made the following estimates for determining the effects of acidic deposition on  
18 tree growth or nutrition:

- 19 • forests have a 50% risk of adverse effects if the Ca/Al ration is 1.0,
- 20 • the risk is 75% if the ratio is 0.5, and
- 21 • the risk approaches 100% if the ratio is 0.2.

22 The Ca/Al ratio of soil solution provides only an index of the potential for Al stress. Cronan and  
23 Grigal (1995) state that the overall uncertainty of the Ca/Al ratio associated with a given  
24 probability ratio is considered to be approximately  $\pm 50\%$ . Determination of thresholds for  
25 potential forest effects requires the use of the four successive measurement endpoints in the soil,  
26 soil solution, and plant tissue listed below.

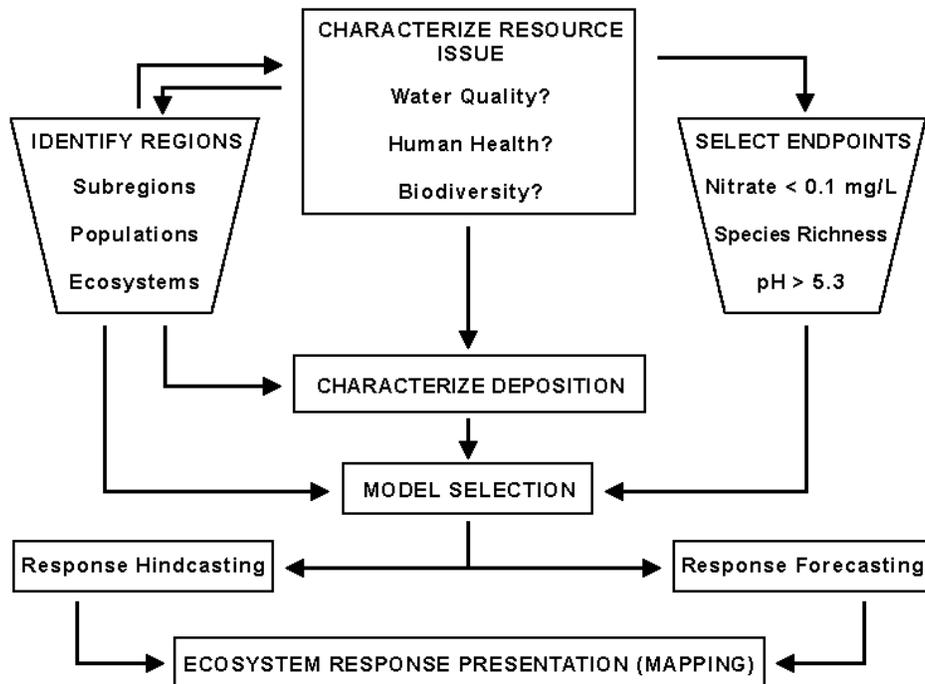

- 27 (1) Soil base saturation less than 15% of effective cation exchange capacity,
- 28 (2) Soil solution Ca/Al molar ratio less than 1.0 for 50% risk,
- 29 (3) Fine roots tissue Ca/Al molar ratio less than 0.2 for 50% risk, and
- 30 (4) Foliar tissue Ca/Al molar ratio less than 12.5 for 50% risk.

1 The application of the Ca/Al ratio indicator for assessment and monitoring of forest health risks  
2 has been recommended for sites or in geographic regions where the soil base saturation < 15%.

3  
4 **Critical Loads.** The critical loads framework for assessing the effects of atmospheric  
5 deposition originated in Europe where the concept has generally been accepted as the basis for  
6 abatement strategies to reduce or prevent injury to the functioning and vitality of forest  
7 ecosystems caused long-range transboundary chronic acidic deposition (Lokke et al., 1996). The  
8 critical load has been defined as a “quantitative estimate of an exposure to one or more  
9 pollutants below which significant harmful effects on specified sensitive elements of the  
10 environment do not occur according to present knowledge” (Lokke et al., 1996).

11 The concept is useful for estimating the amounts of pollutants that sensitive ecosystems  
12 can absorb on a sustained basis without experiencing measurable degradation. The response to  
13 pollutant deposition of an ecosystem is a direct function of the level of sensitivity of the  
14 ecosystem to the pollutant and its capability to ameliorate change. The estimation of ecosystem  
15 critical loads requires an understanding of how an ecosystem will respond to different loading  
16 rates in the long term. The approach can be of special value for ecosystems receiving chronic  
17 deposition of pollutants such as nitrogen and sulfur. A program was designed to develop and  
18 evaluate a framework for setting critical loads of nitrogen and sulfur in the United States in 1989  
19 (Strickland et al., 1993). A flexible six step approach has been outlined for use with the critical  
20 load framework (Figure 4-19). These are (1) selection of ecosystem components, indicators, and  
21 characterization of the resource; (2) definition of the functional subregions; (3) characterization  
22 of deposition within each of the subregions; (4) definition of an assessment endpoint;  
23 (5) selection and application of models; and (6) mapping projected ecosystem responses. The  
24 approach permits variability in ecosystem characteristic and data availability (Strickland et al.,  
25 1993).

26 Ecological endpoints or indicators are measurable characteristics related to the structure,  
27 composition, or functioning of ecological systems (i.e., indicators of condition). One or more  
28 measurable endpoints are associated with each element in Table 4-1. These assessment  
29 endpoints represent a formal expression of the environmental value that is to be protected. If the  
30 assessment endpoint is to be used as a regulatory limit, it should be socially relevant. Selection  
31 of a specific ecosystem for study will depend on the severity of the problem of concern for a

**Figure 4-19. Key elements of proposed framework for determining critical loads for nitrogen and sulfur in the United States.**

Source: Strickland et al. (1993).

1 region. Time scales of response must be considered in selecting and evaluating ecosystem  
 2 response(s) to changes in atmospheric deposition. Responses of aquatic ecosystems to  
 3 depositions can occur quickly. Surface water acidification associated with nitrate leaching  
 4 should respond to decreases in nitrogen loading in a short period of time. However, changes in  
 5 growth responses of vegetation resulting from soil nutrient imbalances may require years or  
 6 decades to detect. The focus of concern should be the populations within an ecosystem that are  
 7 sensitive to nitrogen and sulfur deposition (Hunsaker et al., 1993).

8 Biogeochemicals as indicators for monitoring forest nitrogen status have been proposed by  
 9 Fenn and Poth (1998). Because nitrogen is a major constituent of all forms of life and is cycled  
 10 through a complex web of processes involving many biotic and abiotic mechanisms, evaluating  
 11 forest nitrogen status is a challenge. Indicators of ecosystems at risk of nitrogen saturation  
 12 should include those that can be identified when nitrogen availability exceeds biotic demand.

1 Such indicators typically should monitor parameters that are normally at background or low  
2 levels in nitrogen-limited systems and should be those that commonly respond to excess nitrogen  
3 in a wide range of ecosystems (Fenn and Poth, 1998). Such indicators include foliar nitrogen;  
4 nutrient ratios (N:P,N:cation); foliar nitrate; foliar  $\delta^{15}\text{N}$ ; arginine concentration; soil C:N ratio;  
5  $\text{NO}_3^-$  in soil extracts or in soil solution; and flux rates of nitrogenous trace gasses from soil (Fenn  
6 et al., 1998). The cardinal indicator or manifestation of nitrogen saturation in all ecosystem  
7 types, including California forests and chaparral, is increased and prolonged  $\text{NO}_3^-$  loss below the  
8 main rooting zone and in stream water. Seasonal patterns of stream water nitrate concentrations  
9 are especially good indicators of watershed nitrogen status (see sections on nitrate, sulfur and  
10 acidic deposition; Fenn and Poth, 1998).

11 In Europe, the elements used in the critical load concept are: a biological indicator, a  
12 chemical criterion, and a critical value. The biological indicator is the organism used to indicate  
13 the status of the receptor ecosystem; the chemical criterion is the parameter that results in harm  
14 to the biological indicator; and the critical value is the value of the chemical criterion below  
15 which no significant harmful response occurs to the biological indicator (Lokke et al., 1996).  
16 Trees, and sometimes other plants, are used as the biological indicators in the case of critical  
17 loads for forests. The critical load calculation using the current methodology, is essentially an  
18 acidity/alkalinity mass balance calculation. The chemical criterion must be expressible in terms  
19 of alkalinity. Initially, the Ca/Al ratio was used; but, recently, the (Ca+Mg+K)/Al ratio has been  
20 used (Lokke et al., 1996).

21 Ideally, changes in acidic deposition should result in changes in the status of the biological  
22 indicator used in the critical load calculation. However, the biological indicator is the integrated  
23 response to a number of different stresses. Furthermore, there are other organisms more  
24 sensitive to acid deposition than trees. At high concentrations,  $\text{Al}^{+3}$  is known to be toxic to  
25 plants, inhibiting root growth and, ultimately, plant growth and performance (Lokke et al., 1996;  
26 National Science and Technology Council, 1998). Sensitivity to Al varies considerably between  
27 species and within species because of changes in nutritional demands and physiological status  
28 that are related to age and climate. Experiments have shown that there are large variations in Al  
29 sensitivity, even among ecotypes.

30 Mycorrhizal fungi as possible biological indicators have been suggested by Lokke et al.  
31 (1996) because they are intimately associated with tree roots, depend on plant assimilates, and

1 play an essential role in plant nutrient uptake influencing the ability of their host plants to  
2 tolerate different anthropogenically generated stresses. Mycorrhizas and fine roots are an  
3 extremely dynamic component of below-ground ecosystems and can respond rapidly to stress.  
4 They have a relatively short life span, and their turnover appears to be strongly controlled by  
5 environmental factors. Changes in mycorrhizal species composition or the loss of dominant  
6 mycorrhizal species in areas where diversity is already low may lead to increased susceptibility  
7 of plant to stress (Lokke et al., 1996). Stress affects the total amount of carbon fixed by plants  
8 and modifies carbon allocation to biomass, symbionts, and secondary metabolites. The  
9 physiology of carbon allocation has also been suggested as an indicator of anthropogenic stress  
10 (Andersen and Rygiewicz, 1991). Because mycorrhizal fungi are dependent for their growth on  
11 the supply of assimilates from the host plants, stresses that shift the allocation of carbon reserves  
12 to the production of new leaves at the expense of supporting tissues will be reflected rapidly in  
13 decreased fine root and mycorrhizal biomass (Winner and Atkinson, 1986). Decreased carbon  
14 allocation to roots also affects soil carbon and rhizosphere organisms. Soil dwelling animals are  
15 important for decomposition, soil aeration, and nutrient redistribution in the soil. They  
16 contribute to decomposition and nutrient availability mainly by increasing the accessibility of  
17 dead plant material to microorganisms. Earthworms decrease in abundance and in species  
18 number in acidified soils (Lokke et al., 1996).

19  
20 ***Effects of Wet and Dry Deposition on Biogeochemical Cycling — The Integrated Forest***  
21 ***Study.*** The Integrated Forest Study (IFS; Johnson and Lindberg, 1992a) has provided the most  
22 extensive data set available on wet and dry deposition and deposition effects on the cycling of  
23 elements in forest ecosystems. The overall patterns of deposition and cycling have been  
24 summarized by Johnson and Lindberg (1992a), and the reader is referred to that reference for  
25 details. The following is a summary of particulate deposition, total deposition, and leaching in  
26 the IFS sites.

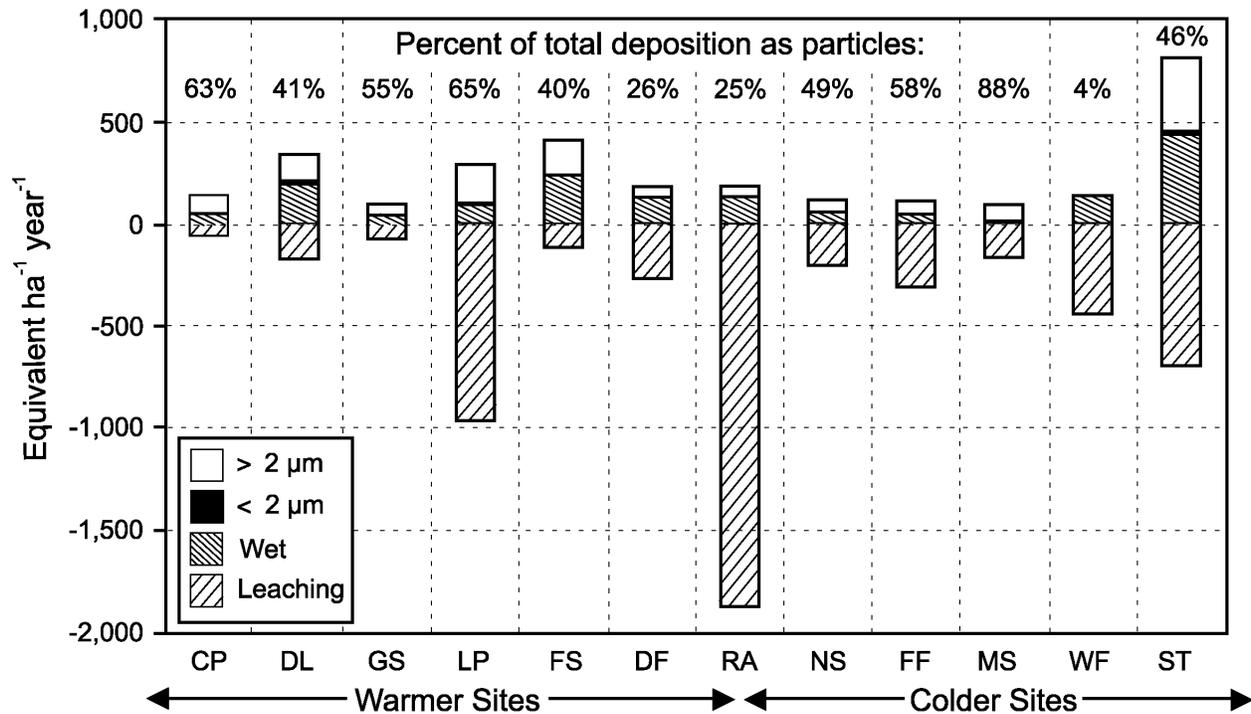

27 Particulate deposition in the IFS was separated at the 2- $\mu\text{m}$  level; a decision was made to  
28 include total particulate deposition in this analysis and may include the deposition of particles  
29 larger than 10  $\mu\text{m}$ . Particulate deposition contributes considerably to the total impact of base  
30 cations to most of the IFS sites. On average, particulate deposition contributes 47% to total  
31 calcium deposition (range: 4 to 88%), 49% of total potassium deposition (range: 7 to 77%),

1 41% to total magnesium deposition (range: 20 to 88%), 36% to total sodium deposition (range:  
2 11 to 63%), and 43% to total base cation deposition (range: 16 to 62%). Of total particulate  
3 deposition, the vast majority (> 90%) is > 2  $\mu\text{m}$ .

4 Figures 4-20 through 4-23 summarize the deposition and leaching of calcium, magnesium,  
5 potassium, and total base cations for the IFS sites. As noted in the original synthesis (Johnson  
6 and Lindberg, 1992a), measurements indicated annual gains of base cations for some sites (i.e.,  
7 total deposition > leaching), some losses (total deposition < leaching), and some are  
8 approximately in balance. Not all cations follow the same pattern at each site. For example, a  
9 net accumulation of calcium occurs at the Coweeta, TN, Durham (Duke), NC, and Florida sites  
10 (Figure 4-20), whereas accumulation of potassium was noted at the Duke, Florida, Thompson,  
11 WA, Huntington Forest, NY, and White Face Mountain, NY, sites (Figure 4-22). Magnesium  
12 accumulated only at the Florida sites (Figure 4-21), and only at the Florida site is there a clear  
13 net accumulation of total base cations (Figure 4-23).

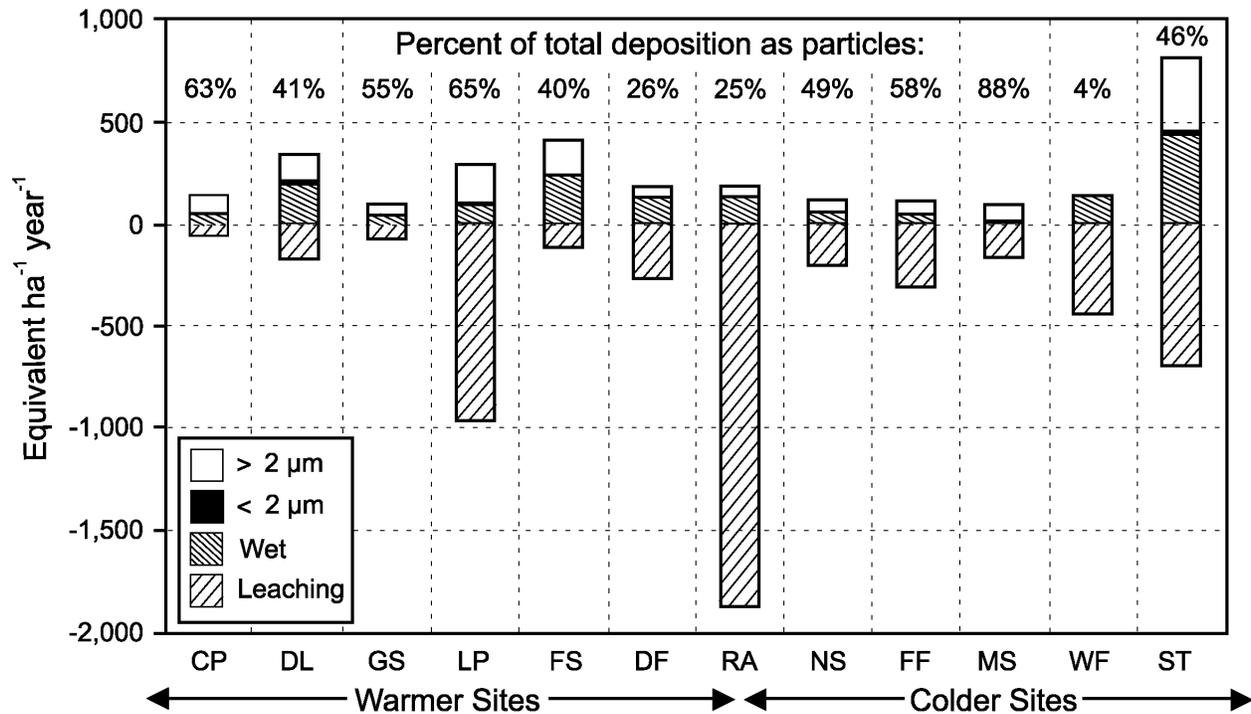

14 As noted previously, the factors affecting net calcium accumulation or loss include the  
15 soil-exchangeable cation composition; base cation deposition rate; the total leaching pressure  
16 because of atmospheric sulfur and nitrogen inputs, as well as natural (carbonic and organic)  
17 acids; and biological demand (especially for potassium). At the Florida site, which has a very  
18 cation-poor, sandy soil (derived from marine sand), the combination of all these factors leads to  
19 net base cation accumulation from atmospheric deposition (Johnson and Lindberg, 1992a). The  
20 site showing the greatest net base cation losses, the red alder stand in Washington state, is one  
21 that is under extreme leaching pressure by nitrate produced because of excessive fixation by that  
22 species (Van Miegroet and Cole, 1984). In the red spruce site in the Smokies, the combined  
23 effects of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  leaching are even greater than in the red alder site (Figure 4-24), but a  
24 considerable proportion of the cations leached from this extremely acid soil consist of  $\text{H}^+$  and  
25  $\text{Al}^{+3}$  rather than of base cations (Johnson and Lindberg, 1992a). Thus, the red spruce site in the  
26 Smokies is approximately in balance with respect to calcium and total base cations, despite the  
27 very high leaching pressure at this site (Figures 4-20 and 4-23).

28 The relative importance of particulate-base-cation deposition varies widely with site and  
29 cation and is not always related to the total deposition rate. The proportion of calcium  
30 deposition in particulate form ranges from a low of 4% at the Whiteface Mountain site to a high  
31 of 88% at the Maine site (Figure 4-20). The proportion of potassium deposition as particles

**Figure 4-20.** Calcium deposition in > 2-µm particles, < 2-µm particles, and wet forms (upper bars) and leaching (lower bars) in the Integrated Forest Study sites. CP = *Pinus strobus*, Coweeta, TN; DL = *Pinus taeda*, Durham (Duke), NC; GS = *Pinus taeda*, B. F. Grant Forest, GA; LP = *Pinus taeda*, Oak Ridge, TN; FS = *Pinus eliottii*, Bradford Forest, FL; DF = *Pseudotsuga menziesii*, Thompson, WA; RA = *Alnus rubra*; Thompson WA; NS = *Picea abies*, Nordmoen, Norway; HF = northern hardwood, Huntington Forest, NY; MS = *Picea rubens*, Howland, ME; WF = *Picea rubens*, Whiteface Mountain, NY; and ST = *Picea rubens*, Clingman's Dome, NC.

1 ranges from 7% at the Smokies site to 77% at the Coweeta site (Figure 4-22), and the proportion  
 2 of total base cation deposition ranges from 16% at the Whiteface site to 62% at the Maine site  
 3 (Figure 4-23). Overall, particulate deposition at the site in Maine accounted for the greatest  
 4 proportion of calcium, magnesium, potassium, and base cation deposition (88, 88, 57, and 62%,  
 5 respectively) even though total deposition was relatively low. At some sites, the relative  
 6 importance of particulate deposition varies considerably by cation. At the Whiteface Mountain  
 7 site, particulate deposition accounts for 4, 20, and 40% of calcium, magnesium, and potassium

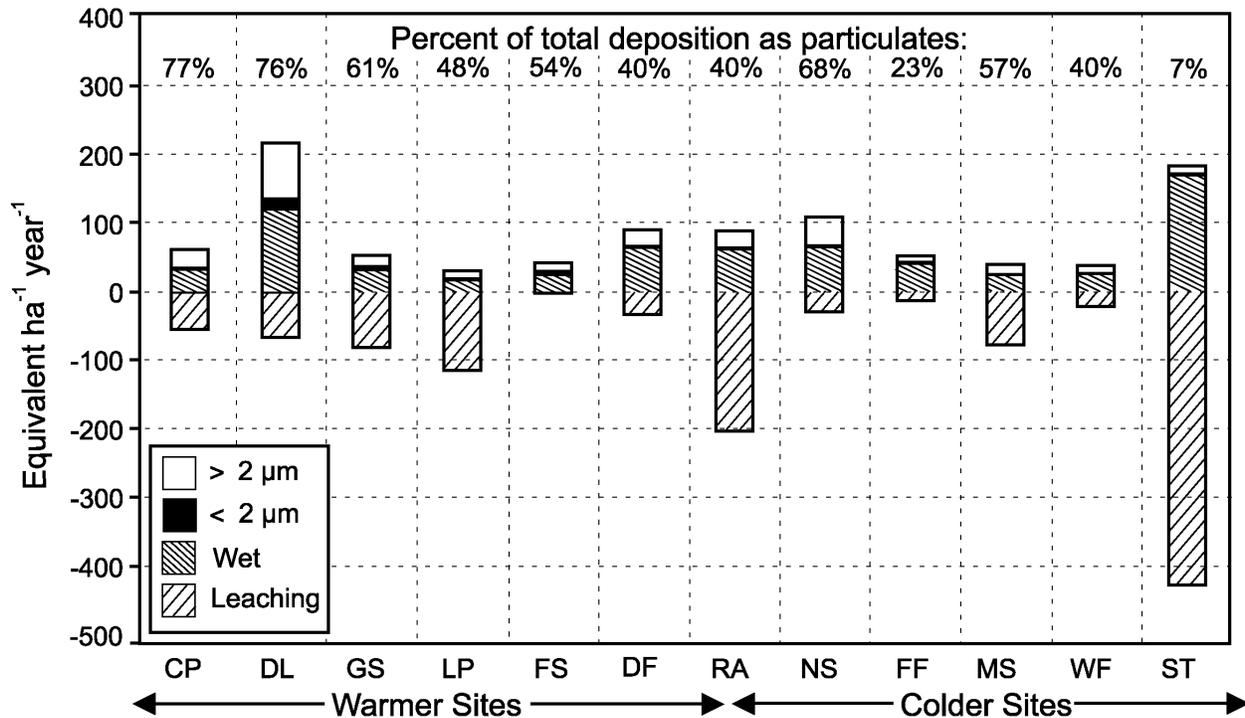

**Figure 4-21. Magnesium deposition in > 2-µm particles, < 2-µm particles, and wet forms (upper bars) and leaching (lower bars) in the Integrated Forest Study sites. See Figure 4-20 for site abbreviations.**

1 deposition, respectively. At the red spruce site in the Smokies, particulate deposition accounts  
 2 for 46, 26%, 7% of calcium, magnesium, and potassium deposition, respectively.

3 As indicated in the IFS synthesis,  $\text{SO}_4^{-2}$  and  $\text{NO}_3^-$  leaching often are dominated by  
 4 atmospheric sulfur and nitrogen (Johnson and Lindberg, 1992a). The exceptions to this are in  
 5 cases where natural nitrogen inputs are high (i.e., the nitrogen-fixing red alder stand), as are  $\text{NO}_3^-$   
 6 leaching rates even though nitrogen deposition is low, and where soils adsorb much of the  
 7 atmospherically deposited  $\text{SO}_4^{-2}$  thus reducing  $\text{SO}_4^{-2}$  leaching compared to atmospheric sulfur  
 8 input.

9 Sulfate and  $\text{NO}_3^-$  leaching have a major effect on cation leaching in many of the IFS sites  
 10 (Johnson and Lindberg, 1992a). Figure 4-24 shows the total cation leaching rates of the IFS sites  
 11 and the degree to which cation leaching is balanced by  $\text{SO}_4^{-2} + \text{NO}_3^-$  deposition. The  $\text{SO}_4^{-2}$  and  
 12  $\text{NO}_3^-$  fluxes are subdivided further into that proportion potentially derived from particulate sulfur

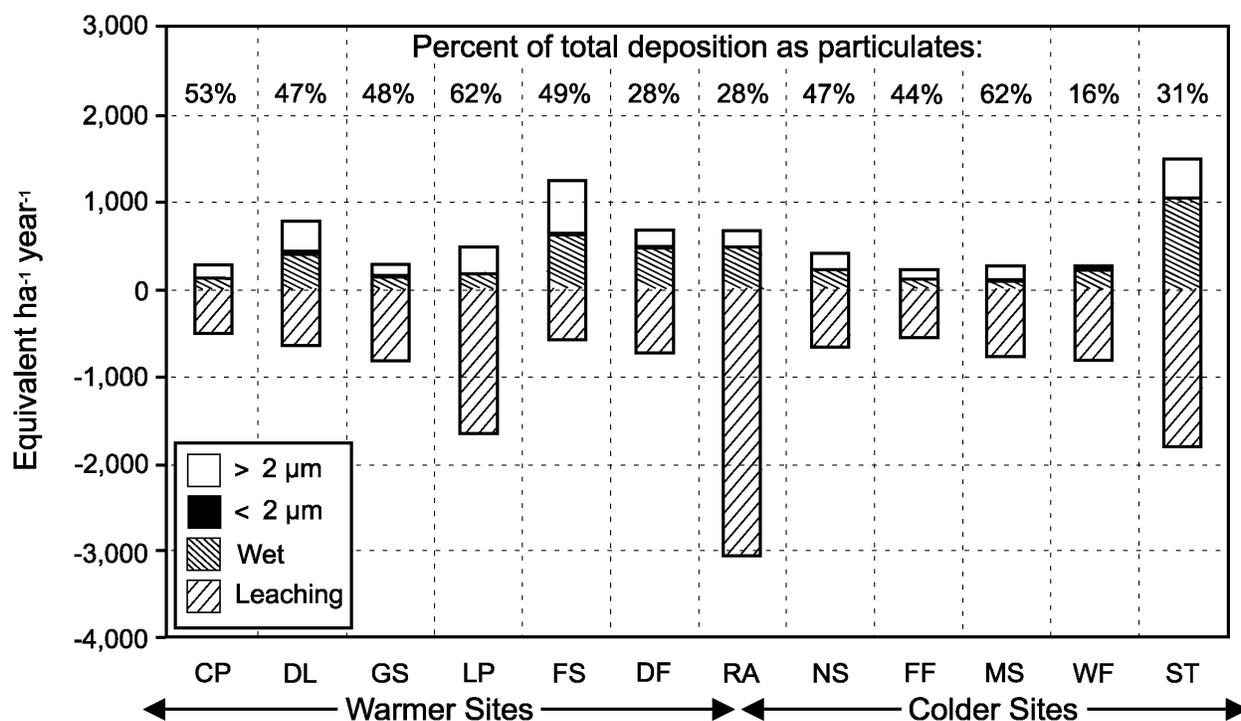

**Figure 4-22. Potassium deposition in > 2-μm particles, < 2-μm particles, and wet forms (upper bars) and leaching (lower bars) in the Integrated Forest Study sites. See Figure 4-20 for site abbreviations.**

1 and nitrogen deposition (assuming no ecosystem retention, a maximum effect) and other sulfur  
 2 and nitrogen sources (wet and gaseous deposition, internal production).

3 As noted in the IFS synthesis, total  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  inputs account for a large proportion  
 4 (28 to 88%) of total cation leaching in most sites. The exception is the Georgia loblolly pine site  
 5 where there were high rates of  $\text{HCO}_3^-$  and  $\text{Cl}^-$  leaching (Johnson and Lindberg, 1992a). The role  
 6 of particulate sulfur and nitrogen deposition in this leaching is generally very small (< 10%),  
 7 however, even if it is assumed that there is no ecosystem sulfur or nitrogen retention.

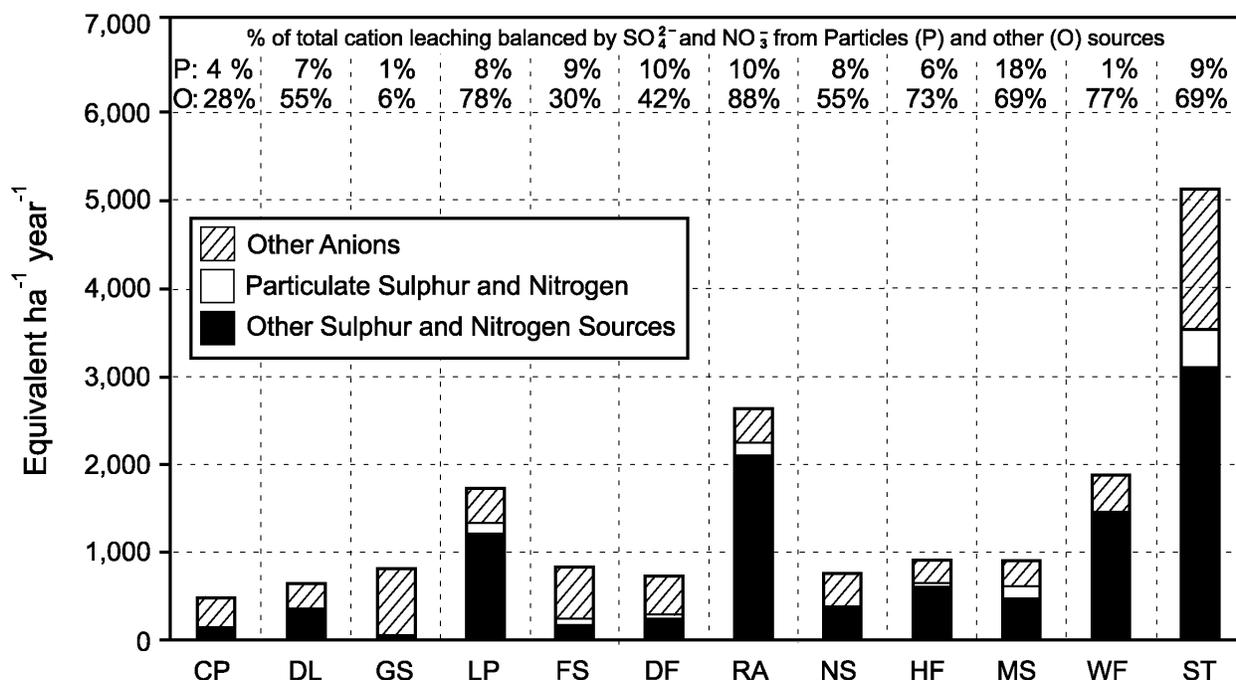

8 It was noted previously in this chapter that the contribution of particles to total deposition  
 9 of nitrogen and sulfur at the IFS sites is lower than that for base cations. On average, particulate  
 10 deposition contributes 18% to total nitrogen deposition (range: 1 to 33%) and 17% to total  
 11 sulfur deposition (range: 1 to 30%). Particulate deposition contributes only a small amount to  
 12 total  $\text{H}^+$  deposition (average = 1%; range: 0 to 2%). (It should be noted, however,  
 13 that particulate  $\text{H}^+$  deposition in the > 2 μm fraction was neglected.)

**Figure 4-23. Base cation deposition in > 2-μm particles, < 2-μm particles, and wet forms (upper bars) and leaching (lower bars) in the Integrated Forest Study sites. See Figure 4-20 for site abbreviation.**

1 Based on the IFS data, it appears that the particulate deposition has a greater effect on base  
 2 cation inputs to soils than on base cation losses associated with inputs of sulfur, nitrogen, and H<sup>+</sup>.  
 3 It cannot be determined what fraction of the mass of these particles are < 10 μm, but only a very  
 4 small fraction is < 2 μm. These inputs of base cations have considerable significance, not only  
 5 to the base cation status of these ecosystems, but also to the potential of incoming precipitation  
 6 to acidify or alkalize the soils in these ecosystems. As noted above, the potential of precipitation  
 7 to acidify or alkalize soils depends on the ratio of base cations to H<sup>+</sup> in deposition, rather than  
 8 simply on the inputs of H<sup>+</sup> alone. In the case of calcium, the term “lime potential” has been  
 9 applied to describe this ratio; the principle is the same with respect to magnesium and potassium.  
 10 Sodium is a rather special case, in that it is a poorly absorbing cation and leaching tends to  
 11 balance input over a relatively short term.

12 Net balances of base cations tell only part of the story as to potential effects on soils; these  
 13 net losses or gains must be placed in the perspective of the soil pool size. One way to express

**Figure 4-24. Total cation leaching (total height of bar) balanced by sulfate and nitrate estimated from particulate deposition (assuming no ecosystem retention, particulate sulfur and nitrogen) and by other sources (both deposition and internal) of sulfate and nitrate (other sulfur and nitrogen sources) and by other anions in the Integrated Forest Study sites. See Figure 4-20 for site abbreviations.**

1 this perspective is to simply compare soil pool sizes with the net balances. This comparison is  
 2 made for exchangeable pools and net balances for a 25-year period in Figures 4-25 to 4-27.  
 3 It readily is seen that net leaching losses of cations pose no threat in terms of depleting  
 4 soil-exchangeable  $\text{Ca}^{+2}$ ,  $\text{K}^+$ , or  $\text{Mg}^{+2}$  within 25 years at the Coweeta, Duke, Georgia, Oak Ridge,  
 5 or Douglas-fir sites. However, there is a potential for significant depletion at the red alder,  
 6 Whiteface Mountain (magnesium), and Smokies red spruce sites.

7 The range of values for soil-exchangeable turnover is very large, reflecting variations in  
 8 both the size of the exchangeable pool and the net balance of the system. Soils with the highest  
 9 turnover rates are those most likely to experience changes in the shortest time interval, other  
 10 things being equal. Thus, the Whiteface Mountains, Smokies, and Maine red spruce sites; the  
 11 Thompson red alder site; and the Huntington Forest northern hardwood site appear to be most

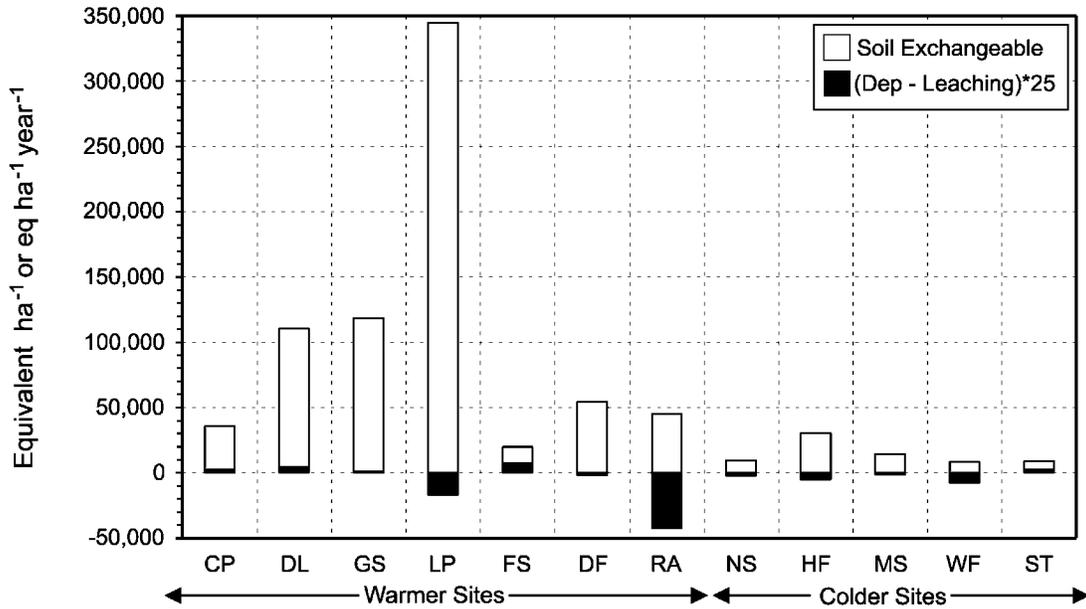

Figure 4-25. Soil exchangeable Ca<sup>2+</sup> pools and net annual export of Ca<sup>2+</sup> (deposition minus leaching times 25 years) in the Integrated Forest Study sites. See Figure 4-20 for site abbreviations.

1 sensitive to change. The actual rates, directions, and magnitudes of changes that may occur in  
 2 these soils (if any) will depend on weathering inputs and vegetation outputs, in addition to  
 3 deposition and leaching. It is noteworthy that each of the sites listed above as sensitive has a  
 4 large store of weatherable minerals; whereas many of the other soils, with larger exchangeable  
 5 cation reserves, have a small store of weatherable minerals (e.g., Coweeta white pine, Duke  
 6 loblolly pine, Georgia loblolly pine, and Oak Ridge loblolly pine; Johnson and Lindberg, 1992a;  
 7 April and Newton, 1992).

8 Base cation inputs are especially important to the Smokies red spruce site because of  
 9 potential aluminum toxicity and calcium and magnesium deficiencies. Johnson et al. (1991a)  
 10 found that soil- solution aluminum concentrations occasionally reached levels found to inhibit  
 11 calcium uptake and cause changes in root morphology in solution culture studies of red spruce  
 12 (Raynal et al., 1990). In a follow-up study, Van Miegroet et al. (1993) found a slight but  
 13 significant growth response to calcium and magnesium fertilizer in red spruce saplings near the  
 14 Smokies red spruce site. Joslin et al. (1992) reviewed soil and solution characteristics of red  
 15 spruce in the southern Appalachians, and it appears that the IFS site is rather typical.

1           Wesselink et al. (1995) reported on the complicated interactions among changing  
2 deposition and soils at this site (including repeated sampling of soil exchangeable base cation  
3 pools) from 1969 to 1991 and compared these results with those of a simulation model. They  
4 identified three basic stages of change in this ecosystem. During Stage 1, there was increased  
5 deposition of sulfur and constant deposition of base cations, causing increased base cation  
6 leaching and reduced base saturation in the soils. During Stage II, sulfur deposition is reduced;  
7 soil solution sulfate and base cation leaching decline accordingly, but base saturation continues  
8 to decrease. During Stage III, two alternative scenarios are introduced: (a) sulfur deposition  
9 continues to decline, whereas base cation deposition stays constant; or (b) both sulfur and base  
10 cation deposition decline. Under Stage III-a, sulfate and base cation leaching continue to  
11 decline, and base saturation begins to increase as base cations displace exchangeable aluminum  
12 and cause it to transfer to the gibbsite pool. Under Stage III-b, this recovery in base saturation is  
13 over-ridden by the reduction in base cation deposition.

14           The IFS project, for the first time, accurately quantified atmospheric deposition inputs to  
15 nutrient cycles using state-of-the-art techniques to measure wet and dry deposition. The  
16 principal aim of the project was to determine the effects of atmospheric deposition on the  
17 nutrient status of a variety of forest ecosystems and to determine if these effects are in any way  
18 related to current or potential forest decline. Acidic deposition is having a significant effect on  
19 nutrient cycling in most of the forest ecosystems studied in the IFS project. The exceptions were  
20 the relatively unpolluted Douglas fir, red alder, and Findley Lakes in Washington state. The  
21 nature of the effects, however, varies from one location to another (Johnson, 1992). In all but the  
22 relatively unpolluted Washington sites, atmospheric deposition was having a significant, often  
23 overwhelming effect on cation leaching from the soils. In general, nutrient budget data from IFS  
24 and the literature suggest that the susceptibility of southeastern sites to base-cation-depletion  
25 from soils and the development of cation deficiencies by that mechanism appears to be greater  
26 than in northern sites (Johnson, 1992).

27           Atmospheric deposition may have affected significantly the nutrient status of some IFS  
28 sites through the mobilization of Al. Soil-solution Al levels in the Smokies sites approach and  
29 sometimes exceed levels noted to impede cation uptake in solution culture studies. It is therefore  
30 possible that the rates of base cation uptake and cycling in these sites have been reduced because  
31 of soil solution Al. To the extent that atmospheric deposition has contributed to these elevated

1 soil-solution Al levels, it has likely caused a reduction in base cation uptake and cycling rates at  
2 these sites. Nitrate and sulfate are the dominant anions in the Smokies sites, and nitrate pulses  
3 are the major cause of Al pulses in soil solution (Johnson, 1992). The connection between Al  
4 mobilization and forest decline is not clear. The decline in red spruce certainly has been more  
5 severe in the Northeast than in the Southeast, yet all evidence indicates that Al mobilization is  
6 most pronounced in the southern Appalachians. However, at the Whiteface Mountain site  
7 selected for study because it was in a state of decline, and soil solution levels were lower than in  
8 the Smokies, which are not in a visibly obvious state of decline (there was no dieback other than  
9 the fir killed by the balsam wooly adelgid, no needle yellowing). Thus, Al mobilization  
10 constitutes a situation worthy of further study (Johnson, 1992).

11 The simple calculations shown above give some idea of the importance of particulate  
12 deposition in these forest ecosystems, but they cannot account for the numerous potential  
13 feedbacks between vegetation and soils nor for the dynamics through time that can influence the  
14 ultimate response. One way to examine some of these interactions and dynamics is to use  
15 simulation modeling. The nutrient cycling model (NuCM) has been developed specifically for  
16 this purpose and has been used to explore the effects of atmospheric deposition, fertilization, and  
17 harvesting on some of the IFS sites (Johnson et al., 1993). The NuCM model is a stand-level  
18 model that incorporates all major nutrient cycling processes (uptake, translocation, leaching,  
19 weathering, organic matter decay, and accumulation).

20 Johnson et al. (1999) used the NuCM model to simulate the effects of reduced S, N, and  
21 base cation ( $C_B$ ) deposition on nutrient pools, fluxes, soil, and soil solution chemistry in two  
22 contrasting southern Appalachian forest ecosystems: the red spruce and Coweeta hardwood sites  
23 from the IFS project. The scenarios chosen for these simulations included “no change”; 50% N  
24 and S deposition; 50%  $C_B$  deposition; and 50% N, S, and  $C_B$  deposition (50% N, S,  $C_B$ ). The  
25 NuCM simulations suggested that, for the extremely acid red spruce site, S and N deposition is  
26 the major factor affecting soil-solution Al concentrations and  $C_B$  deposition is the major factor  
27 affecting soil solution  $C_B$  concentrations. The effects of S and N deposition were largely through  
28 changes in soil solution  $SO_4^{2-}$  and  $NO_3^-$  and, consequently, mineral acid anion (MAA)  
29 concentrations rather than through changes in soils. This is illustrated in Figures 4-28a,b and  
30 4-29a,b, which show simulated soil-solution mineral-acid anions, base cations, Al, and soil base  
31 saturation in B horizon from in the red spruce site. The 50% S and N scenario caused reductions

# Red Spruce

**Figure 4-28b.** Simulated soil solution mineral acid anions and base cations in the red spruce site with no change, 50% N and S deposition, and 50% base cation deposition. Redrawn from Johnson et al. (1999).

**Figure 4-29a.** Simulated soil solution A1 and soil base saturation in the red spruce site with no change, 50% N and S deposition, and 50% base cation deposition. Redrawn from Johnson et al. (1999).

**Figure 4-29b. Simulated soil solution A1 and soil base saturation in the red spruce site with no change, 50% N and S deposition, and 50% base cation deposition. Redrawn from Johnson et al. (1999).**

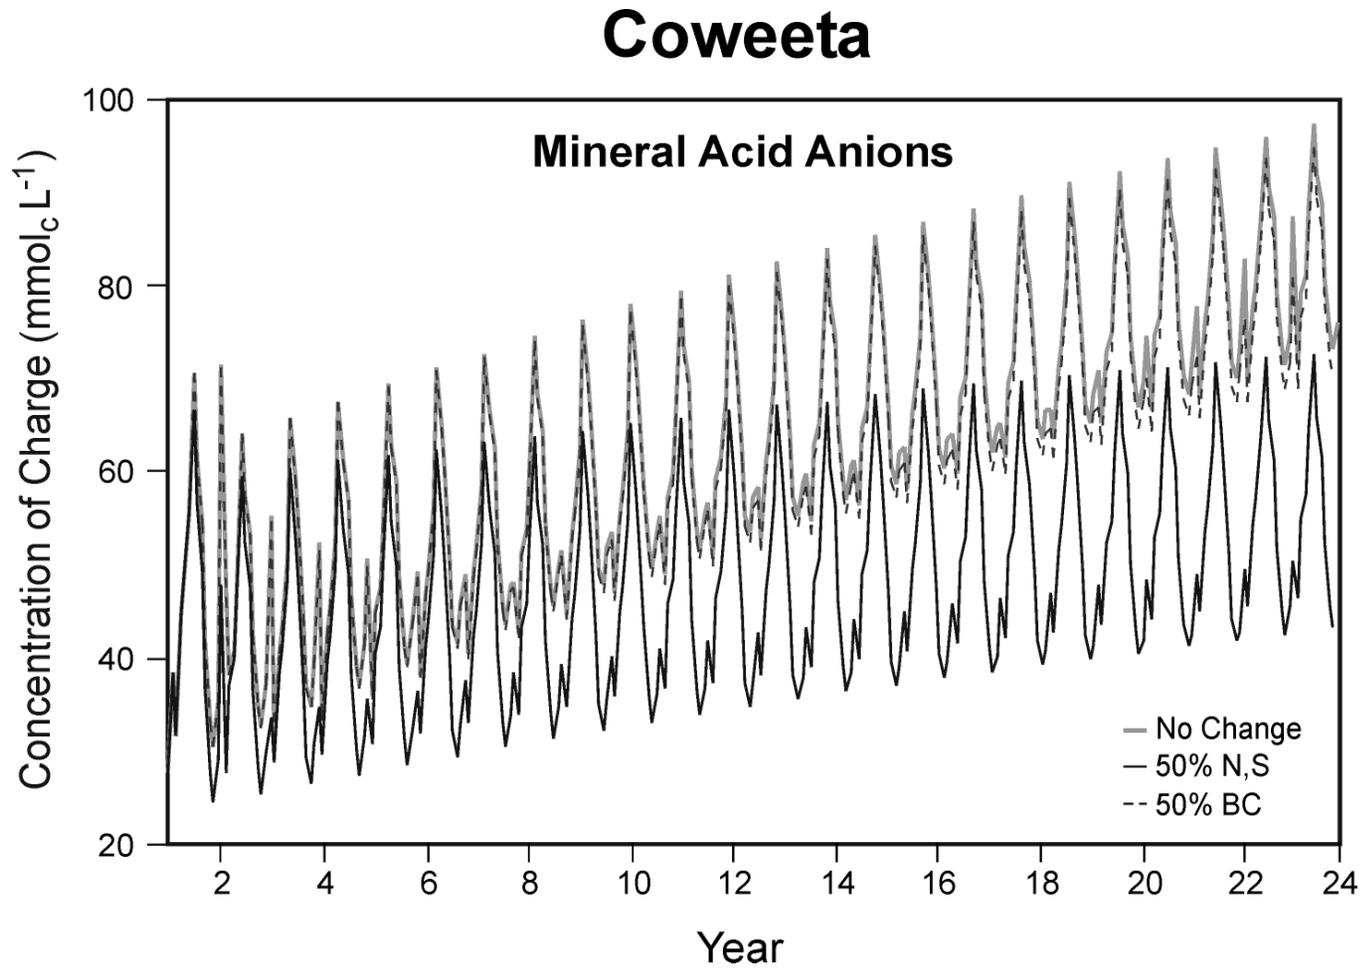

1 in soil solution  $\text{SO}_4^{-2}$ ,  $\text{NO}_3^-$  and, therefore, MAA concentrations, as expected. This, in turn,  
2 caused short-term reductions in base cation concentrations. However, by the end of the 24-year  
3 simulation, base cations in the 50% S, N scenario were nearly as high as in the no change  
4 scenario because base saturation had increased and the proportion of cations as Al decreased.  
5 The 50%  $\text{C}_B$  scenario had virtually no effect on soil solution  $\text{SO}_4^{-2}$ ,  $\text{NO}_3^-$  and, therefore, MAA  
6 concentrations, as expected, but did cause a long-term reduction in base cation concentrations.  
7 This was caused by a long-term reduction in base saturation (Figure 4-29a,b). Thus, the effects  
8 of  $\text{C}_B$  deposition were solely through changes in soils rather than through changes in soil solution  
9 MAA, as postulated by Driscoll et al. (1989). In the less acidic Coweeta soil, base saturation  
10 was high and little affected by the scenario (cited above); Al was unimportant; and S and  
11 N deposition had a much greater effect than  $\text{C}_B$  deposition in all respects (Figure 4-30a,b).

12 In summary, Johnson et al. (1999) found that the results of the red spruce simulations  
13 support the hypothesis of Driscoll et al. (1989) in part:  $\text{C}_B$  deposition can have a major effect on  
14  $\text{C}_B$  leaching through time in an extremely acid system. This effect occurred through changes in  
15 the soil exchanger and not through changes in soil solution MAA concentration. On the other  
16 hand, S and N deposition had a major effect on Al leaching at the Noland Divide site. This  
17 occurred primarily because of changes in soil solution MAA concentration. At the less acidic  
18 Coweeta site,  $\text{C}_B$  deposition had a minor effect on soils and soil solutions; whereas S and N  
19 deposition had delayed but major effects on  $\text{C}_B$  leaching because of changes in  $\text{SO}_4^{-2}$  and MAA  
20 concentrations.

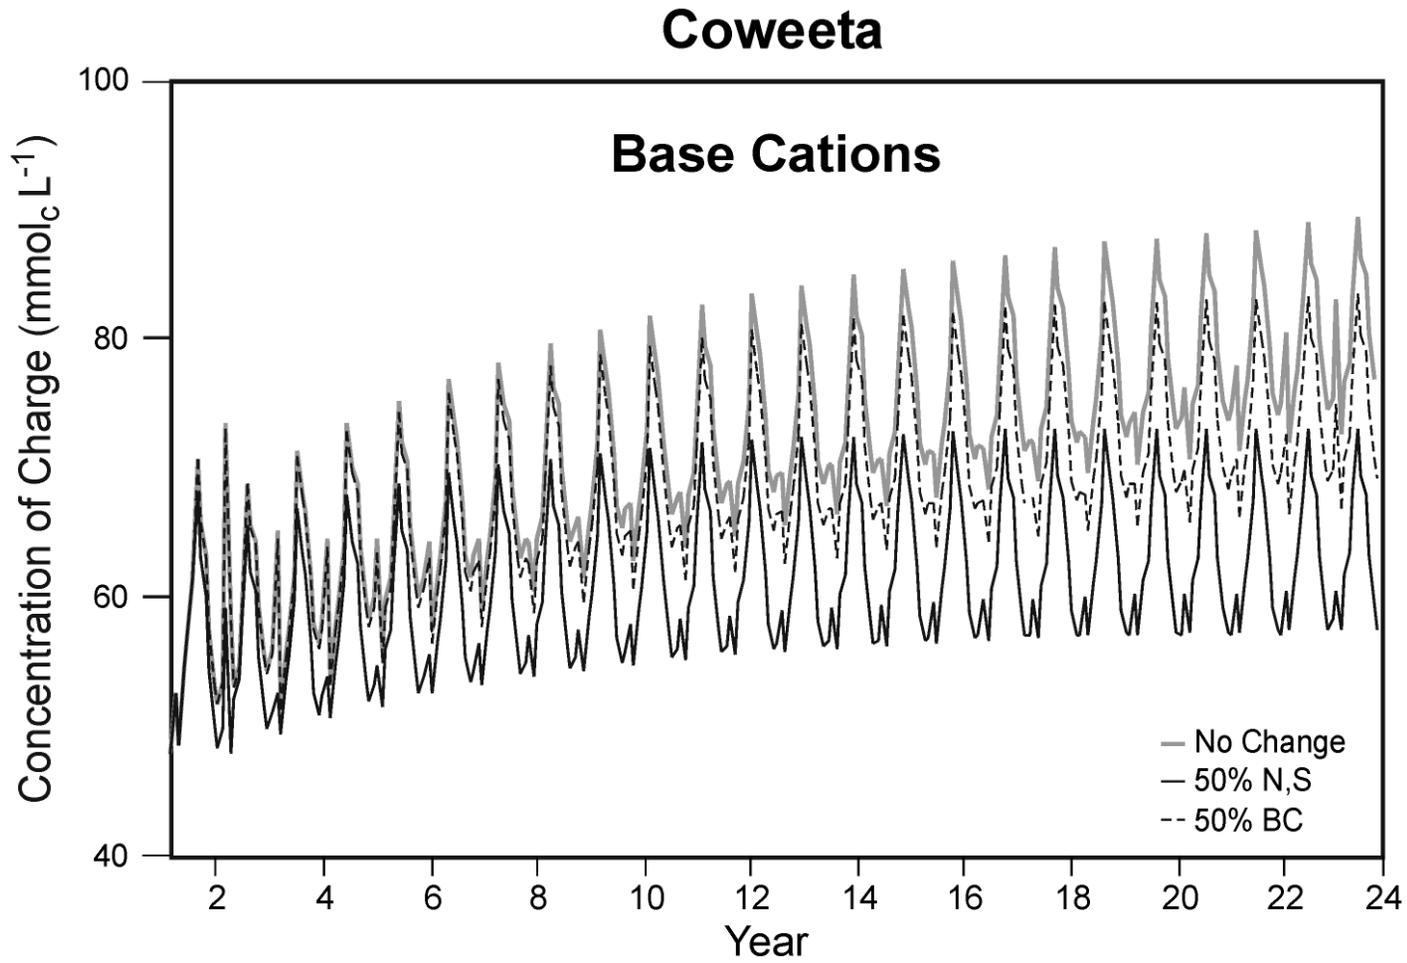

## 21

### 22 **Effects of Trace Elements**

23 Trace metals are natural elements that are ubiquitous in small (trace) amounts in soils,  
24 ground water, and vegetation. Many are essential elements required for growth by plants and  
25 animals as micronutrients. Naturally occurring surface mineralizations can produce metal  
26 concentrations in soils and vegetation that are as high, or higher, than those in the air and  
27 deposited near man-made sources (Freedman and Hutchinson, 1981). The occurrence and  
28 concentration of trace metals in any ecosystem component depend on the sources of the metal  
29 (i.e., via the soil or as a particulate). Even when air pollution is the primary source, continued  
30 deposition can result in the accumulation of trace metals in the soil (Martin and Coughtrey,

**Figure 4-30a.** Simulated soil solution mineral acid anions and base cations in the Coweeta site with no change, 50% N and S deposition, and 50% base cation deposition. Redrawn from Johnson et al. (1999).

**Figure 4-30b. Simulated soil solution mineral acid anions and base cations in the Coweeta site with no change, 50% N and S deposition, and 50% base cation deposition. Redrawn from Johnson et al. (1999).**

1 1981). Many metals are deposited into soils by chemical processes and are not available to  
2 plants (Saunders and Godzik, 1986).

3 When aerial deposition is the primary source of metal particles, both the chemical form and  
4 particle size deposited determine the heavy metal concentration in the various ecosystem  
5 components (Martin and Coughtrey, 1981). Human activities introduce heavy metals into the  
6 atmosphere and have resulted in the deposition of antimony, cadmium, chromium, copper, lead,  
7 molybdenum, nickel, silver, tin, vanadium, and zinc (Smith, 1990c). Extensive evidence  
8 indicates that heavy metals deposited from the atmosphere to forests accumulate either in the  
9 richly organic forest floor or in the soil layers immediately below, areas where the activity in  
10 roots and soil is greatest. The greater the depth of soil, the lower the metal concentration. The  
11 accumulation of metal in the soil layers where the biological activity is greatest, therefore, has  
12 the potential to be toxic to roots and soil organisms and to interfere with nutrient cycling (Smith,  
13 1990c). The shallow-rooted plant species are those most likely to take up metals from the soil  
14 (Martin and Coughtrey, 1981). Though all metals can be directly toxic at high levels, only  
15 toxicity from copper, nickel, and zinc have been documented frequently. Toxicity of cadmium,  
16 cobalt, and lead has been seen only under unusual conditions (Smith, 1990c). Exposures at  
17 lower concentrations have the potential, over the long-term, to interfere with the nutrient-cycling  
18 processes when they affect mycorrhizal function.

19 Biological accumulation of metals through the plant-herbivore and litter-detrivore chains  
20 can occur. A study of the accumulation of cadmium, lead, and zinc concentrations in  
21 earthworms suggested that cadmium and zinc were concentrated, but not lead. Studies indicate  
22 that heavy metal deposition onto the soil, via food chain accumulation, can cause excessive  
23 levels and toxic effects in certain animals. Cadmium appears to be relatively mobile within  
24 terrestrial food chains; however, the subsequent mobility of any metal after it is ingested by a  
25 herbivorous animal depends on the site of accumulation within body tissues. Although food  
26 chain accumulation may not in itself cause death, it can reduce the breeding potential in a  
27 population (Martin and Coughtrey, 1981).

28 In actual case studies, it was observed that the deposition of copper and zinc particles  
29 around a brassworks resulted in an accumulation of incompletely decomposed litter. In one  
30 study, litter accumulation was reported up to 7.4 km from the stack of a primary smelter in  
31 southeastern Missouri. Similar results were reported around a metal smelter at Avonmouth,

1 England. In the latter case, litter accumulation was associated closely with concentrations  
2 specifically of cadmium, as well as with those of lead, copper, and zinc (Martin and Coughtrey,  
3 1981). Experimental data (using mesh bags containing litter) supports the hypothesis that  
4 reduced decomposition occurs close to heavy metal sources.

5 Accumulations of metals emitted in particulate matter also were reported in soil litter close  
6 to a metal smelter at Palmerton, PA, in 1975 and 1978. The continued presence of cadmium,  
7 lead, zinc, and copper in the upper soil horizons (layers) were observed 6 years after the smelter  
8 terminated operation in 1980. Metal levels were highest near the smelter. The relationship of  
9 decreasing amounts of metal in body tissues also held true for amphibians and mammals. Levels  
10 of cadmium in kidneys and liver of white-tailed deer (*Odocoileus virginianus*) were five times  
11 higher at Palmerton than in those collected 180 km southwest downwind. The abnormal  
12 amounts of metal in the tissues of terrestrial vertebrates and the absence or low abundance of  
13 wildlife at Palmerton indicated that ecological processes within 5 km of the zinc smelter  
14 continued to be markedly influenced even 6 years after its closing (Storm et al., 1994).

15 Accumulation of heavy metals in litter presents the greatest potential for interference with  
16 nutrient cycling. Microorganisms are essential for decomposition of organic matter and soil  
17 fertility. Toxic effects on the microflora can be caused by Zn, Cd, and Cu. Addition of a few  
18 mg/kg of soil of Zn can inhibit the more sensitive microbial processes (van Beelen and Doelman,  
19 1997). Experiments by Kandeler et al. (1996) indicated that microbial biomass and enzyme  
20 activities decreased with increasing heavy metal concentrations. The amount of decrease varied  
21 among the enzymes with those involved in carbon cycling least affected, whereas the activities  
22 of the enzymes involved in the cycling of N, P and S, especially arylsulfatase and phosphatase  
23 were dramatically affected.

24 Accumulation of metals in the litter occurs chiefly around brass works and lead and zinc  
25 smelters. There is some evidence that invertebrates inhabiting soil litter do accumulate metals.  
26 Earthworms from roadsides were shown to contain elevated concentrations of cadmium, nickel,  
27 lead, and zinc; however, interference with earthworm activity was not cited (Martin and  
28 Coughtrey, 1981). It has been shown, however, that when soils are acidic, earthworm abundance  
29 decreases, and bioaccumulation of metals from soil may increase exponentially with decreasing  
30 pH (Lokke et al, 1996). Organisms that feed on earthworms living in soils with elevated levels  
31 of Cd, Ni, Pb, and Z for extended periods could accumulate lead and zinc to toxic levels (Martin

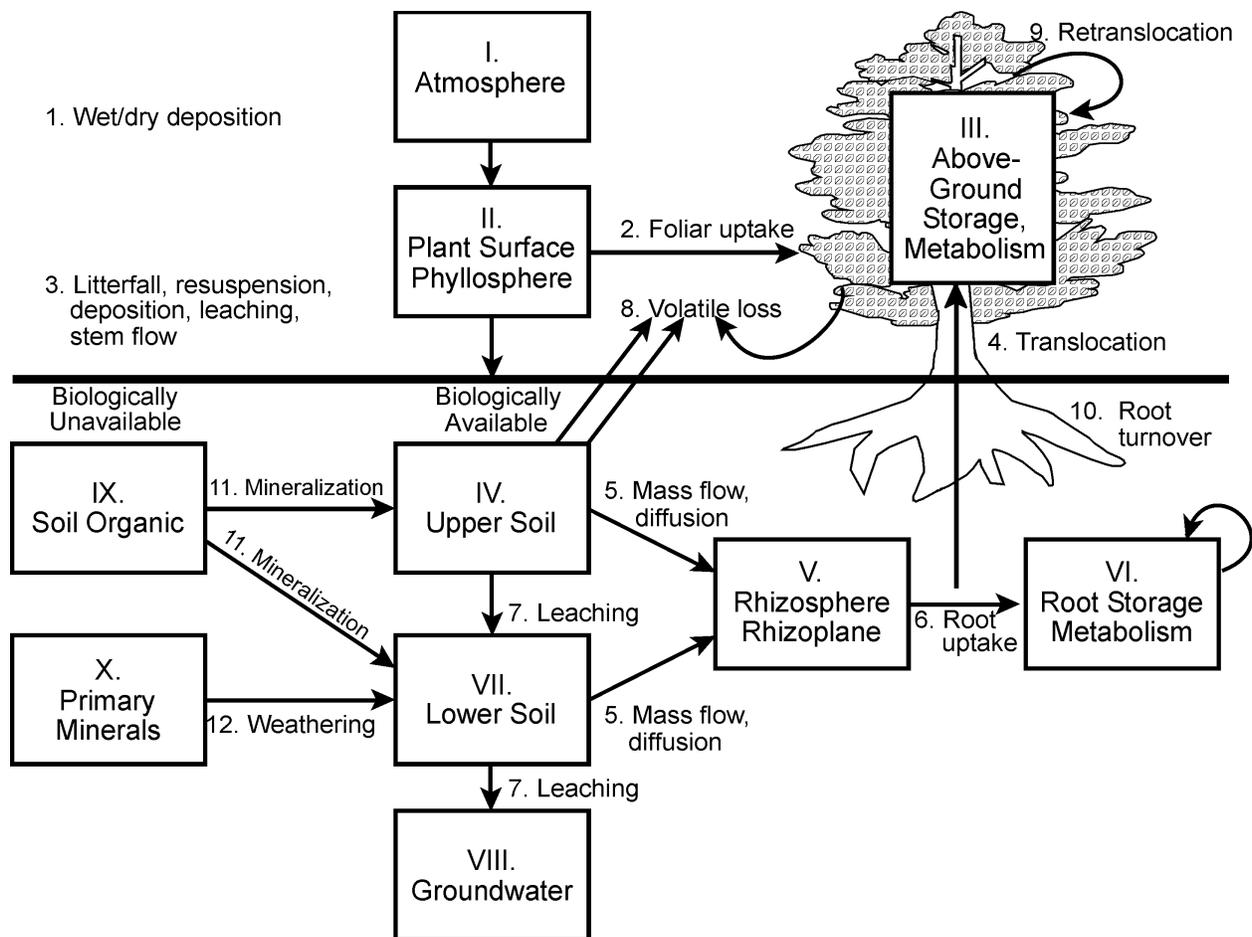

1 and Coughtrey, 1981). Increased concentrations of heavy metals have been found in a variety of  
2 small mammals living in areas with elevated heavy metal concentrations in the soils.

3 Studies by Babich and Stotsky (1978) support the concept that increased accumulation of  
4 litter in metal-contaminated areas is due to the effects on the microorganismal populations.  
5 Cadmium toxicity to microbial populations was observed to decrease and prolong logarithmic  
6 rates of microbial population increase, to reduce microbial respiration and fungal spore  
7 formation and germination, to inhibit bacterial transformation, and to induce abnormal  
8 morphologies. Additionally, the effects of cadmium, copper, nickel, and zinc on the symbiotic  
9 activity of fungi, bacteria, and actinomycetes were reported by Smith (1991). The formation of  
10 mycorrhizae by *Glomus mosseae* with onions was reduced when zinc, copper, nickel, or  
11 cadmium was added to the soil. The relationship of the fungus with white clover, however, was  
12 not changed. It was suggested that the effect of heavy metals on vesicular-arbuscular  
13 mycorrhizal fungi will vary from host to host (Gildon and Tinker, 1983). Studies with ericoid  
14 plants indicated that, in addition to *Calluna vulgaris*, mycorrhizae also protect *Vaccinium*  
15 *macrocarpa* and *Rhodendron ponticum* from heavy metals (Bradley et al., 1981). Heavy metals  
16 tend to accumulate in the roots, and shoot toxicity is prevented.

17 The effects of sulfur deposition on litter decomposition in the vicinity of smelters also must  
18 be considered. Metal smelters emit SO<sub>2</sub> as well as heavy metals. Altered litter decomposition  
19 rates have been well documented near SO<sub>2</sub> sources (Prescott and Parkinson, 1985). The  
20 presence of sulfur in litter has been associated with reduced microbial activity (Bewley and  
21 Parkinson, 1984). Additionally, the effects on symbiotic activity of fungi, bacteria, and  
22 actinomycetes were reported by Smith (1990d).

23 The potential pathways of accumulation of trace metals in terrestrial ecosystems, as well as  
24 the possible consequences of trace metal deposition on ecosystem functions, is summarized in  
25 Figure 4-31. The generalized trophic levels found in an ecosystem and the various physiological  
26 and biological processes that could be affected by trace metals are shown in the figure.  
27 Reduction in physiological processes can affect productivity, fecundity, and mortality (Martin  
28 and Coughtrey, 1981). Therefore, any effects on structure and function of an ecosystem are  
29 likely to occur through the soil and litter (Tyler, 1972).

30 Certain species of plants are tolerant of metal-contaminated soils (e.g., soils from mining  
31 activities) (Antonovics et al., 1971). Certain species of plants also have been used as

**Figure 4-31. Relationship of plant nutrients and trace metals with vegetation. Compartments (roman numerals) represent potential storage sites; whereas arrows (arabic numerals) represent potential transfer routes.**

1 bioindicators of metals (e.g., *Astragalus* is an accumulator of selenium). The sources of both  
 2 macroelements and trace metals in the soil of the Botanical Garden of the town of Wroclow,  
 3 Poland, were determined by measuring the concentrations of the metals in *Rhododendron*  
 4 *catawbiense*, *Ilex aquifolium*, and *Mahonia aquifolium* growing in a garden and comparing the  
 5 results with the same plant species growing in two botanical gardens in nonpolluted areas. Air  
 6 pollution deposition was determined as the source of metals in plants rather than the soil  
 7 (Samecka-Cymerman and Kempers, 1999).

8 The effects of lead in ecosystems are discussed in the EPA document *Air Quality Criteria*  
 9 *for Lead* (U.S. Environmental Protection Agency, 1986). Studies have shown that there is cause

1 for concern in three areas in which ecosystems may be extremely sensitive to lead: (1) delay of  
2 decomposition because the activity of some decomposer microorganisms and invertebrates is  
3 inhibited by lead, (2) subtle shifts toward plant populations tolerant of lead, and (3) lead in the  
4 soil and on the surfaces of vegetation which may circumvent the processes of biopurification.  
5 The problems cited above arise because lead is deposited on the surface of vegetation,  
6 accumulates in the soil, and is not removed by the surface and ground water of the ecosystem  
7 (U.S. Environmental Protection Agency, 1986).

#### 9 **4.2.4 Urban Ecosystems**

10 Humans dominate Earth's ecosystems. Their influence on the environment has been  
11 pervasive for thousands of years. Evidence has been accumulating from anthropological and  
12 archeological research that human influence has been pervasive for thousands of years (Grimm  
13 et al., 2000). Major human effects on the environment probably began as early as 12,000 to  
14 15,000 years ago and continue to be a major influence on all natural ecosystems. Nowhere has  
15 human action been more intense than in cities, suburbs, exurbs and in the supporting hinterlands  
16 (Grimm et al., 2000). This fact has led to much recent interest in the study of urban ecological  
17 systems.

18 Vitousek et al. (1997) point out that understanding a human-dominated planet requires that  
19 the human dimensions of global change — the social, cultural, and other drivers of human  
20 actions — need to be included within ecological analyses. Therefore, humans must be integrated  
21 into models for a complete understanding of extant ecological systems. Development of more  
22 realistic models for ecological systems will lead to greater success in finding solutions to  
23 environmental problems.

24 In the past, ecological plant or animal studies conducted in urban settings used traditional  
25 ecological approaches and considered humans as agents of disturbance. Although the term urban  
26 ecosystem has been used to describe human-dominated ecosystems, it does not adequately take  
27 into account the developmental history, sphere of influence, and potential impacts required in  
28 order to understand the true nature of an urban ecosystem (McIntyre, et al., 2000). Because  
29 urbanization is both an ecological and a social phenomenon, urban ecology implicitly recognizes  
30 the role humans play in developing unique systems. Therefore, if urban ecology is to be a truly

1 interdisciplinary field, it is crucial that it integrate both social and natural sciences into the study  
2 of urban ecosystems (McIntyre, et al., 2000).

3 Although the study of ecological phenomena in urban environments is not a new area of  
4 science, the concept of the city as an ecosystem is relatively new for the field of ecology (Grimm  
5 et al., 2000). There is a wealth of information on the terrestrial components of urban ecological  
6 systems. However, much of it is organized from the perspective of ecology *in* cities while the  
7 more comprehensive perspective identified as ecology *of* cities is needed (Pickett et al., 2001).  
8 The basic questions addressed by the literature of ecology *in* cities are how do ecological  
9 patterns and processes differ in cities as compared with other environments? What is the effect  
10 of the city (i.e., a concentration of human population and activities) on the ecology of organisms  
11 inside and outside of its boundary and influence? The concept of ecology *of* cities has to do with  
12 how aggregated parts make up the whole (i.e., how cities process energy or matter relative to  
13 their surroundings; Grimm et al., 2000). The latter concept includes primary production, species  
14 richness, biogeophysical budgets, ecosystem patterns and processes, and an open definition of  
15 urban ecosystems that incorporates the exchanges of materials and influence between cities and  
16 surrounding landscapes (Pickett et al., 2001). If ecosystems are to be understood, there is a need  
17 for a new integrative ecology that explicitly incorporates human decisions, culture, institutions,  
18 and economic systems (Grimm et al., 2000). This fact makes an ecological approach to land use  
19 planning not only necessary but essential to maintain long-term sustainability of ecosystem  
20 benefits, services, and resources (Zipperer et al., 2000). The ecological and social effects of  
21 “edge city” need to be studied as they may be greater than the previous patterns of  
22 suburbanization. The classical ecosystem approach and a patch dynamic approach are needed  
23 to understand and manage the dynamics of urban and urbanizing ecosystems (Zipperer et al.,  
24 2000).

25 There has been little work on the rates of atmospheric deposition to urban ecosystems  
26 despite the large body of knowledge on concentrations and chemical reactions of air pollutants in  
27 cities. A search of the abundant literature produced no references that dealt with the effects of  
28 PM deposition. Lovett et al. (2000), however, reported that urban ecosystems are likely to be  
29 subjected to large rates of deposition of anthropogenic pollutants. Decades of research on urban  
30 air quality indicate that cities are often sources of nitrogen oxides, sulfur oxides, and dust,  
31 among many other pollutants. Some of these air pollutants are major plant nutrients (e.g.,

1 nitrogen) and may be affecting nutrient cycles in plant-dominated areas in and around cities.  
2 The gases and particles in urban air can increase atmospheric deposition within and downwind of  
3 the city. Studying the deposition rates of atmospheric pollutants in urban areas can provide a  
4 quantitative estimate of the amounts of gaseous and particulate air pollutants that are removed by  
5 urban vegetation.

6 To determine the patterns of atmospheric deposition and throughfall in the vicinity of a  
7 large city, Lovett et al. (2000) measured bulk deposition, oak forest throughfall, and particulate  
8 dust at sites along a transect within and to the north of New York City. They observed that  
9 concentrations and fluxes of  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{Ca}^{+2}$ ,  $\text{Mg}^{+2}$ ,  $\text{SO}_4^{-2}$ , and  $\text{Cl}^-$  in throughfall all declined  
10 significantly with distance from the city, while hydrogen ion concentration and flux increased  
11 significantly with distance from the city. Most of the change in concentrations and fluxes  
12 occurred within 45 km of the city. Additionally, it was observed that throughfall nitrogen was  
13 twice as high in the urban areas when compared with the suburban and rural sites. Most of the  
14 dry deposition of nitrate was from gaseous nitrogen oxides. As mentioned above, the effects of  
15 the atmospheric deposition of the particulate pollutants was not mentioned.

16 McDonnell et al. (1997) in a 10-year study of ecosystem processes along an urban-rural  
17 gradient included plant litter dynamics and nitrogen cycling of two key components of a forest  
18 ecosystem: litter decomposition and heavy metal levels in soil and foliar litter. Foliar litter  
19 decomposition integrates many features of the abiotic and biotic environment. It is an important  
20 site of heavy metal incorporation into ecosystems and provides a both a habitat and a resource  
21 for fungi, bacteria, and invertebrates. Litter decomposition integrates the effects of resource  
22 quality, environmental factors, and activities of decomposer organisms on nutrient cycling and  
23 serves as an easily measured indicator of the effect of urbanization on an important ecosystem  
24 function. McDonnell et al. (1997) noted that levels of heavy metals in the foliar litter in urban  
25 forest soils were higher than in rural forest soils. The levels in urban forest stands approached or  
26 exceeded the levels reported to affect soil invertebrates, macrofungi, and soil microbial  
27 processes. The urban forests exhibited reduced fungal biomass and microarthropod densities  
28 when compared to rural stands. These results supported the concept that urban forests have  
29 depauperate communities because of anthropogenic stress resulting from poor air quality due to  
30 high levels of  $\text{SO}_2$ , sulfate, ozone, and nitrogen; elevated levels of soil- and forest-floor-heavy  
31 metals; and low water availability such as those caused by hydrophobic soils (McDonnell

1 et al.,1997). Thus, forests at the urban end of the gradient exhibited reduced fungal and  
2 microarthropod populations and poorer leaf quality than the more rural forests. The potential  
3 effect of these conditions on the ecosystem processes of decomposition and nitrogen cycling in  
4 urban forests appeared to be ameliorated by two other anthropogenic factors: increased average  
5 temperatures caused by the heat island effect and the introduction and successful colonization of  
6 earthworms in the urban forests (McDonnell et al.,1997).

7 McDonnell et al. (1997) observed that the changes in forest nitrogen dynamics were related  
8 to increased anthropogenic nitrogen deposition in an urban environment. The studies of Aber  
9 et al. (1989) in the northeastern United States on forest nitrogen dynamics demonstrated that  
10 elevated nitrogen deposition over many years results in increased nitrification and the  
11 mineralization of more nitrogen than can be taken up by plants and microorganisms.  
12 Nitrification can precipitate decreases in fine root biomass and increases in nitrate leaching  
13 below the root zone. These effects of nitrogen deposition were not related to inputs from a  
14 specific source such as PM.

15 There have also been studies of heavy metal deposition in or near cities; but the studies do  
16 not cite the effects of metals in the soil. Pouyat and McDonnell (1991) discuss heavy metal  
17 accumulations in forest soils along an urban-rural gradient in southeastern New York.  
18 Variations in the amounts of Zn, Cu, Ni, and Cd appeared indicative of a pattern of atmospheric  
19 deposition near point sources (Section 4.3.2.6). The concentrations of heavy metals in forest  
20 floor and soils corresponded closely with the urban-rural land use gradient. Again, as in the  
21 study by Lovett et al. (2000), the pollutants were highest near the urban end of the gradient and  
22 declined toward rural sites, with Pb, Ni and Cu highest near the urban end.

23 The air quality of the region around East St. Louis has been of concern due to industries in  
24 the area (Kaminski and Landsberger, 2000a), which include ferrous and nonferrous metal  
25 smelters (Pb, Zn, Cu, and Al), coal-fired power plants, producers of organic and inorganic  
26 chemicals, municipal waste incinerators, and petroleum refineries. The city is also in the path of  
27 diverse plumes from refineries to the north, coal-fired power plants to the west, and nonferrous  
28 smelters to the south. Concentrations of heavy metals and metalloids (As, Cd, Cu, Hg, Pb, Sb,  
29 Zn) in the soil provided a basis for analysis (Kaminski and Landsberger, 2000b). These studies  
30 of the extent of long-term metal deposition on the soil surface and depth of soil contamination,  
31 as well as the leaching dynamics of heavy metals were made to determine possible effects on

1 biota uptake or groundwater contamination. The effects on biota are not mentioned; however,  
2 the soils in the area acted as a sink and there was little groundwater mobility (Kaminski and  
3 Landsberger, 2000b).

4 Overall, the above assessment of new information leads to the clear conclusion that  
5 atmospheric PM at levels currently found in the United States have the potential to alter  
6 ecosystem structure and function in ways that may reduce their ability to meet societal needs.  
7 The possible direct effects of airborne PM on individual plants were discussed in Section 4.2.2.1.

## 10 **4.3 AIRBORNE PARTICLE EFFECTS ON VISIBILITY**

### 11 **4.3.1 Introduction**

12 Visibility may be thought of as the degree to which the atmosphere is transparent to visible  
13 light (National Research Council, 1993). The beauty of scenic vistas in many parts of the U.S. is  
14 often diminished by haze that reduces contrast, washes out colors, and renders distant landscape  
15 features indistinct or invisible. This degradation of visibility is due primarily to the scattering  
16 and absorption of light by fine particles suspended in the atmosphere. One quantitative measure  
17 of visibility, used traditionally by meteorologists, is the visual range, defined as the farthest  
18 distance at which a large black object can be distinguished against the horizon sky (U.S.  
19 Environmental Protection Agency, 1979).

20 In August 1977, Congress amended the Clean Air Act (CAA) to establish as a national goal  
21 “the prevention of any future and remedying of any existing impairment of visibility in  
22 mandatory Class I Federal areas (many national parks and wilderness areas), which impairment  
23 results from manmade air pollution” (Title I Part C Section 169A, U.S. Code [1990]). The 1977  
24 Amendments also included provisions requiring applicants for new major source permits to  
25 assess the potential for their projects to cause adverse effects on air quality-related values,  
26 including visibility, in nearby Class I areas. In 1980, the EPA established regulatory  
27 requirements under Section 169A to address Class I protection from “reasonably attributable”  
28 visibility impairment; i.e., visibility impairment attributable to a single source or small group of  
29 sources.

30 The CAA, as amended in 1990 (section 169B), required the U.S. Environmental Protection  
31 Agency to conduct research on regional visibility impairment and to establish the Grand Canyon

1 Visibility Transport Commission (GCVTC). The GCVTC was charged with assessing and  
2 providing recommendations to help preserve clear days and to improve visibility in the 16  
3 national parks and wilderness areas located on the Colorado Plateau. The GCVTC also was  
4 mandated to provide recommendations to the U.S. Environmental Protection Agency for the  
5 reduction of visibility impairment due to regional haze, described as any perceivable change in  
6 visibility (light extinction, visual range, contrast, or coloration) from that which would have  
7 existed under natural conditions that is caused predominantly by a combination of many  
8 anthropogenic sources over a wide geographical area (U.S. Environmental Protection Agency,  
9 1999a). In July 1999, the U.S. Environmental Protection Agency published the Regional Haze  
10 Rule (Federal Register, 1999). The regulation established a program for the improvement and  
11 protection of visibility in the 156 protected Class I parks and wilderness areas and included the  
12 establishment of baseline and current visibility conditions and the tracking of changes in  
13 visibility conditions over time. Implementation of the regional haze regulations is supported by  
14 the U.S. Environmental Protection Agency's PM<sub>2.5</sub> monitoring network and an expanded  
15 Interagency Monitoring of Protected Visual Environments (IMPROVE) network. The PM<sub>2.5</sub>  
16 monitoring network and the IMPROVE network are described briefly later in this section and in  
17 more detail elsewhere (National Park Service, 1998; Evans and Pitchford, 1991; U.S.  
18 Environmental Protection Agency, 2000b; U.S. Environmental Protection Agency, 2001).

19 The objective of the visibility discussion in this section is to provide a brief description of  
20 the fundamentals of atmospheric visibility and to summarize the linkage between particulate  
21 matter and visibility. Visibility is an effect of air quality and, unlike the particulate matter  
22 concentration, is not a property of an element of volume in the atmosphere. Visibility can be  
23 quantified only for a sight path and depends on the illumination of the atmosphere and the  
24 direction of view. However, the concentration of particles in the atmosphere plays a key role in  
25 determining visibility. Therefore, visibility impairment may be controlled by control of particle  
26 concentrations. The relationships between particles, other factors, and visibility impairment are  
27 described in this section. For a more detailed discussion on visibility, the reader is referred to  
28 the 1996 Air Quality Criteria for Particulate Matter (1996 PM AQCD; U.S. Environmental  
29 Protection Agency, 1996a); the Recommendations of the Grand Canyon Visibility Transport  
30 Commission (Grand Canyon Visibility Transport Commission, 1996); the National Research  
31 Council (National Research Council, 1993); the National Acid Precipitation Assessment

1 Program (Trijonis et al., 1991); Interim Findings on the Status of Visibility Research (U.S.  
2 Environmental Protection Agency, 1995a); Visibility: Science and Regulation (Watson, 2002),  
3 and reports summarizing visibility science and data from the IMPROVE visibility monitoring  
4 network (Malm et al., 2000; Sisler, 1996; Sisler et al., 1993).

### 6 **4.3.2 Factors Affecting Atmospheric Visibility**

7 The visual perception of a distant object is influenced by a large number of factors  
8 including human vision (the eye), the brain's response to signals received from the eye, the  
9 interaction of light with the atmosphere (e.g., atmospheric illumination, path and transmitted  
10 radiance, contrast, and optical properties), and atmospheric pollution from natural and  
11 anthropogenic sources. Detailed discussion of this full range of topics can be found in the 1996  
12 PM AQCD (U.S. Environmental Protection Agency, 1996a) and other general references (Malm,  
13 1999, Watson, 2002). This section focuses only on those topics that have been addressed by  
14 more recent research, including atmospheric illumination, the optical properties of gases and  
15 particles in the atmosphere, and the effects of relative humidity on the optical properties of  
16 particles.

#### 18 **4.3.2.1 Optical Properties of the Atmosphere and Atmospheric Particles**

19 Atmospheric particles and gases attenuate image-forming light as it travels from a viewed  
20 object to an observer. The fractional attenuation of light per unit distance is known as the light  
21 extinction coefficient. The light extinction coefficient,  $b_{ext}$ , is expressed in units of one over  
22 length, for example inverse kilometers ( $\text{km}^{-1}$ ) or inverse megameters ( $\text{Mm}^{-1}$ ). The light  
23 extinction coefficient can be expressed as the sum of the light scattering and light absorption  
24 coefficients of particles and gases.

$$26 \quad b_{ext} = b_{ap} + b_{ag} + b_{sg} + b_{sp} \quad (4-7)$$

27  
28 where the subscripts  $p$  and  $g$  signify particles and gases, and  $s$  and  $a$  signify scattering and  
29 absorption.

30 The light extinction coefficient can be measured with a reasonable degree of accuracy or  
31 can be calculated with the size, composition, shape, and the orientation of the particles. The

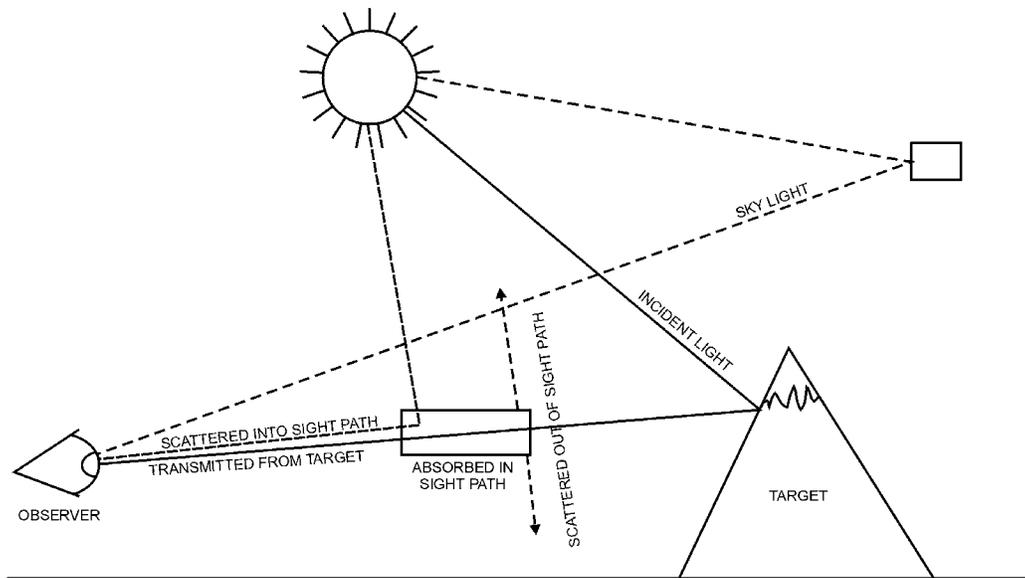

1 light extinction coefficient is influenced by meteorological conditions and optical properties  
2 along the sight path.

### 4 **Relationship Between Light, Targets, and Objects in a Sight Path**

5 The appearance of a distant object is determined by light from two sources: the light  
6 reflected from the object itself (initial radiance) and the light reflected by the intervening  
7 atmosphere (path radiance). Human vision and the brain's response to signals received from the  
8 eye distinguishes between objects by contrast or differences in the radiance of adjacent objects.  
9 Light reflected by objects is attenuated by scattering and absorption as it travels through the  
10 atmosphere toward the observer. The portion that reaches the observer is the transmitted  
11 radiance. During the daytime, the sight path is illuminated by the direct rays of the sun, diffuse  
12 skylight, light that has been reflected from the surface of the Earth, etc. Some of this  
13 illumination is scattered toward the observer by the air molecules and particulate matter in the  
14 sight path. The accumulation of the light scattered into the sight path is the path radiance or air  
15 light. The path radiance significantly influences the light transmitted by the object being  
16 viewed. As the path radiance increases, the light transmitted by an object decreases.

17 The transmitted radiance carries the information about the object; the path radiance only  
18 carries information about the intervening atmosphere and is often quite featureless. When the  
19 transmitted radiance is dominant, visibility is good. Conversely, when the path radiance is  
20 dominant, visibility is poor. In a dense fog, the transmitted radiance from nearby objects can be  
21 seen, but the transmitted radiance from more distant objects is completely overwhelmed by the  
22 path radiance (i.e., the light scattered by the fog). Distant objects are lost in the white (or gray)  
23 of the fog (Gazzi et al., 2001).

24 Figure 4-32 illustrates the radiance seen by an observer looking at a hillside or through the  
25 aperture of a measurement instrument. The radiance that enters the eye of the observer (or the  
26 aperture of a measurement instrument) is known as the apparent radiance (i.e., the sum of the  
27 transmitted and path radiance). The competition between the transmitted radiance and the path  
28 radiance determines visibility.

**Figure 4-32. Light reflected from a target toward an observer. The intervening atmosphere scatters a portion of this light out of the sight path and scatters light from the sun into the sight path. Some particles and gases also absorb a portion of the light from the target. The light scattered into the sight path increases with distance from the target, whereas the light transmitted from the target decreases with distance from the target. The visual range is the closest distance between the target and the observer at which the transmitted light no longer can be distinguished from the light scattered into the sight path.**

Source: Watson and Chow (1994).

## 1 **Light Absorption and Scattering by Gases**

2 In the ambient atmosphere the only visible-light-absorbing gas of any consequence is  
 3 nitrogen dioxide (NO<sub>2</sub>), which primarily absorbs blue light and, if present in sufficient  
 4 concentration across a sight path, causes yellow or brown color seen in urban hazes. Usually the  
 5 absorption by NO<sub>2</sub> is much smaller than the scattering by particles that are typically present in  
 6 polluted environments, such as urban areas. The most common exception to this situation of  
 7 relatively small NO<sub>2</sub> absorption is in effluent plumes from combustion facilities where the  
 8 particles are effectively removed but the nitrogen oxide (NO), which can convert rapidly to NO<sub>2</sub>,  
 9 is not removed. Except for such particle-depleted NO plumes, the light absorption coefficient  
 10 for gases is usually ignored in determinations of the light extinction.

1 Scattering by gases in the atmosphere is described by the Rayleigh scattering theory (van  
2 de Hulst, 1981) and is referred to as Rayleigh scattering. The magnitude of the Rayleigh  
3 scattering depends on the gas density of the atmosphere and varies from about  $9 \text{ Mm}^{-1}$   
4 to  $11 \text{ Mm}^{-1}$  for most locations of interest, depending primarily on site elevation. To simplify  
5 comparisons of light extinction coefficient values among sites at a variety of elevations, a  
6 standard value of  $10 \text{ Mm}^{-1}$  is often used for the Rayleigh scattering component (Malm, 2000).

### 7 8 **Light Absorption and Scattering by Particles**

9 Particle scattering tends to dominate light extinction except under pristine atmospheric  
10 conditions when Rayleigh scattering by gas molecules is the largest contributor. If the particle  
11 size, refractive index, and shape are known, the extinction coefficient can be calculated. For  
12 particles of sizes similar to the wavelength of visible light, Mie equations for homogeneous  
13 spheres can be used to calculate the scattering and absorption of individual particles.

14 Absorption by particles is primarily caused by elemental carbon (also referred to as soot or  
15 light-absorbing carbon) generated by the incomplete combustion of fossil fuels. Some minerals  
16 in crustal particles also absorb light and can be a significant factor during fugitive dust episodes.

17  
18 Most particle absorption data are determined by measuring light transmission or reflection  
19 of particles captured on filter media. Absorption estimates made in this way are sensitive to the  
20 filter substrate used, the optical configuration of the transmission measurement, particle loading  
21 on the filter, and particle scattering albedo with the result that there are significant uncertainties  
22 for measurements of filtered particles (Horvath, 1993). Another approach to estimating aerosol  
23 light absorption is by subtracting concurrent light scattering measurements made with a  
24 nephelometer from light extinction measurements made with a transmissometer. Substantial  
25 uncertainty in this difference approach results from the assumption that the point measurement  
26 of scattering is representative of the scattering over a long path (1 to 10 km) that is typically  
27 required for transmissometers measurements. A recently field-tested prototype photoacoustic  
28 spectrometer designed to determine absorption of suspended aerosol and an enclosed-folded path  
29 transmissometer offers hope of resolving the problems of the filter-based and difference  
30 approaches to the measurement of light absorption by particles (Arnott et al., 1999).

1           The relationship between elemental carbon concentration and particle absorption can be  
2 calculated using Mie equations for particles with known size distribution, particle density, index  
3 of refraction, shapes, and for various internal mixtures with non-absorbing aerosol materials  
4 (Fuller et al., 1999). Mie equations are used to determine the efficiency factors for extinction  
5  $Q_{\text{ext}}$ ,  $Q_{\text{scat}}$ , and  $Q_{\text{abs}}$ . The efficiency factors represent the fraction of light falling on a circle with  
6 the same diameter and index of refraction as the particle. While such application of this theory  
7 can provide a range of absorption efficiencies for various model aerosol distributions, it is rare  
8 that sufficiently detailed particle characterization data for ambient aerosols are available. Also,  
9 although elemental carbon is the strongest and most common of the absorbing particles, light  
10 absorption by elemental carbon particles can be reduced when the particle is covered by other  
11 chemical species (Dobbins et al., 1994) or may be enhanced when coated with a non-absorbing  
12 refractive material such as ammonium sulfate (Fuller et al., 1999).

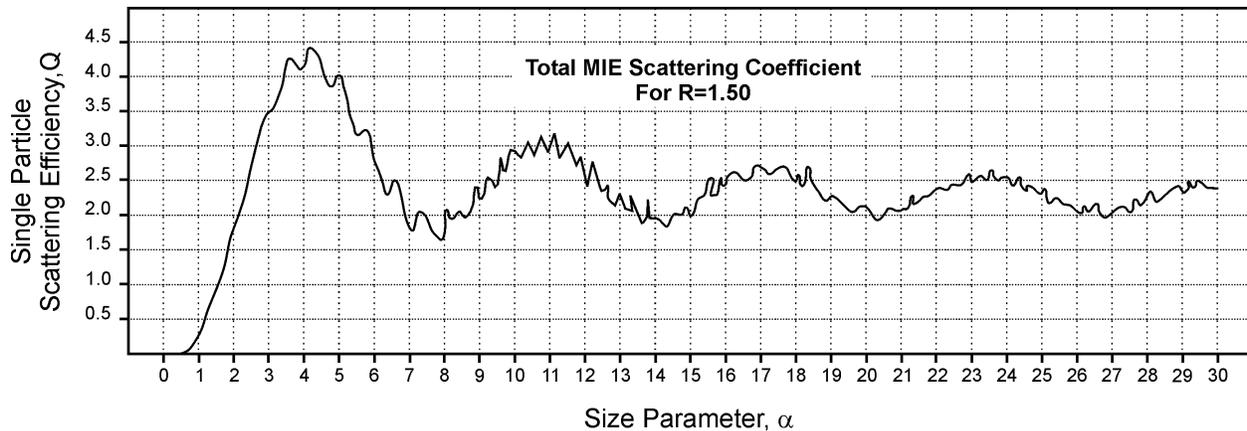

13           More commonly, estimates of elemental carbon absorption efficiency are empirically  
14 determined from the ratios of or the slopes of regression analysis fits to absorption coefficient  
15 and corresponding elemental carbon concentration measurements. Use of the regression  
16 approach permits the inclusion of crustal component concentrations as a second dependent  
17 parameter, so that crustal absorption can also be estimated. Uncertainties in the absorption  
18 efficiency determined empirically are a combination of the measurement uncertainties for the  
19 absorption coefficients, elemental carbon concentrations, and where used, the crustal  
20 concentrations. In reviews of estimates of elemental carbon light absorption mass efficiency  
21 (i.e., the absorption coefficient per carbon mass concentration), Horvath (1993) and Liousse et  
22 al. (1993) found values ranging from 2 to 17 m<sup>2</sup>/g. Moosmüller et al. (1998) showed that by  
23 limiting the absorption coefficient estimates to those using photoacoustic methods, the  
24 absorption efficiency shows a wavelength dependence with highest values (17 m<sup>2</sup>/g) at the  
25 shortest wavelength used ( $\lambda = 0.42 \mu\text{m}$ ) and lowest values (3 m<sup>2</sup>/g) at the longest wavelengths  
26 used ( $\lambda = 0.8 \mu\text{m}$ ). The center of the visible light wavelength ( $\lambda = 0.53 \mu\text{m}$ ) yielded elemental  
27 carbon absorption efficiencies values of approximately 10 m<sup>2</sup>/g, a commonly used value for  
28 elemental carbon absorption efficiency. Fuller et al. (1999) suggested that isolated spheres of  
29 light absorbing carbon have a specific absorption of less than 10 m<sup>2</sup>/g. Light absorption by  
30 carbon particles will be greater than 10 m<sup>2</sup>/g only if the particles are internally mixed and the

1 occluding particles are sufficiently large. Absorption values for graphitic and amorphous carbon  
2 for primary sizes typical of diesel soot are approximately  $5 \text{ m}^2/\text{g}$ .

3 Particle scattering tends to dominate light extinction except under pristine atmospheric  
4 conditions when Rayleigh scattering by gas molecules is the largest contributor. Light-scattering  
5 by particles has been reported to account for 68 to 86% of the total extinction coefficient in  
6 several cities in California (Eldering et al., 1994). When light-scattering increases, visibility is  
7 impaired because of a decrease in the transmitted radiance and an increase in the path radiance.  
8 The single most important factor that determines the amount of light scattered by a particle is its  
9 size, as shown in Figure 4-33 (based on Mie calculations). The maximum single-particle  
10 scattering efficiency (i.e., scattering per cross-sectional area of a particle) is associated with  
11 particles with diameters of about the wavelength of visible light (centered at  $0.53 \mu\text{m}$ ).  
12 For particles that are small compared to the wavelength of light, the single- particle scattering  
13 efficiency is low. For particles larger than the wavelength, the single particle scattering  
14 efficiency initially decreases with diameter and then fluctuates around a value of two as size  
15 increases. However, a larger particle always scatters more light than a smaller particle because  
16 particle cross-sectional area increases faster with diameter than does the decrease in single-  
17 particle scattering efficiency at any point on the scattering efficiency curve. The mass scattering  
18 efficiency (i.e., the scattering per mass concentration) peaks for particles that are about  $0.5 \mu\text{m}$  to  
19  $0.8 \mu\text{m}$  in diameter. Smaller particles are much less efficient at scattering light, while larger  
20 particles have mass that increases with particle size faster than the increase in the amount of light  
21 they scatter.

22 Use of the Mie equation to calculate light scattering or the light scattering efficiency of  
23 particles in the atmosphere is severely limited by the general lack of sufficiently detailed particle  
24 characterization data. At a minimum, size-resolved particle composition data (e.g., aerosol  
25 collected on an 8-stage impactor) are needed to permit meaningful Mie scattering calculations.  
26 The chemical composition provides clues to the appropriate particle density and index of  
27 refraction, while the size distribution is inferred by fitting a distribution function to the  
28 concentration for each stage. Assumptions are still necessary to address the particle component  
29 mixture characteristics of the aerosol. Resulting scattering calculations can be compared to  
30 directly measured particle extinction to assess the reasonableness of the Mie calculations.

31

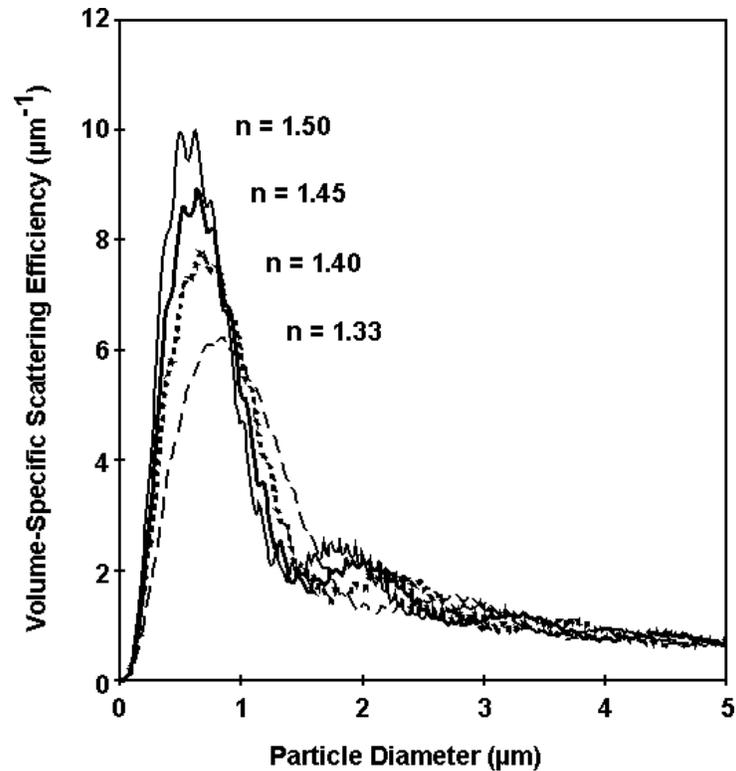

**Figure 4-33. Light-scattering efficiency factor (per cross sectional area), Q, for a homogeneous sphere with an index of refraction of 1.50 as a function of the size parameter,  $\alpha = \pi D/\lambda$ .**

Source: Penndorf (1958).

1            Reported calculated scattering efficiencies for sulfates range from 1.2 to 5.6 m<sup>2</sup>/g. Sulfate  
 2 scattering efficiencies have been reported to increase by a factor of two when the size  
 3 distribution increased from 0.15 to 0.5  $\mu\text{m}$  (McMurry et al., 1996). Calculated scattering  
 4 efficiencies for carbon particles ranged from 0.9 to 8.1 m<sup>2</sup>/g. A scattering efficiency of 1.0 and  
 5 0.6 m<sup>2</sup>/g was reported for soil and coarse mass, respectively (U.S. Environmental Protection  
 6 Agency, 1996a; Sisler and Malm, 2000).

7            Figure 4-34 gives the volume-specific light scattering efficiency in units of  $\mu\text{m}^{-1}$  as a  
 8 function of particle diameter. The light scattering coefficient is derived by multiplying the  
 9 volume-specific light scattering efficiency factor by the volume concentration. The mass-  
 10 specific light scattering efficiency can be obtained by dividing the values for the curves by the  
 11 density of the particulate matter.

12           Similar results have been produced in field nephelometer measurements of ambient particle  
 13 scattering. A variety of nephelometer configurations, unrestricted or size selective inlets and the  
 14 control of sample air temperature and relative humidity, permit the composite scattering  
 15 properties of ambient aerosol to be directly observed (Day et al., 1997). When sample-  
 16 controlled nephelometer data are combined with collocated particle speciation data, composite

**Figure 4-34. Volume-specific light-scattering efficiency as a function of particle diameter  $D_p$ . The calculations were performed for the indicated indices of refraction and a wavelength of 550 nm. For large particle diameters the scattering efficiencies tend toward a value of  $3/D_p$ . Mass-specific light-scattering efficiencies (in units of  $m^2/g$ ) can be obtained by dividing the values of the curves by the particle density (in units of  $g/cm^3$ ).**

Source: U.S. Environmental Protection Agency (1996a).

1 particle scattering efficiency values for ambient aerosol can be empirically derived (Malm et al.,  
 2 2000).

3 The scattering efficiency for particles have been reported by White et al. (1994) for dry  
 4 particles less than 2.5  $\mu m$  (2.4 and 2.5  $m^2/g$ ) and coarse particles 0.34 to 0.45  $m^2/g$ ). Other  
 5 reported values for coarse particles include 0.4 and 0.6  $m^2/g$  (White and Macias, 1990 and  
 6 Trijonis and Pitchford, 1987). Nephelometer measurements for light scattering by coarse  
 7 particles is underestimated (White et al., 1994). Chow et al. (2002a) reported scattering  
 8 efficiencies of 2 to 3  $m^2/g$  but in some cases  $> 5 m^2/g$  for dry particles less than 2.5  $\mu m$ .

#### 4.3.2.2 Relative Humidity Effects on Particle Size and Light-Scattering Properties

The ability of some commonly occurring chemical components of atmospheric aerosol to absorb water from the vapor phase has a significant effect on particle light scattering. Hygroscopic particulate materials, which typically include sulfuric acid, the various ammonium sulfate salts, ammonium nitrate, and sodium chloride, change size by the accumulation and loss of water as they maintain equilibrium with the vapor phase as a function of changes in relative humidity. For some materials (e.g., sulfuric acid), the growth is continuous and reversible over the entire range of relative humidity. For other materials, water absorption begins abruptly for a dry particle at a specific relative humidity known as the deliquescent point (e.g., ~80% for ammonium sulfate) and continues as relative humidity increases. There is a hysteresis effect with these materials in that, once wet, the relative humidity can be reduced below the deliquescent point until crystallization occurs at a substantially lower relative humidity (e.g., ~30% for ammonium sulfate). Figure 4-35 shows the water vapor growth curve for ammonium sulfate.

Water growth behavior for hygroscopic materials commonly found in atmospheric aerosol in pure form or in some mixtures is generally well known as a result of laboratory measurements (Tang and Munkelwitz, 1994; Tang, 1997). Models that calculate water growth of mixtures from known solubility properties of many common water-soluble chemicals have long been available (Zdanovskii, 1948) and have been successfully applied to determine growth for particles with known composition (Saxena and Peterson, 1981; Pilinis et al., 1995; Saxena et al., 1993).

The water growth of individual ambient particles can be directly measured using a humidity-controlled tandem differential mobility analyzer or TDMA (McMurry and Stolzenburg, 1989; Zhang et al., 1993). Inferences can be made about the mixtures of soluble and insoluble particle components by comparing TDMA measured growth and size-resolved aerosol composition data with water growth model predictions (Pitchford and McMurry, 1994; Zhang et al., 1993; Saxena et al., 1995). A practical limitation of TDMA measurements in investigating aerosol optical properties is that particles with diameter greater than 0.5  $\mu\text{m}$  are not well measured by this approach.

Accounting for water growth of atmospheric aerosols is important in determining visibility because particles containing hygroscopic or deliquescent materials change size, index of

**Figure 4-35. Particle growth curve as a function of relative humidity showing deliquescent growth of ammonium sulfate [(NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>] particles at the deliquescent point (A, about 80% relative humidity [RH]), reversible hygroscopic growth of ammonium sulfate solution droplets at RH greater than 80%, and hysteresis (the droplet remains supersaturated as the RH decreases below 80%) until the crystallization point (B, about 38% RH) is reached.**

Source: Adapted from National Research Council (1993) and Tang (1980).

1 refraction, and hence scattering efficiency, with changing relative humidity. The nonlinear  
 2 nature of particle growth curves for hygroscopic aerosols means that substantial light scattering  
 3 changes result from modest relative humidity changes under humid conditions (relative humidity  
 4 > 90%). The magnitude of the water growth effect on light scattering for ambient aerosols can  
 5 be directly measured with humidity-controlled nephelometer measurements (Day et al., 1997).  
 6 Measurements of water growth effects on scattering are compared to results of water growth and  
 7 Mie scattering models applied to size-resolved composition data using various mixture  
 8 assumptions to infer average mixture and other aerosol characteristics (Malm et al., 2000).

9 While the importance of inorganic hygroscopic particles is well understood, the role of  
 10 organic compounds in particle water growth has been the subject of recent investigations.  
 11 In their interpretation of TDMA and particle composition data from two locations, Saxena et al.  
 12 (1995) made the case that organic components of the aerosol enhanced water absorption by

1 particles at a remote desert location and retarded water absorption at an urban location. They  
2 speculated that the latter might be due to hydrophobic organic material coatings on inorganic  
3 hygroscopic particles.

4 While some of the thousands of organic compounds that are in atmospheric aerosols are  
5 known to be hygroscopic and while a significant fraction of the organic aerosol material is  
6 known to be water soluble, there is a lack of water absorption data for most organic compounds.  
7 The incomplete water solubility data combined with incomplete data on the abundance of the  
8 numerous organic compounds in ambient aerosols means that organic water growth model  
9 calculations are not a reasonable approach to assessing the importance of water growth by  
10 organic aerosol components in the atmosphere. To overcome this constraint, Saxena et al.  
11 (1995) compared organic concentration to the difference between total aerosol water measured  
12 by TDMA and model-estimated water for the inorganic hygroscopic aerosol components. In  
13 contrast, Pitchford and McMurry (1994) used the same remote location data set and showed that  
14 on six of the eight sampling days water uptake by the sulfates and nitrates could account for all  
15 of the measured water absorption.

16 Swietlicki et al. (1999) made TDMA measurements in northern England and found that  
17 growth takes place in two modes, one mode being less hygroscopic than the other. They  
18 concluded that growth could be attributed to the inorganic content of the aerosol. Cocker et al.  
19 (2001) measured hygroscopic properties of Pasadena, California aerosol and concluded that  
20 growth factors increased when forest fires were present. McDow et al. (1995) measured water  
21 uptake by diesel soot, automobile exhaust, and wood smoke particles. They found all three  
22 emission types absorbed water: the wood smoke sample weight increased by about 10% as  
23 sample relative humidity was increased; whereas diesel soot sample weight increased by only  
24 2% to 3%. Chughtai et al. (1999) examined hydration characteristics of a number of  
25 anthropogenic and natural organic materials. They found surface water adsorption increased  
26 with age and surface oxidation. Hemming and Senfield (2001) evaluated the relative  
27 hygroscopicity of different organics, the differences in the amount of water taken up by  
28 mixtures, and the individual components of the mixtures in their pure state using the UNIFAC.  
29 They found that mixtures take up less water than the individual components in the pure state.  
30 The relative hygroscopicity of atmospheric organics was diacids > monoacids > alcohols  
31 > carbonyls. Analysis of humidity-controlled and size-resolved chemistry data from Great

1 Smoky Mountains and Grand Canyon National Parks (Malm et al., 1997; Malm and  
2 Kreidenweis, 1996; Malm et al., 2000) show that ambient organic aerosol are at most weakly  
3 hygroscopic to within the measurement uncertainty and modeling assumptions.

4 A more detailed discussion of the effects of relative humidity on the size distribution of  
5 ambient particles appears in Chapter 2 of this document.

### 7 **4.3.3 Relationships Between Particles and Visibility**

8 Visibility, referring to the appearance of scenic elements in an observer's line of sight,  
9 depends on more than the optical characteristics of the atmosphere. Numerous scene and  
10 lighting characteristics are important to this broad definition of visibility. However, under a  
11 variety of viewing conditions, visibility reduction or haziness is directly related to the extinction  
12 coefficient.

13 Light extinction, the sum of the light scattered and absorbed by particles and gases, is  
14 frequently used to estimate the effect of air pollution on visibility. Light extinction is usually  
15 quantified using the light extinction coefficient, that is the sum of the light scattering and  
16 absorption coefficients for gases and particles (see Section 4.3.2.1).

17 The influence of particles on visibility degradation is dependent on the particle size,  
18 composition, and solubility (Pryor and Steyn, 1994). Fine particles (particles with mass mean  
19 diameters less than or equal to 2.5  $\mu\text{m}$ ) scatter more light than coarse particles. Fine particle  
20 species included sulfates (assumed to be ammonium sulfate), nitrates (assumed to be ammonium  
21 nitrate), organics, light-absorbing carbon and soil (Malm et al., 1994). Of the fine particle  
22 species, sulfates and nitrates are the most hygroscopic and require the use of a relative humidity  
23 adjustment factor. The effect of particle light extinction can be determined by totaling the  
24 scattering and absorption of light by multiplying the mass-specific efficiency values and the  
25 mass concentration for each of the particle species. The effect of relative humidity and the  
26 relative humidity adjustment factors are discussed in Section 4.3.2.2. Visibility is measured by  
27 human observation, the light extinction coefficient (light scattering and absorption by particles  
28 and gases), and parameters related to the light extinction coefficient (visual range, deciview) and  
29 fine particle mass concentrations. Using the equation for the light extinction coefficient, light  
30 extinction by particles can be expressed as

$$b_{ext} = b_{ap} (b_{EC}) + b_{sp} (b_{SO_4} + b_{NO_3} + b_{OC} + b_{Soil} + b_{Coarse} + b_{sg}) \quad (4-8)$$

where

$$b_{ap} = 10[\text{mass of elemental carbon}]$$

$$b_{SO} = 3[\text{mass concentration of } (NH_4)_2SO_4]f(RH)$$

$$b_{NO_3} = 3[\text{mass concentration of } (NH_4)_2SO_4]f(RH)$$

$$b_{OC} = 4[OC]$$

$$b_{soil} = 1[Soil]$$

$$b_{sg} = 10 [\text{Rayleigh scattering by gases}]$$

The visual range method of visibility measurement, commonly taken to be the greatest distance that a large dark object (e.g., a mountain in shadow) can be seen against the background sky (Middleton, 1952), was developed for and continues to function well as an aid in military operations and transportation safety. Visual range is inversely proportional to the light extinction. Visual range can be calculated from a point measurement of light, assuming that the atmosphere and the illumination over the sight path is uniform and the threshold contrast is 2% of the extinction coefficient

$$\text{Visual Range} = K/b_{ext} \quad (4-9)$$

where visual range is in kilometers,  $b_{ext}$  is in  $km^{-1}$ , and a threshold contrast of 2% is assumed.

If  $b_{ext}$  is in  $Mm^{-1}$ , the Koschmieder constant becomes 3,912.

A new index of haziness, expressed in deciview (dv) units, is also very simply related to the light extinction coefficient (Pitchford and Malm, 1994).

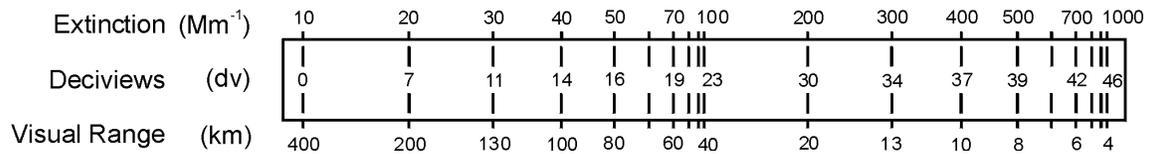

$$\text{Haziness (dv)} = 10 \ln(b_{ext}/10 Mm^{-1}) \quad (4-10)$$

An important characteristic of this visibility index is that it is more nearly linearly related to perceived changes in haze level than either visual range or light extinction. A change of 1 or

1 2 dv in uniform haze under many viewing conditions will be seen as a small but noticeable  
 2 change in the appearance of a scene regardless of the initial haze condition.

3 Figure 4-36 illustrates the relationship of light extinction in  $Mm^{-1}$ , deciview index, and  
 4 visual range in kilometers. Although the deciview is related to extinction, it is scaled in such a  
 5 way that is perceptually correct (Fox et al., 1999).

6  
 7

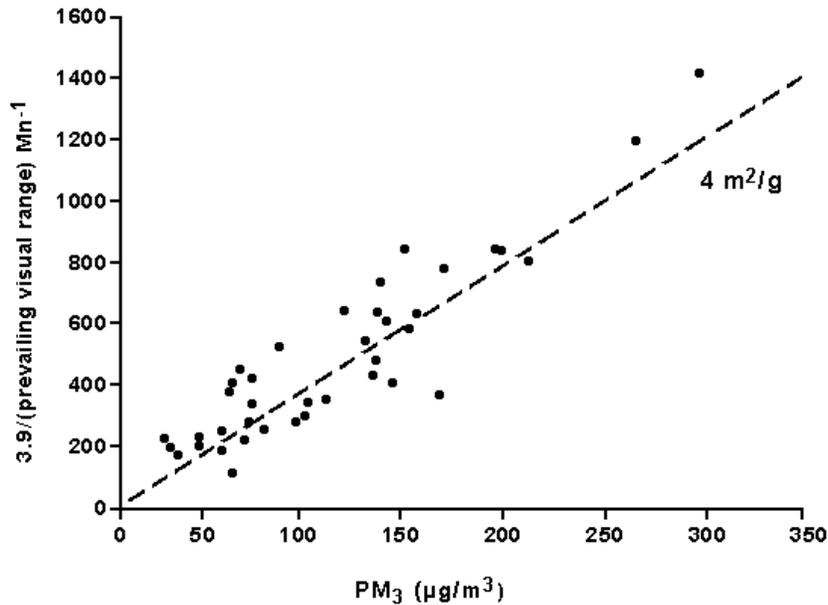

**Figure 4-36. Comparison of extinction ( $Mm^{-1}$ ) and visual range (km).**

Source: Fox et al. (1999).

1 Several early studies have demonstrated a relationship between enclosed nephelometer  
 2 light scattering measurements and fine particle mass collected on a filter (Waggoner et al., 1981;  
 3 Samuels et al., 1973). However, the relationship between fine particle mass and light scattering  
 4 may differ between locations and for different times of the year. The relationship is improved by  
 5 using the same size selective inlet on both the nephelometer and filter sampler (White et al.,  
 6 1994) and by minimizing the effect of high relative humidity on filter specimens and in the  
 7 nephelometer scattering chamber. When particle speciation data for the major aerosol  
 8 components are available, the relationship between particles and light extinction can be further  
 9 improved by treating the individual major components separately. A recent study by Chow et al.  
 10 (2002a) also suggested that continuous light scattering measurements may be useful as an  
 11 indicator of short-term variations in  $PM_{2.5}$  mass concentrations when the measurements are made  
 12 under dry conditions. Figure 4-37 shows the relationship between fine particle mass and  
 13 calculated light extinction.

14 Most routine aerosol monitoring programs and many special study visibility  
 15 characterization programs were designed to measure the major aerosol components (Malm et al.,  
 16 1994; Tombach and Thurston, 1994; Watson et al., 1990); they were not designed to determine

**Figure 4-37. Proportionality of observed daytime haziness to fine particle mass concentration in Los Angeles. Visual ranges are 8-h averages of hourly human observations, plotted as extinction according to Koschmieder formula. Mass concentrations are from 8-h samples collected behind a cyclone with 3-µm cut point. Relative humidities were  $\leq 70\%$ .**

Source: Chow et al. (2002b).

1 the microphysical and chemical characteristics of these species. However, the inherent  
 2 limitations of estimating aerosol optical properties from bulk aerosol measurements have been  
 3 addressed, at least in part, by a number of authors. For instance, Ouimette and Flagan (1982)  
 4 have shown from basic theoretical considerations that if an aerosol is mixed externally (i.e.,  
 5 separate particles contain the major aerosol components) or if in an internally mixed aerosol the  
 6 index of refraction is not a function of composition or size and the aerosol density is independent  
 7 of volume, then

$$b_{sp} = \sum \alpha_i m_i \quad (4-11)$$

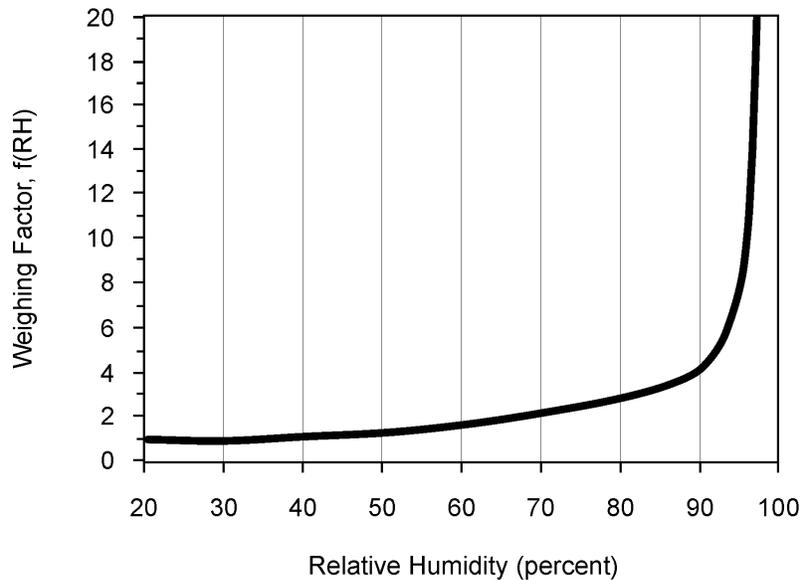

10 where  $\alpha_i$  is the specific mass scattering efficiency and  $m_i$  is the mass of the individual aerosol  
 11 species.  
 12

1 Sloane (1983, 1984, 1986), Sloane and Wolff (1985), and more recently Lowenthal et al.  
2 (1995) and Malm and Kreidenweiss (1997) have shown that differences in estimated specific  
3 scattering between external and internal model assumptions are usually less than about 10%.  
4 In the absence of detailed microphysical and chemical information of ambient particles, the  
5 above studies demonstrate that a reasonable estimate of aerosol extinction can be achieved by  
6 assuming each species is externally mixed.

7 The latest IMPROVE Program report (Malm, 2000) includes calculated aerosol light  
8 extinction for each of the five major fine fraction particle ( $PM_{2.5}$ ) components, coarse fraction  
9 mass ( $PM_{10-2.5}$ ), and Rayleigh scattering by gases and sums them for an estimate of total light  
10 extinction in  $Mm^{-1}$  using the following algorithm:

$$\begin{aligned} b_{ext} = & (3) f(RH) [SULFATE] + \\ & (3) f(RH) [NITRATE] \\ & +(4) [ORGANIC CARBON] \\ & +(10) [LIGHT ABSORBING CARBON] \\ & +(1) [SOIL] \\ & +(0.6) [COARSE PM] \\ & +10 \text{ (for Rayleigh scattering by gases)} \end{aligned} \tag{4-12}$$

19  
20 where each PM term is the product of a constant dry extinction efficiency for that species, the  
21 mass concentration of the species, and, for sulfate and nitrate, an adjustment factor that is a  
22 function of relative humidity to account for their hygroscopic behavior. The relative humidity  
23 adjustment term for sulfate and nitrate, shown in Figure 4-38, is based upon the ammonium  
24 sulfate growth curve, shown in Figure 4-28, smoothed between the upper and lower curves of the  
25 hysteresis loop for the relative humidity range of 30-80%. The extinction efficiencies for soil  
26 and coarse mass used in this algorithm are taken from a literature review by Trijonis et al.  
27 (1987). The extinction efficiency for light absorbing (elemental) carbon of  $10 \text{ m}^2/\text{g}$  is consistent  
28 with the value reported by Moosmüller et al. (1998) corresponding to  $\lambda = 0.53$  in the middle of  
29 the visible light spectrum. The dry extinction efficiencies of  $3 \text{ m}^2/\text{g}$  for sulfate and nitrate  
30 species and  $4 \text{ m}^2/\text{g}$  for organic species are based on literature reviews by Trijonis et al. (1991)  
31 and by White (1991). Trijonis' best estimate for sulfates is  $2.5 \text{ m}^2/\text{g}$  with an uncertainty of a

**Figure 4-38. Relative humidity adjustment factor, f(RH), for ammonium sulfate as a function of relative humidity.**

Source: Malm et al. (2000).

1 factor of 2, while White's average low and high estimates for the rural West are 3.0 and  
 2 3.7 m<sup>2</sup>/g. For organics, Trijonis estimates a dry extinction efficiency of 3.75 m<sup>2</sup>/g with an  
 3 uncertainty of a factor of 2, and White's range for the rural West is 1.8 to 4.1 m<sup>2</sup>/g. Malm et al.  
 4 (1996) and Malm (2000) used this algorithm to successfully reconstruct scattering at a total of  
 5 eleven IMPROVE monitoring sites.

6 Malm (2000) used additional sophisticated aerosol size, composition, and microphysical  
 7 data from a special study at the Great Smoky Mountain National Park to compare the  
 8 performance of a number of models for calculating light extinction. He found that the simplest  
 9 approach adequately predicted for periods of low light scattering but under-predicted by about  
 10 30% during periods of high sulfate concentration. The greatest improvement over the simple  
 11 model was obtained by including the degree of sulfate ammoniation in the model. This  
 12 produced better estimates of the extinction coefficient over the entire range. Table 4-15 lists  
 13 various visibility metrics and methods for visibility measurement.

14

TABLE 4-15. VISIBILITY MEASUREMENT TECHNIQUES

Visibility Metric and Method	Measurement Principle
Visual Range	Human observation of prevailing visibility. Targets are selected at known distances from an observer. Nighttime targets require lights and may differ from daytime targets. Each hour, the observer records the distance (i.e., VR) corresponding to the furthest target that is visible. This method provides the longest history of visibility measurements in the United States, as it was used at most U.S. airports from 1948 to 1995.
Light extinction ( $b_{ext}$ )	Directly measures the radiance of a constant light source (transmitter) after the light travels over a finite atmospheric path.
Long-path transmissometer	The transmittance of the path is calculated by dividing the measured radiance by the calibrated initial intensity of the light source. The average extinction of the path is calculated from the transmittance and length of the path.
Short-path transmissometer	Starting in the early 1990s, many sites replaced human observations with automated sensors (i.e., Automated Surface Observing System [ASOS], Automated Weather Observing System [AWOS]) to measure 1-min-average light extinction. The visibility sensor measures forward scattering using a xenon flash lamp source. Instruments can provide measurements up to 48 km, but they are not recorded beyond 16 km.
<u>Contrast transmittance:</u> Teleradiometer	A telescope is focused on a distant target and the background. Changes in radiance are measured by photodiode detectors. Measurements can be made at different wavelengths (e.g., 450, 550, and 630 nm) using narrow band filters. Measures effects of particles of all sizes. Sensitive to variations in inherent contrast (e.g., bright or dark cloud behind the target) and nonuniform illumination conditions. Because path radiance depends on how the atmosphere is illuminated, contrast transmittance represents human perception better than air quality.
Photographs and time-lapse film	A densitometer measures light transmitted through different portions of a color slide. The film's light-response function (the gamma curve) determines target-sky contrast. Computerized photographic simulations can change contrast transmittance for different meteorological and atmospheric conditions, and can be used to judge how people react to these changes.
Particle scattering ( $b_{scat,p}$ )	Air is drawn into a nephelometer chamber that is illuminated with white or filtered (typically 500-550 nm) light. Light is detected at 90° to the direction of illumination to measure the amount scattered out of the light path. Chamber dimensions limit the integrated arc to ~ 10-170° instead of a full 0-180°, which results in some forward scattering from coarse particles being underestimated. Nephelometers are calibrated with gases of known indices of refraction. Particles (especially hygroscopic and volatile species) may be modified as they pass through the chamber, which is inadvertently heated by the illumination source.
Integrating nephelometer	

**TABLE 4-15 (cont'd). VISIBILITY MEASUREMENT TECHNIQUES**

Visibility Metric and Method	Measurement Principle
<u>Particle absorption (<math>b_{\text{abs,p}}</math>):</u> Aethalometer or particle soot absorption photometer	Particles are collected on a quartz-fiber filter tape. The change in transmittance at selected wavelengths (e.g., 880 nm) across the filter before and after sampling is measured or compared with the reference area. When the filter spot darkens, a new portion of the tape is moved into the sampling position. Assumes a constant relationship between BC mass and quartz filter transmittance of $\sim 19\text{m}^2/\text{g}$ . Assumes a relationship of $10\text{m}^2/\text{g}$ between BC absorption and concentration.
Photoacoustic spectroscopy	Particles absorb energy from a modulated laser ( $\sim 514.5$ nm) and transfer heat to the surrounding air. Expansion of the heated gas produces sound waves (acoustic signals) that are proportional to the amount of absorbed energy. These are detected by a high-sensitivity microphone. Absorption appears to vary with illumination wavelength.
Filter transmittance, reflectance	Uses densitometer, integrating plate, or integrating sphere spectrophotometer to measure how much light is transmitted or reflected. The difference in the logarithms of light transmission through the filter before and after sampling is proportional to the particle deposit. Light transmission of particles collected on a filter may overestimate light absorption because some of the incident light is scattered within the filter and by other particles in the deposit. There are no absolute calibration standards for densitometry, integrating plate, or sphere methods.
Suspension of insoluble elemental carbon	Particles collected on a Nuclepore polycarbonate-membrane filter are extracted in 30% isopropanol/70% distilled deionized water to form a suspension of insoluble EC particles. Using a spectrophotometer, light transmission (e.g., 400-650 nm, peaking at 575 nm) is measured through the liquid extract.
Component extinction ( $b_{\text{ext}}$ ) (sum of $b_{\text{scat,p}}$ , $b_{\text{scat,g}}$ , $b_{\text{abs,p}}$ , and $b_{\text{abs,g}}$ )	The sum of clean air scattering estimated from temperature and pressure, $\text{NO}_2$ absorption estimated from $\text{NO}_2$ concentrations, particle scattering measured by nephelometer, and particle absorption ( $b_{\text{abs,p}}$ ) measured by one of the $b_{\text{abs,p}}$ methods. Measurements are at a single location rather than along a sight path.
<u>Chemical extinction (<math>b_{\text{ext}}</math>):</u> Filter measurements for $\text{SO}_4^{-2}$ , $\text{NO}_3^-$ , organics, EC, fine soil, and coarse mass, plus clear air scattering	Six aerosol chemical components are used to calculate chemical extinction.

#### 4.3.4 Photographic Modeling of Visibility Impairment

None of the visibility indices communicate visibility associated with various aerosol conditions as well as directly seeing their effects on a scene. However, photographic modeling for the representation of haze can be useful in portraying changes in visibility specifically due to changes in air pollutant concentrations. Photographic modeling holds constant the effects of sun angle, cloud cover, and relative humidity and is a cost-effective method of evaluating various air quality scenarios. Photographic modeling is difficult to do with actual photographs because of the range of possible conditions in the same scene over multiple days; and, over time, photographs can be expensive to produce. Another limitation in using photographic models for representation of haze is that haze is assumed to be uniformly distributed throughout the scene and selected conditions are idealized, so the full range of conditions that occur in a scene are not represented.

Eldering et al. (1996) proposed the use of a model that uses simulated photographs from satellite and topographic images to evaluate the effect of atmospheric aerosols and gases on visibility. Use of this model requires ground-based photography and data concerning the size distribution and chemical composition of atmospheric aerosols, NO<sub>2</sub> concentration, temperature, and relative humidity for a clear day. Light extinction and sky color are then calculated based on differences in aerosol size distribution, NO<sub>2</sub> concentration, temperature, and relative humidity. The images created represent natural landscape elements.

Molenaar et al. (1994) provides a discussion of existing visual air quality simulation methods based on techniques under development for the past 20 years. A photograph taken on a very clean, cloud-free day serves as the base image. The photograph is taken during the season and at the same time of day as the scene to be modeled. The light extinction represented by the scene is derived from aerosol and optical data associated with the day the image was taken, or it is estimated from contrast measurements of features in the image. The image is then digitized to assign an optical density to each picture element (pixel) for the wavelength bands of interest. A detailed topographic map and an interactive image-processing display system is used to determine the specific distance, elevation angle, and azimuth angle for each element in the picture with respect to the observer's position.

Various models are employed to allow the presentation of different air quality scenarios. The output from atmospheric aerosol models (e.g., extinction, scattering coefficients, single

1 scattering albedo, and scattering phase matrix) is incorporated into radiative transfer models to  
2 calculate the changes in radiant energy (path radiance, image radiance, sky radiance, terrain  
3 radiance) caused by scattering and absorption by gases and particles as it passes through the  
4 atmosphere. Atmospheric aerosol models are also use to model the effect of relative humidity  
5 on the visual air quality (Molenar et al., 1994).

6 Molenar et al. (1994) has developed a system call WinHaze that permits the viewing of  
7 computer-generated uniform hazes superimposed on digitized scenic photographs of both remote  
8 and urban scenes. The program simulates changes in visual air quality imagery from user-  
9 specified changes in optical parameters (e.g.,  $\sigma_{\text{ext}}$ , visual range, or deciview values) or aerosol  
10 species concentrations. WinHaze includes imaging for various Class I national parks and  
11 wilderness areas and Boston, MA; Dallas, TX; Denver, CO; Fort Collins, CO; Phoenix, AZ;  
12 and Tucson, AZ. The computer software is available through the IMPROVE website  
13 (<http://vista.cira.colostate.edu/improve/>).

#### 14 15 **4.3.5 Visibility Monitoring Methods and Networks**

16 Visibility monitoring studies measure the properties of the atmosphere either at the sampler  
17 inlets (point measurements), as is the case with air quality measurements, or by determining the  
18 optical properties of a sight path through the atmosphere (path measurements). Instrumental  
19 methods for measuring visibility are generally of three types: (1) direct measurement of light  
20 extinction of a sight path using a transmissometer, (2) measurement of light scattering at one  
21 location using an integrating nephelometer, and (3) measurement of ambient aerosol mass  
22 concentration and composition (Mathai, 1995).

23 The largest instrumental visibility monitoring network in the United States is the  
24 Automated Surface Observing System (ASOS), commissioned by the National Weather Service,  
25 Federal Aviation Administration, and Department of Defense at more than 900 airports. The  
26 system is designed to objectively measure the clarity of the air versus the more subjective  
27 evaluations of human observations. The system provides real-time data for airport visibility.

28 The visibility sensor, instead of measuring how far one can see, measures the clarity of the  
29 air using a forward-scatter visibility meter. The clarity is then converted to what would be  
30 perceived by the human eye using a value called Sensor Equivalent Visibility (SEV). Values  
31 derived from the sensor are not affected by terrain, location, buildings, trees, lights, or cloud

1 layers near the surface. The amount of moisture, dust, snow, rain, and particles in the light beam  
2 will affect the amount of light scattered. The sensor transmits 1-min values based on rolling  
3 10-min periods. Hourly visibility range data are available only at a quantized resolution of  
4 18 binned ranges with a visual range of up to 10 miles. The value provides a generally accurate  
5 and representative visibility measurement within a 2 to 3 mile radius of the site. The forward  
6 scatter meter was found to correlate fairly well with extinction coefficient measurements from  
7 the Optec Transmissometer (National Weather Service, 1998).

8 Visibility data from the ASOS network is reported in terms of visual range in increments of  
9 1/4 to 1 statute mile. Visual range conditions exceeding 10 miles are truncated to 10 miles for  
10 real-time reporting purposes. Data is not extensively archived at ASOS locations; however,  
11 researchers are able to download the raw data directly from certain sites. In addition, since 1998,  
12 the raw visibility data (including light extinction measurements corresponding to visual ranges  
13 exceeding 10 miles) have been archived for a number of sites. Visual range measurements  
14 beyond 10 miles may be used to derived particulate matter concentrations except in clean  
15 environments. These data are available from the National Climatic Data Center.

16 The largest monitoring network that includes both visibility and aerosol conditions is the  
17 Interagency Monitoring of Protected Visual Environments (IMPROVE) network. This network  
18 was formed in 1987 as a collaborative effort between Federal, regional, and state organizations  
19 responsible for protection of visibility in the 156 mandatory Class I Federal areas (national parks  
20 and wilderness areas) and other areas of interest to land management agencies, states, tribes, and  
21 other organizations (National Park Service, 1998; U.S. Environmental Protection Agency,  
22 1996a; U.S. Environmental Protection Agency, 1995b; Eldred et al., 1997; Perry et al., 1997;  
23 Sisler and Malm, 2000; U.S. Environmental Protection Agency, 1999b). It is predominantly a  
24 rural-based network with more than 140 sites across the country. The primary monitoring  
25 objectives of the IMPROVE program are to document current visibility conditions in the  
26 mandatory Class I areas, to identify anthropogenic chemical species and emission sources of  
27 visibility impairment through the collection of speciated PM<sub>2.5</sub> data, and to document long-term  
28 trends for assessing progress towards elimination of anthropogenic visibility impairment. The  
29 IMPROVE network has also been involved in visibility related research, including the  
30 advancement of visibility monitoring instrumentation and analysis techniques and visibility

1 monitoring and source attribution field studies (National Park Service, 1998; Evans and  
2 Pitchford, 1991).

3 Visibility monitoring under the IMPROVE network can be divided into three categories:  
4 aerosol, optical, and scene. Twenty-four hour  $PM_{2.5}$  and  $PM_{10}$  aerosol samples are collected by  
5 filters at least every third day. The  $PM_{2.5}$  samples are analyzed to determine the mass  
6 concentration of the major particulate constituents (sulfates, nitrates, organic carbon compounds,  
7 elemental carbon, chlorides, and crustal elements) and for elements that indicate sources of  
8 visibility-impairing particles (trace elements and ions). Optical monitoring provides a direct  
9 measurement of light scattering and absorption. Color photographic imaging documents the  
10 appearance of the scene under a variety of air quality and illumination conditions (U.S.  
11 Environmental Protection Agency, 1999b). It is anticipated that all data generated by the  
12 IMPROVE network will be added to the AIRS database.

13 The U.S. Environmental Protection Agency has deployed a new national monitoring  
14 network (Federal Reference Method Monitoring network) designed to assess  $PM_{2.5}$   
15 concentrations and composition. There are over 1,000 monitoring sites in operation and many  
16 sites report data to the Aerometric Information Retrieval System (AIRS). Analyses of these  
17 data are expected to provide a more complete understanding of visibility conditions, in particular  
18 urban visibility, across the country. The  $PM_{2.5}$  monitoring effort has been coordinated with  
19 visibility monitoring efforts currently in place to maximize the benefits of all of the monitoring  
20 programs (U.S. Environmental Protection Agency, 1997b; U.S. Environmental Protection  
21 Agency, 2000b; U.S. Environmental Protection Agency, 2001).

22 The Northeast States for Coordinated Air Use Management (NESCAUM) has established a  
23 real-time visibility monitoring network (CAMNET) using digital photographic imaging.  
24 Currently, there is digital photographic imaging for five urban locations (Boston, MA;  
25 Burlington, VT; Hartford, CT; Newark, NJ; and New York City, NY), and two rural locations  
26 (Acadia National Park, ME and Mt. Washington, NH). The visibility images are updated every  
27 15 minutes. Near real-time air pollution and meteorological data are updated every hour.  
28 Archived images will be available for studies of the visual effects of particulate matter air  
29 pollution in the Northeast. CAMNET may be accessed at [www.hazecam.net](http://www.hazecam.net) (Northeast States  
30 for Coordinated Air Use Management, 2002; Leslie, 2001).

1 The Midwest Regional Planning Organization, in cooperation with a number of other  
2 groups, has also developed a real-time visibility camera network (hazecam). The camera  
3 network includes several urban (Chicago, IL; Indianapolis, IN; and Cincinnati, OH) and rural  
4 locations (Seney NWR, MI; Mayville, WI; and Isle Royale National Park, MI/Grand Portage,  
5 MN). The Midwest hazecam can be found at <http://www.mwhazecam.net>.

#### 7 **4.3.6 Visibility Impairment: Trends and Current Conditions**

8 In the United States, visibility impairment is caused by particles primarily composed of  
9 sulfates, nitrates, organic compounds, carbon soot, and crustal dust. Visibility is best in Alaska  
10 and the western Great Basin. Moderate levels of light extinction are common on the Pacific  
11 Coast, including the western slopes of the Sierra Nevadas in California and the Cascade Range in  
12 Oregon and Washington. Visibility is most impaired in the areas encompassing and adjacent to  
13 the Ohio and Tennessee River Valleys. Visibility gradually improves along the Atlantic  
14 seaboard northeast of New York City (Watson, 2002). Estimates of natural visibility for the  
15 eastern and western United States are  $26 \pm 7 \text{ Mm}^{-1}$  natural extinction,  $12 \text{ Mm}^{-1}$  for clean air and  
16  $17 \pm 2.5 \text{ Mm}^{-1}$  natural extinction,  $11 \text{ Mm}^{-1}$  for clean air, respectively (Watson, 2002).

##### 18 **4.3.6.1 Trends in Visibility Impairment**

19 Trends in visibility impairment or haziness often are used as indicators of trends in fine  
20 particles mass. Observations of visual range, obtained by the National Weather Service and  
21 available through the National Climatic Data Center of the National Oceanic and Atmospheric  
22 Administration provide one of the few truly long-term, daily records of impairment related to air  
23 pollution. After some manipulation including correction for relative humidity effects, the visual  
24 range data can be used as an indicator of fine mode particle pollution. The data reduction  
25 process and analyses of resulting trends have been reported by Schichtel et al. (2001), Husar  
26 et al. (1994), Husar and Wilson (1993), and Husar et al. (1981).

27 There are many statistical approaches to estimating trends. These approaches include  
28 simple correlation and regression analyses, time series analyses, and methods based on  
29 non-parametric statistics. A discussion and comparison of the methods for the detection of linear  
30 trends is provided in Hess et al. (2001). Schimek (1981) provides a discussion of nonlinear  
31 trends. In its annual air quality trends report, the U.S. Environmental Protection Agency

1 characterized trends using a non-parametric regression analysis approach commonly referred to  
2 as the Theil test (U.S. Environmental Protection Agency, 1998; Hollander and Wolfe, 1973).

### 4 *Regional Trends and Class I Areas*

5 The two largest contributors to visibility impairment are sulfates and carbon-based  
6 particles. In the east, sulfates are responsible for 60 to 86% of the visibility impairment. The  
7 sulfate contribution decreases further west but is still responsible for between 25 to 50% of the  
8 visibility impairment. Carbon-based particles are responsible for 10 to 18% of the visibility  
9 impairment in the East and 25 to 40% in the West. Nitrates account for only 7 to 16% of the  
10 light extinction in the East but are responsible for between 5 to 45% of the light extinction in the  
11 West. Crustal material can be a major contributor in the West, accounting for 5 to 25% of the  
12 light extinction. Elemental carbon also is contributor to light extinction but to a much lesser  
13 degree (U.S. Environmental Protection Agency, 2001).

14 The U.S. Environmental Protect Agency designated five regional groupings as part of the  
15 regional haze program. The regions are Northeast (Mid-Atlantic/Northeast Visibility Union),  
16 Southeast (Visibility Improvement State and Tribal Association of the Southeast), Central  
17 (Central States Regional and Air Partnership), Midwest (Midwest Regional Planning  
18 Organization), and West (Western Regional Air Partnership). The regional groupings serve as  
19 consensus organizations comprised of states, tribes, and federal agencies coordinating the  
20 implementation of the regional haze rule.

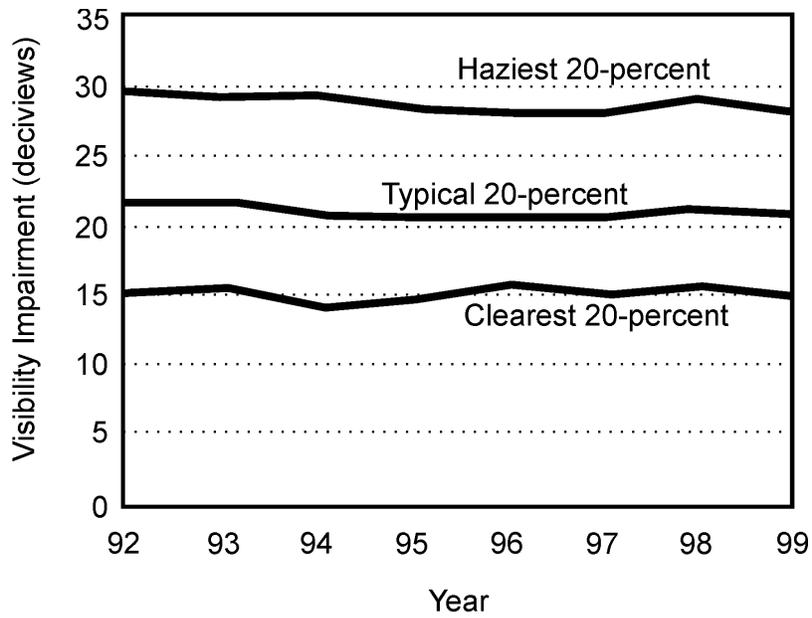

21 Using hourly prevailing daytime visibility data from human observations at weather  
22 stations, Schichtel et al. (2001) observed that haziness declined approximately 10% across the  
23 United States between 1980 and 1995. The decrease in haziness was highest in the southeastern  
24 United States with a 20% decrease in the 90<sup>th</sup> percentile light extinction and a 12% decrease in  
25 the 75<sup>th</sup> percentile over the 15 year period. There was a 17% decrease in the 90<sup>th</sup> percentile and a  
26 9% decrease in the 75<sup>th</sup> percentile over the eastern United States. Over the eastern United States,  
27 haziness was greatest during the summer months. The greatest visibility impairment was  
28 adjacent to the Appalachian Mountains in Tennessee and the Carolinas (extinction coefficient of  
29  $> 0.2 \text{ km}^{-1}$  equivalent to 6 miles). During the cold season, elevated haze (extinction coefficient  
30 of  $> 0.2 \text{ km}^{-1}$ ) was seen between the Great Lakes and the Ohio River Valley, over the Gulf States

1 between Texas and Florida, along the coast from North Carolina to New Jersey, and along the  
2 Pacific coast, particularly central and south California.

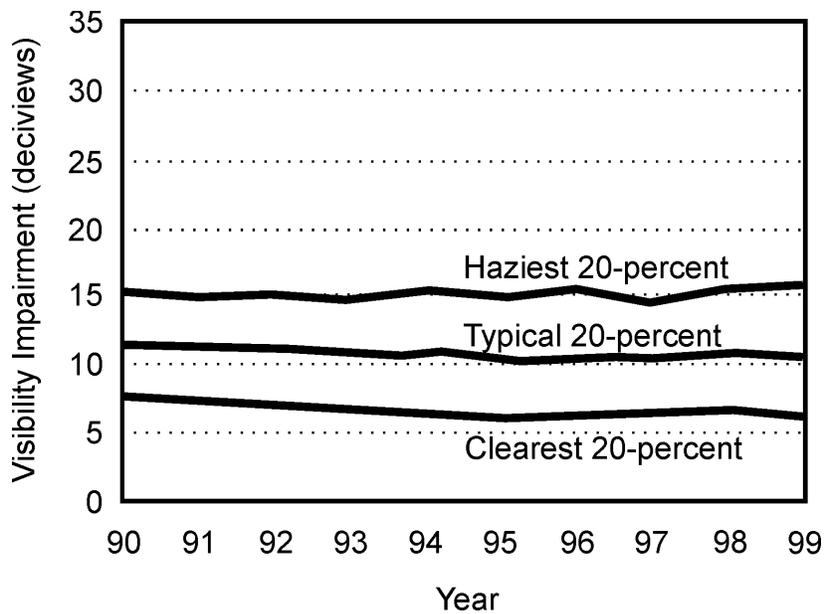

3 Visibility impairment or haziness in the southeastern United States from sulfate emissions  
4 is greatest in the humid summer months because of the ability of sulfate to absorb atmospheric  
5 water vapor. Summer haziness increased in the southeastern United States from the 1950s to  
6 1980 along with increasing SO<sub>2</sub> emissions. A statistically significant increase in summer sulfate  
7 concentrations was noted in two Class I areas in the eastern United States (Shenandoah and the  
8 Great Smoky Mountains) from 1982 to 1992 (Eldred et al., 1993; Cahill et al., 1996). During  
9 that time, the majority of the Southwest showed decreasing sulfur concentrations (Eldred et al.,  
10 1993; Eldred and Cahill, 1994). Increasing summer sulfate concentrations were later shown at  
11 those two locations by Iyer et al. (2000).

12 Limited visibility measurements are available for the upper Midwest region (Illinois,  
13 Indiana, Michigan, Ohio, and Wisconsin and the tribal lands located in the states). The Midwest  
14 Regional Planning Organization conducted an initial assessment of the regional haze problem in  
15 this region using existing reports and available air quality data for four major urban areas (St.  
16 Louis, Chicago, Detroit, Cincinnati) and Class I areas. The “worst” and “best” visibility days  
17 occur throughout the year. Particulate sulfates were the major contributors to light extinction  
18 during the summer months, and nitrates dominated on the worst visibility days during the winter  
19 and fall in both urban and Class I areas. Organics also were significant contributors to light  
20 extinction in urban areas. Higher PM<sub>2.5</sub> concentrations were correlated with poorer visibility in  
21 the southern portion of the region (Midwest Regional Planning Organization, 2001).

22 The U.S. Environmental Protection Agency’s National Air Quality and Emission Trends  
23 Report summarized an estimated of the regional trends and current conditions in 35 Class I areas  
24 and one urban area (Washington, DC), using chemical concentrations data from the IMPROVE  
25 network (U.S. Environmental Protection Agency, 2001). The visibility trends analysis is an  
26 aggregate of 10 eastern Class I areas and 26 western Class I areas. Trends were presented for  
27 annual average values for the clearest (“best”) 20% , middle (“typical”) 20%, and haziest  
28 (“worst”) 20% of the days monitored each year. The visibility trends, given in changes in  
29 deciview values, for the eastern and western sites are illustrated in Figures 4-39a and 4-39b.  
30 From the figures it can be seen that the haziest days in the West are equivalent to the best days in  
31 the East. In the East, there was a 16% (1.5 deciview) improvement in haziness on the clearest

**Figure 4-39a. Aggregate visibility trends (in deciviews) for 10 eastern Class 1 areas.**

**Figure 4-39b. Aggregate visibility trends (in deciviews) for 26 western Class 1 areas.**

Source: U.S. Environmental Protection Agency (2001).

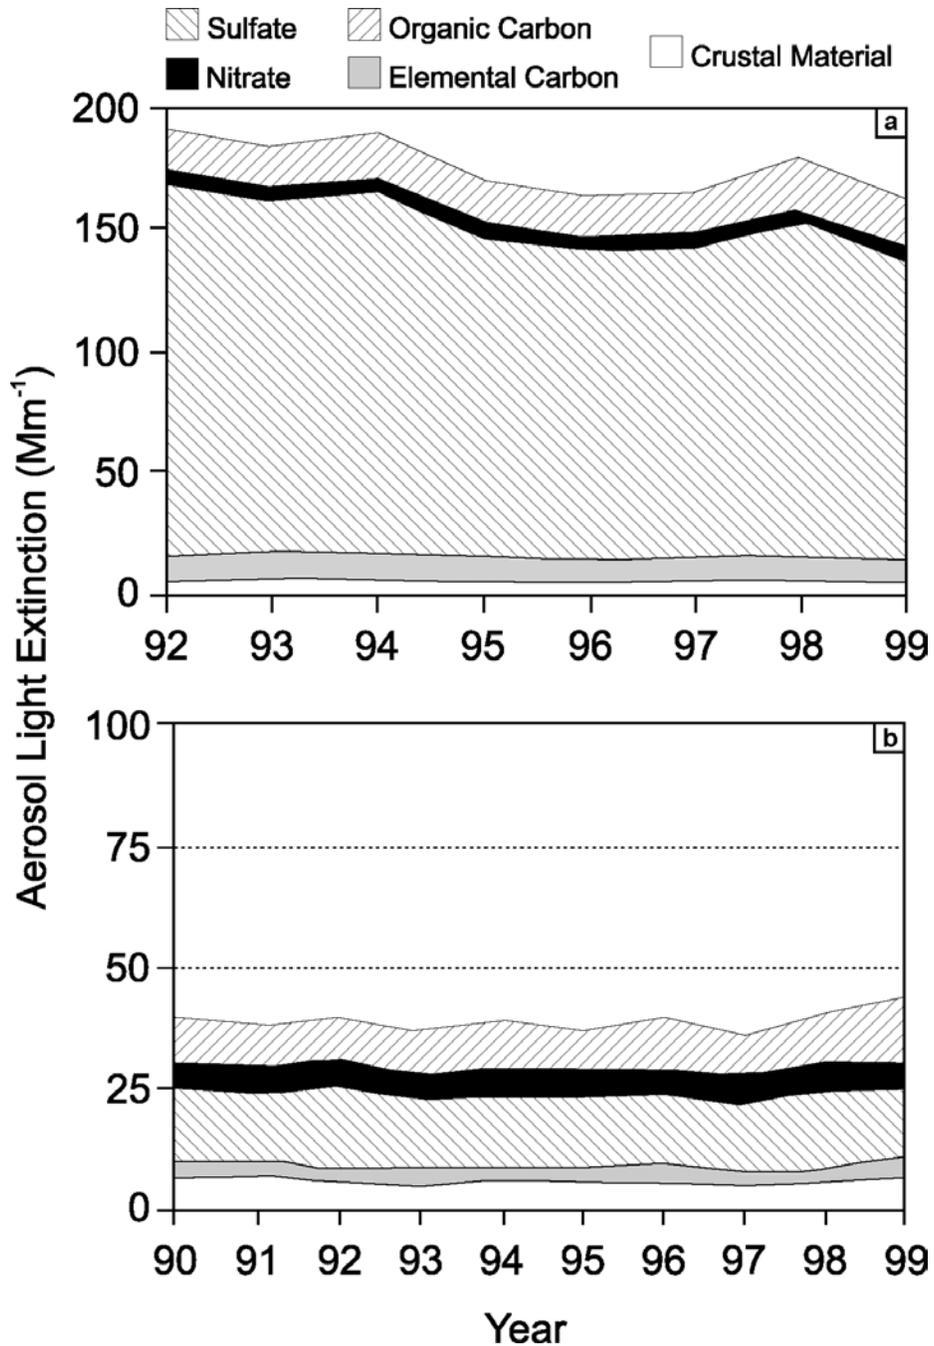

1 days since 1992. Improvements in visibility were noted in the East for the haziest days;  
2 however, based on monitoring data for 1999, visibility remains significantly impaired, with a  
3 visual range of 23 km for the haziest days compared to a mean visual range of 84 km for the  
4 clearest days. A 25% and a 14% improvement in visibility impairment were seen for the clearest  
5 and middle days in the West, respectively; whereas conditions for the haziest days degraded by  
6 18.5% (1.7 deciviews) between 1997 and 1999, but were relatively unchanged compared to 1990  
7 conditions (U.S. Environmental Protection Agency, 2001).

8 Figures 4-40a and 4-40b illustrate aggregate trends in aerosol light extinction, including  
9 trends by major aerosol component for the haziest 20% of days monitored for the 10 eastern  
10 Class I areas from 1992 to 1999 and the haziest 20% of days monitored for the 26 western  
11 Class I areas from 1990 to 1999. The report also includes a number of maps characterizing  
12 aerosol light extinction and key components at 36 IMPROVE sites (all rural except Washington,  
13 DC) for 1997 through 1999 (U.S. Environmental Protection Agency, 2001).

#### 14 15 *Urban Trends*

16 Most of the available visibility measurements, with the exception of the airport visual  
17 range measurements, focus on the impact of pollution on visibility in scenic vistas and regional  
18 haze (Class I areas). Many urban metropolitan areas are monitoring daily visibility conditions.  
19 These findings are generally not available in a published form and may not distinguish between  
20 pollution- and weather-related effects. Although the EPA Regional Haze Rule addresses  
21 visibility impairment in Class I areas and calls for states to establish goals for improving  
22 visibility in these areas and to develop long-term strategies for reducing emissions of air  
23 pollutants that cause visibility impairment, the steps states take to implement the regulation will  
24 also improve visibility and health in broad areas across the country.

25 Kleeman et al. (2001), citing previously published studies, provided an historical  
26 description of visibility conditions in Southern California from the early 1930s. Based on airport  
27 observation data for 1932 to 1949, visibility conditions began to decrease in Los Angeles with  
28 the advent of industrialization and population growth. Visibility conditions were worse during  
29 the 1940s than the 1930s, and the lowest visibility conditions occurring between 1944 and 1947.  
30 During this period, there was nearly a complete loss of extremely good visibility days. Between

**Figure 4-40. (a) Eastern class I area aggregate trends in aerosol light extinction on the 20% haziest days, including trends by major aerosol component; (b) Western class I area aggregate trends in aerosol light extinction on the 20% haziest days, including trends by major aerosol component.**

Source: U.S. Environmental Protection Agency (2001).

1 1943 and 1947, the number of extremely good visibility days during the summer season dropped  
2 to 0.2% from 21%.

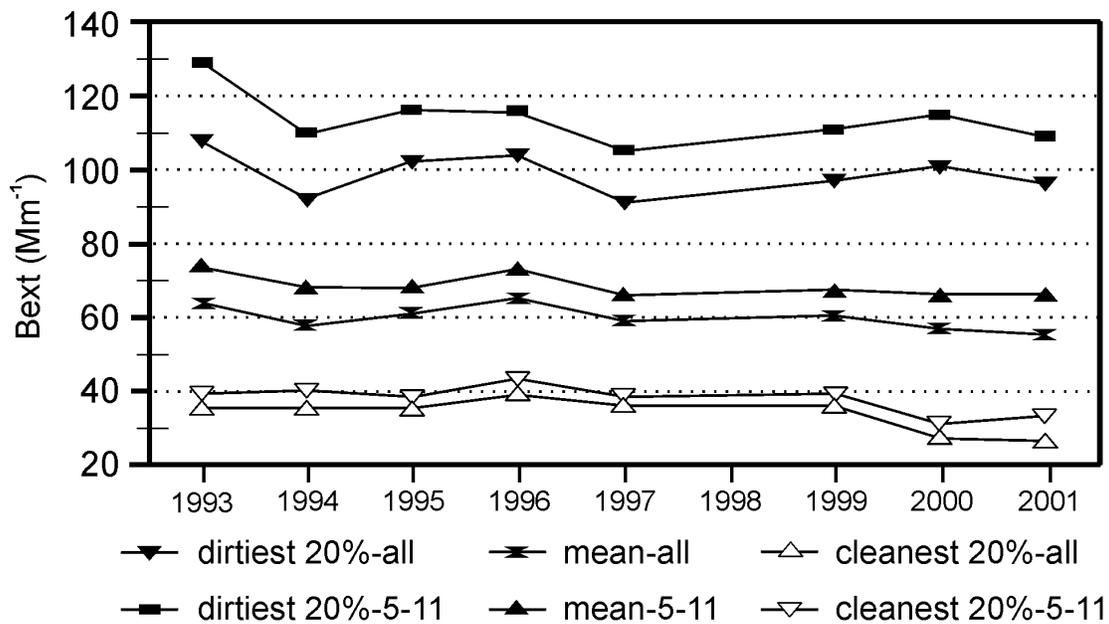

3 Between 1950 and 1961, deteriorating visibility conditions extended eastward from  
4 Los Angeles along the corridor adjacent to the foothills of the San Gabriel and San Bernardino  
5 Mountains. The visual range in the areas nearest Los Angeles was  $\leq 3$  miles for more than  
6 140 days per year when the relative humidity was  $< 70\%$ . Further east of Los Angeles, past  
7 Ontario and San Bernardino, the visibility was  $\leq 3$  miles for 110 days per year during the same  
8 time period.

9 Improvements in visibility conditions have been made since the 1970s. The largest have  
10 been made in the western Los Angeles Basin. In Ontario, the average number of days per year  
11 when visual range was greater than 10 miles was 99 between 1976 and 1978 and increased to  
12 113 between 1988 and 1990 (Kleeman et al., 2001). In contrast to the Los Angeles Basin and  
13 Ontario, Denver and surrounding areas have experienced high pollution episodes since the  
14 1970s. Climate changes trap cooler air under a cover of warm air causing the pollution to remain  
15 stagnant over the area producing a brown cloud comprised of a variety pollutants including  
16 nitrogen and sulfur oxides, and the grit and dust.

17 Debate over the cause of the increasing pollution in the Denver area and the controversy  
18 over converting coal-fired power plants to a cleaner natural gas system led to initiation of the  
19 1973 Denver Air Pollution Study, 1978 Denver Winter Haze Study, 1987-1988 Metro Denver  
20 Brown Cloud Study, and the 1993 Denver Brown Cloud Modeling Study. In 1990, in an effort  
21 to improve air quality, Denver adopted a visibility standard of 0.076/km (units of atmospheric  
22 extinction per kilometer; 20.1 deciviews) averaged over 4 h. While this is a step towards  
23 reducing air pollution, the Denver region still exceeds the visibility standard 50 to 80 times per  
24 year (Lloyd, 2002).

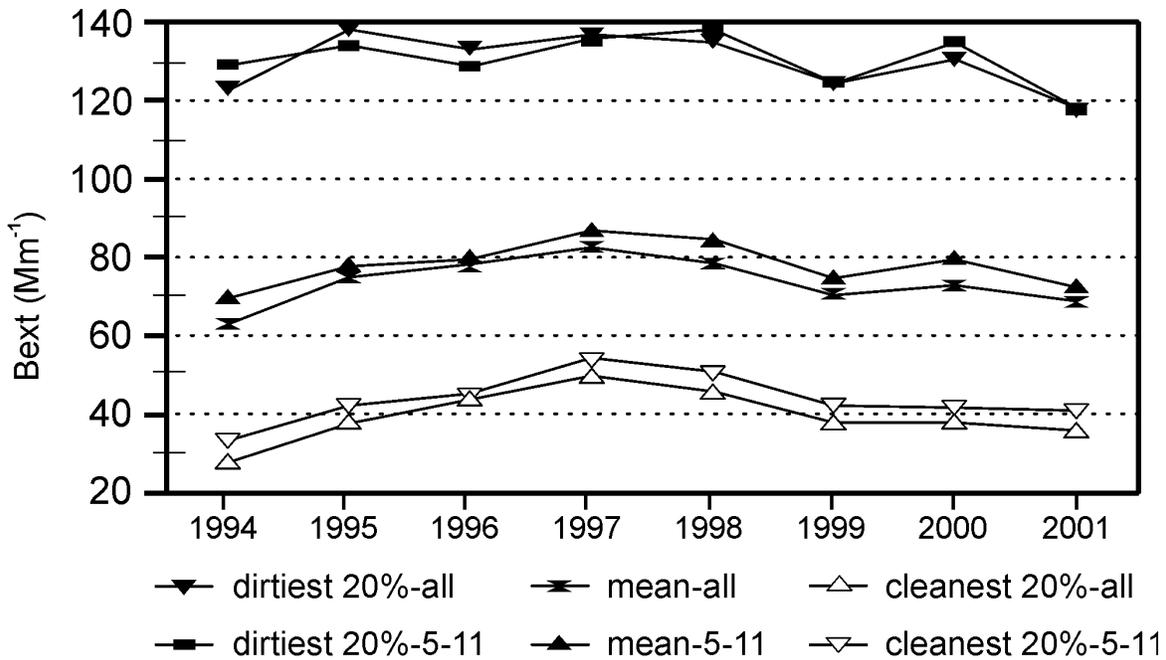

25 A major air quality study was conducted in Phoenix, AZ, during the fall and winter of 1988  
26 to 1990 to address degrading visibility conditions in Phoenix and other urban areas. The  
27 objectives were to (1) develop a data base of visibility, air quality, and meteorological  
28 measurements; (2) establish quantitative relationships between light extinction and emission  
29 sources; and (3) evaluate measurement systems for short-term and long-term monitoring in  
30 Phoenix. The major contributors to light extinction in Phoenix were residual wood burning,  
31 primary mobile source emissions, and secondary ammonium nitrate (Chow et al., 1990).

1 The Arizona Department of Environmental Quality has conducted optical measurements of  
 2 visibility in Tucson since 1993 and in Phoenix since 1994. The measurements are divided into  
 3 the mean of the “dirtiest” 20% of all hours, the mean of all hours, and the mean 20% “cleanest”  
 4 of all hours for the entire day and for the 5:00 to 11:00 a.m. period. Figures 4-41a,b represent  
 5 the trends in visibility conditions from 1993 to 2001 for Tucson and from 1994 to 2001 for  
 6 Phoenix. Visibility on the dirtiest days in the Phoenix metropolitan area has not changed since  
 7 visibility monitoring started; but, visibility on the best days has significantly degraded. There is  
 8 a seasonally related effect on visibility in Phoenix: the mean and the dirtiest 20% of all hourly  
 9 light extinction are more pronounced during the winter and fall months (Arizona Department of  
 10 Environmental Quality, 2002). Daytime visibility is worst during the morning. Samples taken  
 11 from 1994 to 1996 showed that organic and elemental carbon dominated visibility impairment  
 12 during the dirtiest and cleanest days, whereas ammonium nitrate was an important contributor  
 13 during the 20% dirtiest days (Neuroth and Heisler, 2000).  
 14  
 15

Source: Arizona Department of Environmental Quality (2002).

**Figure 4-41b. Light extinction trends in Phoenix, Arizona from 1994 to 2001.**

Source: Arizona Department of Environmental Quality (2002).

1           The State of Virginia compared visibility trends at five locations both with and without  
 2 pre-1948 airport visual range data. Average annual airport visual-range-data from Roanoke  
 3 (1936 to 1998), DC Reagan National (1930 to 1998), Richmond (1942 to 1998), Lynchburg  
 4 (1935 to 1998), and Elkins, WV (1936 to 1994) were used in the analysis. Their findings  
 5 indicate that trends in visibility conditions were dependent on the baseline year used for  
 6 visibility measurements. When airport visual range data from 1948 are used as the baseline data  
 7 for visibility conditions, the trend in visual range shows declining conditions for all sites. When  
 8 pre-1948 data are included in the analysis, visibility conditions basically are unchanged or  
 9 improved (except for Elkins). When 1948 data are used as the baseline for visibility trends  
 10 measurements, visual range decreases at all locations. Average annual visual ranged varied  
 11 between 7+ miles and 8+ miles for all sites (Virginia Climate Advisory, 2000).  
 12  
 13

#### 1 **4.4.6.2 Current Conditions**

2 Current visibility conditions have been well-characterized for Class I areas using updated  
3 data from the IMPROVE network (U.S. Environmental Protection Agency, 2001; Malm et al.,  
4 2000; IMPROVE, 1998). During recent decades, daytime visibility conditions at all major  
5 airports throughout the United States were recorded hourly by human observation. These data  
6 were used to determine current visibility conditions and visibility trends in the United States,  
7 as well as the spatial distribution of visibility conditions (Trijonis et al., 1991). The use of  
8 human observation is being replaced by an automated observing system, the Automated Surface  
9 Observing System (ASOS). More than 900 airports are currently commissioned. In addition,  
10 the U.S. Environmental Protection Agency has deployed a new national monitoring network to  
11 assess PM<sub>2.5</sub> concentrations and composition.

12 More detailed information on visibility conditions for urban and suburban areas will  
13 become more widely available as data from the national PM<sub>2.5</sub> speciation monitoring network  
14 and the ASOS airport visibility network are further analyzed. Efforts are currently underway to  
15 develop a web-based system to allow the use of the high resolution ASOS data in air quality  
16 monitoring and assessment programs. The objectives are to collect and quality control an  
17 archive of the ASOS visibility data, to deliver processed hourly visibility data to public and air  
18 quality communities, and to use the web-based system to support the acquisition and  
19 dissemination of visibility data (Falke, 2001).

#### 21 **4.3.7 Economics of Particulate Matter Visibility Effects**

22 Society recognizes the need to impose remedies for repairing and preventing further  
23 anthropogenic pollutant-related effects on visibility conditions. Various methods have been  
24 utilized to help determine the economic valuation of changes in visibility. Where possible,  
25 direct economic valuation can be determined using marketplace cost estimates. Avoided-cost  
26 methods estimate the costs of pollution by using the expenditures that are made necessary by  
27 pollution damage. As an example, if ambient levels of PM result in increased frequency of  
28 building cleaning or repainting, the appropriately calculated increase in these costs is a  
29 reasonable estimate of true economic damage. Benefits associated with reductions in the  
30 pollution levels are then represented by the avoided costs of these damages.

1 Estimating the benefits of clear skies is a more difficult and less precise exercise because,  
2 although the public values aesthetic views, they are not directly bought and sold in the  
3 marketplace. However, there are several methods available to economists to estimate the  
4 economic impact of these kinds of changes in environmental conditions (Freeman, 1993). These  
5 methods include hedonic valuation or pricing, contingent valuation and contingent choice, and  
6 travel cost (Johnson and Desvousges, 1997; Hanley and Spash, 1993). The primary methods  
7 used to date for valuation of visibility have been the hedonic price and contingent valuation  
8 methods (Hanley and Spash, 1993); but this is not an exact science, and there are still issues and  
9 limitations associated with each of these methods.

10 Hedonic pricing can be used to estimate economic valuations for environmental effects that  
11 have a direct effect on market values. It relies on the measurement of differentials in property  
12 values under various environmental quality conditions including air pollution and environmental  
13 amenities, such as aesthetic views. The hedonic method works by analyzing the way that market  
14 prices change with changes in environmental quality. Part of the economic costs imposed by  
15 PM-related reductions in visibility can be estimated by looking at the differences in sales price  
16 between otherwise identical houses that have different degrees of visibility impairment.

17 The contingent valuation method (CVM) is the most widely used method for estimating  
18 value changes in both visibility and ecosystem functions (Hanley and Spash, 1993; Chestnut,  
19 1997; Watson and Chow, 1993). The CVM creates hypothetical markets for goods and services  
20 that have no market-determined price. For determination of visibility evaluation, individuals are  
21 shown photographs with perceivable differences in visibility levels. Carefully structured surveys  
22 are administered to estimate the amount of compensation equivalent to a given change in  
23 environmental quality or, equivalently, how much an individual would be willing to pay (WTP)  
24 for improvements in environmental quality or willing to accept (WTA) existing conditions  
25 without further deterioration. There is an extensive scientific literature and body of practice on  
26 both this theory and technique; however, there are still concerns about the use of this technique  
27 for quantitative purposes.

28 The travel-cost method estimates can be used to estimate the value of recreational benefits  
29 of an ecosystem based on the environmental quality at the site. The travel-cost method uses  
30 information on actual behavior rather than responses to hypothetical scenarios. The time and  
31 travel expenses incurred to visit a site represents the price of access to the site. The willingness

1 to pay to maintain the site is determined by the number of times the individual visits the site at  
2 different travel costs.

3 The effects of PM on visibility may differ widely between urban residential and  
4 recreational areas. Therefore, separate estimates are needed to account for impact associated  
5 with changes in visibility in residential and recreational (Class I) areas. Chestnut and Dennis  
6 (1997) compared the findings of the more recent studies on the economic impact of changes in  
7 regional haze using the contingent valuation method in residential areas in several eastern cities  
8 and in Los Angeles and San Francisco and using the hedonic value method in Los Angeles and  
9 San Francisco. The findings of the contingent valuation studies are discussed in Table 4-16.  
10 Findings using the contingent and hedonic methods of valuation for Los Angeles and San  
11 Francisco are compared in Table 4-17.

12 Using the contingent valuation method, Chestnut and Rowe (1990) found that 83% of those  
13 individuals responding to a survey on visibility were willing to pay to improve visibility in the  
14 National Parks. Survey participants were selected from California, Arizona, Missouri,  
15 New York, and Virginia. The National Parks from three regions (California, southwestern  
16 United States, and southeastern United States) were considered in different versions of the  
17 survey. The survey included questions on past and future visitations to national parks, potential  
18 pollution effects from human activities outside of the park, three hypothetical visibility  
19 scenarios, socioeconomic characteristics, and various photographic presentations of visibility  
20 conditions within the parks. Higher responses were noted for residents residing in the state or  
21 region where the national park was located; responses for males and the elderly were generally  
22 lower and there was a direct correlation between household income and the response.

23 Using the results from the Chestnut and Rowe (1990) study, Chestnut and Dennis (1997)  
24 calculated an extinction coefficient of 85 for in-state residents and 50 for out-of-state residents.  
25 These extinction coefficients were suggested to represent an annual willingness to pay per  
26 household of \$15 and \$9 for a 20% improvement in visual range.

#### 4.4 PARTICULATE MATTER EFFECTS ON MATERIALS

Effects of air pollution on materials are related to both aesthetic appeal and physical damage. Studies have demonstrated that particles, primarily consisting of carbonaceous compounds, cause soiling of commonly used building materials and culturally important items, such as statutes and works of art. Physical damage from the dry deposition of air pollutants, such as PM (especially sulfates and nitrates) and SO<sub>2</sub>, and the absorption or adsorption of corrosive agents on deposited particles also can result in the acceleration of naturally occurring weathering processes of man-made building and cultural materials.

In the atmosphere, PM may be “primary,” existing in the same form in which it was emitted, or “secondary,” formed by the chemical reactions of free, absorbed, or dissolved gases. The major constituents of atmospheric PM are sulfate, nitrate, ammonium, and hydrogen ions; particle-bound water; elemental carbon; a great variety of organic compounds; and crustal material. A substantial fraction of the fine particle mass, particularly during the warmer months, is secondary sulfate and nitrate. Sulfates may be formed by the gas-phase conversion of SO<sub>2</sub> to H<sub>2</sub>SO<sub>4</sub> by OH radicals and aqueous-phase reactions of SO<sub>2</sub> with H<sub>2</sub>O<sub>2</sub>, O<sub>3</sub>, or O<sub>2</sub>. During the day, NO<sub>2</sub> may be converted to nitric acid (HNO<sub>3</sub>) by reacting with OH radicals. Nitrogen dioxide

1 also can be oxidized to HNO<sub>3</sub> by a sequence of reactions initiated by O<sub>3</sub>. A more detailed  
2 discussion of the atmospheric chemistry of PM appears in Chapter 2 of this document.

#### 3 4 **4.4.1 Corrosive Effects of Particles and Sulfur Dioxide on** 5 **Man-Made Surfaces**

6 Limited new studies have been published that better define the role of air pollution in  
7 materials damage. This section briefly summarizes information on exposure-related effects on  
8 materials and sulfur-containing pollutants (formed by the chemical reactions of SO<sub>2</sub> with other  
9 atmospheric pollutants) addressed in the 1996 PM AQCD (U.S. Environmental Protection  
10 Agency, 1996a) and presents relevant information published since completion of that document.  
11 The effects of nitrates on man-made building materials and naturally occurring cultural materials  
12 were discussed in the earlier EPA Nitrogen Oxides Criteria Document (U.S. Environmental  
13 Protection Agency, 1993).

##### 14 15 **4.4.1.1 Metals**

16 Metals undergo natural weathering processes in the absence of environmental pollutants.  
17 The additive effect of pollutants on the natural weathering processes depend on the nature of the  
18 pollutant, the deposition rate (the uptake of a pollutant by the material's surface), and the  
19 presence of moisture. The influence of the metal-protective corrosion film, the presence of other  
20 surface electrolytes, the orientation of the metal surface, the presence of surface moisture, and  
21 the variability in the electrochemical reactions will also contribute to the effect of pollutant  
22 exposure on metal surfaces.

23 Several studies demonstrate the importance of the duration of surface wetness (caused by  
24 dew and fog condensation and rain) on metals. Surface moisture facilitates the deposition of  
25 pollutants, especially SO<sub>2</sub>, and promotes corrosive electrochemical reactions on metals (Haynie  
26 and Upham, 1974; Sydberger and Ericsson, 1977). Of critical importance is the formation of  
27 hygroscopic salts on the metal that increases the duration of surface wetness and, thereby,  
28 enhances the corrosion process.

29 Pitchford and McMurry (1994) and Zhang et al. (1993) demonstrated particle-size-related  
30 effects of relative humidity. The effect of temperature on the rate of corrosion is complex.  
31 Under normal temperature conditions, temperature would not have an effect on the rate of  
32 corrosion; but when the temperature decreases, the relative humidity increases and the diffusivity

1 decreases. The corrosion rate decreases as the temperature approaches freezing because ice  
2 prohibits the diffusion of SO<sub>2</sub> to the metal surface and minimizes electrochemical processes  
3 (Haynie, 1980; Biefer, 1981; Sereda, 1974).

4 The metal protective corrosion film (i.e., the rust layer on metal surfaces) provides some  
5 protection against further corrosion. The effectiveness of the corrosion film in slowing down the  
6 corrosion process is affected by the solubility of the corrosion layer and the concentration and  
7 deposition rate of pollutants. If the metal-protective corrosion film is insoluble, it may add some  
8 protection against acidic pollutants. An atmospheric corrosion model that considers the  
9 formation and dissolution of the corrosion film on galvanized steel was proposed by Spence  
10 et al. (1992). The model considers the effects of SO<sub>2</sub>, rain acidity, and duration of wetness on  
11 the rate of corrosion. Although the model does not specifically characterize particle effects, the  
12 contribution of particulate sulfate was considered in model development.

13 Whether suspended particles actually enhance the corrosion of metals is not clear. Several  
14 studies suggest that suspended particles will promote the corrosion of metals (Goodwin et al.,  
15 1969; Barton, 1958; Sanyal and Singhanian, 1956; Baedecker et al., 1991); however, other studies  
16 have not demonstrated a correlation between particle exposure and metal corrosion (Mansfeld,  
17 1980; Edney et al., 1989). Walton et al. (1982) suggested that catalytic species within several  
18 species in fly ash promote the oxidation of SO<sub>x</sub> to a corrosive state. Still other researchers  
19 indicate that the catalytic effect of particles is not significant and that the corrosion rate is  
20 dependent on the conductance of the thin-film surface electrolytes during periods of wetness.  
21 Soluble particles likely increase the solution conductance (Skerry et al., 1988; Askey et al.,  
22 1993). The corrosion of most ferrous metals (iron, steel, and steel alloys) is increased by  
23 increasing SO<sub>2</sub> exposure. Steels are susceptible to corrosion when exposed to SO<sub>2</sub> in the absence  
24 of protective organic or metallic coatings. Studies on the corrosive effects of SO<sub>2</sub> on steel  
25 indicate that the rate of corrosion increases with increasing SO<sub>2</sub> and is dependent on the  
26 deposition rate of the SO<sub>2</sub> (Baedecker et al., 1991; Butlin et al., 1992a). The corrosive effects of  
27 SO<sub>2</sub> on aluminum is exposure-dependent, but appears to be insignificant (Haynie, 1976; Fink  
28 et al., 1971; Butlin et al., 1992a). The rate of formation of the patina (protective covering) on  
29 copper can take as long as five years and is dependent on the SO<sub>2</sub> concentration, deposition rate,  
30 temperature, and relative humidity (Simpson and Horrobin, 1970). Further corrosion is  
31 controlled by the availability of copper to react with deposited pollutants (Graedel et al., 1987).

1 Butlin et al. (1992a), Baedecker et al. (1991), and Cramer et al. (1989) reported an average  
2 corrosion rate of 1  $\mu\text{m}/\text{year}$  for copper; however, less than a third of the corrosion was attributed  
3 to  $\text{SO}_2$  exposure, suggesting that the rate of patina formation was more dependent on factors  
4 other than  $\text{SO}_2$ . A report by Strandberg and Johansson (1997) showed relative humidity to be  
5 the primary factor in copper corrosion and patina formation. The results of the studies on  
6 particles and  $\text{SO}_2$  corrosion of metals are summarized in Table 4-18.

#### 8 **4.4.1.2 Painted Finishes**

9 Exposure to air pollutants affects the durability of paint finishes by promoting  
10 discoloration, chalking, loss of gloss, erosion, blistering, and peeling. Evidence exists that  
11 indicates particles can damage painted finishes by serving as carriers for corrosive pollutants  
12 (Cowling and Roberts, 1954) or by staining and pitting of the painted surfaces (Fochtman and  
13 Langer, 1957; Wolff et al., 1990).

14 The erosion rate of oil-based house paint has been reported to be enhanced by exposure to  
15  $\text{SO}_2$  and high humidity. In a study by Spence et al. (1975), an erosion rate of  
16  $36.71 \pm 8.03 \mu\text{m}/\text{year}$  was noted for oil-based house paint samples exposed to  $\text{SO}_2$  ( $78.6 \mu\text{g}/\text{m}^3$ ),  
17  $\text{O}_3$  ( $156.8 \mu\text{g}/\text{m}^3$ ), and  $\text{NO}_2$  ( $94 \mu\text{g}/\text{m}^3$ ), and low humidity (50%). The erosion rate increased  
18 with increased  $\text{SO}_2$  and humidity. The authors concluded that  $\text{SO}_2$  and humidity accounted for  
19 61% of the erosion. Acrylic coil coating and vinyl coil coating shows less pollutant-related  
20 erosion. Erosion rates range from 0.7 to 1.3  $\mu\text{m}/\text{year}$  and 1.4 to 5.3  $\mu\text{m}/\text{year}$ , respectively.  
21 Similar findings on  $\text{SO}_2$ -related erosion of oil-based house paints and coil coatings have been  
22 reported by other researchers (Davis et al., 1990; Yocom and Grappone, 1976; Yocom and  
23 Upham, 1977; Campbell et al., 1974). Several studies suggest that the effect of  $\text{SO}_2$  is caused by  
24 its reaction with extender pigments such as calcium carbonate and zinc oxide (Campbell et al.,  
25 1974; Xu and Balik, 1989; Edney, 1989; Edney et al., 1988, 1989). However, Miller et al.  
26 (1992) suggested that calcium carbonate acts to protect paint substrates. Another study indicated  
27 that exposure to  $\text{SO}_2$  can increase the drying time of some paints by reacting with certain drying  
28 oils and will compete with the auto-oxidative curing mechanism responsible for crosslinking the  
29 binder (Holbrow, 1962).

**TABLE 4-18. CORROSIVE EFFECTS OF PARTICULATE MATTER AND SULFUR DIOXIDE ON METALS**

<b>Metal</b>	<b>Exposure Conditions</b>	<b>Comments</b>	<b>Source</b>
Mild Steel Galvanized Steel	Specimens exposed to SO <sub>2</sub> and O <sub>3</sub> under natural and artificial conditions, and to NO <sub>2</sub> under natural conditions. SO <sub>2</sub> concentrations ranged from 2.1 to 60 µg/m <sup>3</sup> . Annual average concentrations were about 20 µg/m <sup>3</sup> . Meteorological conditions were unaltered. Specimens exposed at 29 sites for 2 years for mild steel and 1 y for galvanized steel.	Steel corrosion was dependent on long-term SO <sub>2</sub> exposure. The corrosion rate was about 50 µm/year for mild steel specimens for most industrial sites, but ranged from 21 to 71 µm/year. The corrosion rate ranged from 1.45 to 4.25 µm/year for galvanized steel. The authors concluded that rainfall also may have a significant effect on galvanized steel based on a corrosion rate of 3.4 µm/year seen at a very wet site.	Butlin et al. (1992a)
Zinc	Rolled zinc specimens exposed at various sites around the country (rural, industrialized, marine) for up to 20 years. Actual pollutant exposures not reported.	The highest corrosion rates were associated with industrialized environments and marine environments in direct contact with salt spray.	Showak and Dunbar (1982)
Zinc	Specimens exposed at 5 sites for 1 to 5 years. Average SO <sub>2</sub> concentrations ranged from 2 ± 4 to 15 ± 17 ppb (5.2 ± 10.4 to 39.3 ± 44.5 µg/m <sup>3</sup> ). PM concentrations ranged from 14 to 60 µg/m <sup>3</sup> . Highest pollutant concentrations recorded at 1 year exposure site.	Average corrosion rate ranged from 0.63 to 1.33 µm/y. The highest corrosion was noted in the most industrialized area. However, the corrosion rates did not differ significant regardless of the SO <sub>2</sub> concentration, suggesting that SO <sub>2</sub> exposure may not be the dominant factor in zinc corrosion.	Baedecker et al. (1991) Cramer et al. (1989)
Carbon Steel Weathering Steel	See Baedecker et al. (1991) above for exposure conditions.	Average corrosion rate for samples exposed for 5 years ranged from 6.6 to 12.8 µm/year for carbon steel and 3.7 to 5.0 µm/year for weathering steel. Highest corrosion rate noted for samples exposed for 1 year.	Baedecker et al. (1991) Cramer et al. (1989)
Aluminum	See Baedecker et al. (1991) above for exposure conditions.	Corrosion rate was very low at all sites and ranged from 0.036 to 0.106 µm/year.	Baedecker et al. (1991)
Aluminum	See Butlin et al. (1992a) above for exposure conditions.	Corrosion greater on the under side of specimens, possibly because of lack of washoff and increased PM in area. Maximum corrosion rate was 0.85 µm/year. Pit depths of up to 72 µm were noted after 2 years of exposure.	Butlin et al. (1992a)

**TABLE 4-18 (cont'd). CORROSIVE EFFECTS OF PARTICULATE MATTER AND SULFUR DIOXIDE ON METALS**

<b>Metal</b>	<b>Exposure Conditions</b>	<b>Comments</b>	<b>Source</b>
Copper	See Baedecker et al. (1991) above for exposure conditions.	Average corrosion rate for 3- and 5-year exposures was about 1 $\mu\text{m}/\text{year}$ but the soluble portion was less than a third of that which could be contributed to $\text{SO}_2$ exposure. Dry deposition of $\text{SO}_2$ was not as important in patina formation as wet deposition of $\text{H}^+$ .	Baedecker et al. (1991)
Copper	See Butlin et al. (1992a) above for exposure conditions.	Majority of test sites showed a corrosion rate of $1 \pm 0.2 \mu\text{m}/\text{year}$ . The corrosion rate was $1.48 \mu\text{m}/\text{year}$ at the site receiving the most rainfall. The lowest corrosion rate, $0.66 \mu\text{m}/\text{year}$ , was associated with low rainfall, low $\text{SO}_2$ .	Butlin et al. (1992a)
Copper	Specimens exposed to 4 to 69 ppb (10.4 to $180.7 \mu\text{g}/\text{m}^3$ ) and 1.0 ppm ( $2,618.7 \mu\text{g}/\text{m}^3$ ) $\text{SO}_2$ for 20h at various relative humidities.	$\text{SO}_2$ had no effect on copper when relative humidity was $<75\%$ . Increasing relative humidity increases patina formation in presence of trace $\text{SO}_2$ . No $\text{SO}_2$ -related effects were noted on copper specimens exposed to high $\text{SO}_2$ regardless of the percent relative humidity.	Strandberg and Johansson (1997)
Copper	Specimens exposed artificially to $0.49 \pm 0.01$ ppm ( $187 \pm 3.8 \mu\text{g}/\text{m}^3$ ) $\text{SO}_2$ for 4 weeks at 70 and 90% relative humidity.	Corrosive effect of $\text{SO}_2$ on copper increased with increasing relative humidity.	Eriksson et al. (1993)
Iron	Specimens from restorations of Acropolis monuments over many years. The oldest specimens were 142 years old. Other specimens used for monument restoration after 1950.	Specimens used after 1950s had an oxidation rate 25% greater than those specimens before 1950. The accelerated oxidation had a negative impact on the structure, producing a quicker formation of cracks inside the marble.	Zuburtikudis and Triantafyllou (2001)

### 4.4.1.3 Stone and Concrete

Numerous studies suggest that air pollutants can enhance the natural weathering processes on building stone. The development of crusts on stone monuments has been attributed to the interaction of the stone's surface with sulfur-containing pollutants, wet or dry deposition of atmospheric particles, and dry deposition of gypsum particles from the atmosphere. Because of a greater porosity and specific surface, mortars have a greater potential for reacting with environmental pollutants (Zappia et al., 1998). Details on these studies are discussed in Table 4-19. The stones most susceptible to the deteriorating effects of sulfur-containing pollutants are the calcareous stones (limestone, marble, and carbonated cement). Exposure-related damage to building stones result from the formation of salts in the stone that are subsequently washed away during rain events, leaving the stone surface more susceptible to the effects of pollutants. Dry deposition of sulfur-containing pollutants promotes the formation of gypsum on the stone's surface. Gypsum is a gray to black crusty material comprised mainly of calcium sulfate dihydrate from the reaction of calcium carbonate (calcite) in the stone with atmospheric SO<sub>2</sub> and moisture (relative humidities exceeding 65%) according to the following reaction.

The sulfate anions formed in the moist air reacts with the Ca<sup>+2</sup> through diffusion processes forming the gypsum (Zuburtikudis and Triantafyllou, 2001). Approximately 99% of the sulfur in gypsum is sulfate because of the sulfonation process caused by the deposition of SO<sub>2</sub> aerosol. Sulfites also are present in the gypsum layer as an intermediate product (Sabbioni et al., 1996; Ghedini et al., 2000; Gobbi et al., 1998; Zappia et al., 1998). Gypsum is more soluble than calcite and is known to form on limestone, sandstones, and marble when exposed to SO<sub>2</sub>. Gypsum also has been reported to form on granite stone by replacing silicate minerals with calcite (Schiavon et al., 1995). Gypsum occupies a larger volume than the original stone, causing the stone's surface to become cracked and pitted. The rough surface serves as a site for deposition of airborne particles. As the gypsum grows, it becomes loose and falls apart (Zuburtikudis and Triantafyllou, 2001).

**TABLE 4-19. CORROSIVE EFFECTS OF PARTICULATE MATTER AND SULFUR DIOXIDE ON STONE**

Stone	Exposure Conditions	Comments	Source
Vermont marble	Runoff water was analyzed from seven summer storms. SO <sub>2</sub> concentration stated to be low.	Between 10 to 50% of calcium in runoff water estimated from gypsum formation from dry deposition of SO <sub>2</sub> .	Schuster et al. (1994)
Marble sandstone	Analysis of runoff water for five slabs test exposed to ambient conditions at a angle of 30° to horizontal.	Pollutant exposure related erosion was primarily caused by dry deposition of SO <sub>2</sub> and nitric acid between rain events and wet deposition of hydrogen ion. Recession estimates ranged from 15 to 30 µm/year for marble and 25 to 45 µm/year for limestone. A large portion of the erosion results from the reaction of CO <sub>2</sub> with the calcium in the stone.	Baedecker et al. (1992)
Limestone	Ambient air conditions. Exposure ranged from 70 to 1065 days. Averaged pollutant exposure ranged from 1.4 to 20.4 ppb (3.7 to 53.4 µg/m <sup>3</sup> ) SO <sub>2</sub> ; 4.1 to 41.1 ppb NO <sub>x</sub> ; 2.4 to 17.4 ppb (4.5 to 32.7 µg/m <sup>3</sup> ) NO <sub>2</sub> ; 10.1 to 25.6 ppb (19.8 to 50.2 µg/m <sup>3</sup> ) O <sub>3</sub> .	Increased stone weight loss with increased SO <sub>2</sub> . Rainfall did not significantly affect stone degradation. Stone loss associated with SO <sub>2</sub> exposure estimated to be 24 µm/year. Slight trend in decreasing stone loss with increasing length of exposure.	Webb et al. (1992)
Portland limestone White Mansfield dolomitic sandstone Monk's Park limestone	Experimental tablets exposed under sheltered and unsheltered ambient air conditions. Exposure for 1 and 2 years.	Significant correlations existed between the mean annual SO <sub>2</sub> concentration, rainfall volume, and hydrogen ion loading and the weight changes.	Butlin et al. (1992b)
Sandstones (calcite and noncalcite stones)	Ambient air; low concentrations of sulfates, SO <sub>2</sub> , and nitrates; RH sufficient to produce condensation on stones rarely occurred.	Insignificant differences in erosion rate found between calcite and noncalcite sandstone. Moisture affected the rate of pollutant deposition and enhanced susceptibility to pollutant related erosion. Rain events given as primary factor affecting stone erosion. Pollutant related erosion judged to be insignificant.	Petuskey et al. (1995)
Limestones Sandstones Marble Granite Basalt	Ambient air; urban and rural locations in Mediterranean.	Crusts on stones were found to contain two layers; top layer, usually black in color, composed of gypsum between 40 and 400 µm thick. Innermost layer, ranging from brown to orange in color, primarily consisted of calcite, between 10 and 600 µm thick. Gypsum-rich layer thought to be the result of sulfation of the calcitic layer by atmospheric pollutants or dry or wet deposition of atmospheric dust.	Garcia-Vallès et al. (1998)
Portland limestone Massangis Jaune Roche limestone White Mansfield dolomitic	Samples exposed to SO <sub>2</sub> , NO <sub>2</sub> , and NO at 10 ppmv, both with and without O <sub>3</sub> and under dry (coming to equilibrium with the 84% RH) or wetted with CO <sub>2</sub> -equilibrated deionized water conditions. Exposure was for 30 days.	In the absence of moisture, little reaction is seen. SO <sub>2</sub> is oxidized to sulfates in the presence of moisture. The effect is enhanced in the presence of O <sub>3</sub> . Massangis Jaune Roche limestone was the least affected by the pollutant exposure. Crust lined pores of specimens exposed to SO <sub>2</sub> .	Haneef et al. (1993)

**TABLE 4-19 (cont'd). CORROSIVE EFFECTS OF PARTICULATE MATTER AND SULFUR DIOXIDE ON STONE**

Stone	Exposure Conditions	Comments	Source
Monk's Park Portland limestone	Samples exposed for 2 mo under both sheltered and unsheltered conditions. Mean daily atmospheric SO <sub>2</sub> concentration was 68.7 µg/m <sup>3</sup> and several heavy rainfalls.	Significant amounts of gypsum were noted on the Portland stone. Sheltered stones also showed soiling by carbonaceous particles and other combustion products. Etch holes and deep etching was noted in some of the exposed unsheltered samples.	Viles (1990)
Carrara marble Travertine Tranistone	Sample exposed in laboratory to 3 ppm SO <sub>2</sub> and 95% RH at 25 °C for 150 days. Samples were coated with three carbonaceous particle samples from combustion sources, and with activated carbon and graphite.	Exposure to particles from combustion processes enhanced sulfation of calcareous materials by SO <sub>2</sub> because of metal content of particles.	Sabbioni et al. (1996)
Carrara marble Georgia marble	Samples exposed in sheltered ambient environment for 6, 12, or 20 mo.	Carrara marble found to be more reactive with SO <sub>2</sub> than Georgia marble possibly because of the compactness of the Georgia marble. Greater effects noted when samples were also exposed to NO <sub>2</sub> .	Yerrapragada et al. (1994)
Carrara marble	Samples exposed for 6 mo (cold and hot conditions) in ambient environment. PM concentrations ranged from 57.3 to 116.7 µg/m <sup>3</sup> (site 1) and 88 to 189.8 µg/m <sup>3</sup> (site 2). Some exposures also were associated with high SO <sub>2</sub> , NO, and NO <sub>2</sub> .	Pollutant exposed samples showed increased weight gain over that expected from natural weathering processes. There was a blackening of stone samples exposed to carbonaceous rich particulate matter.	Realini et al. (1995)
Monk's Park limestone Portland limestone	Samples artificially exposed to fly-ash containing 1309.3 µg/m <sup>3</sup> SO <sub>2</sub> (0.5 ppm) at 95% RH and 25 °C for 81 or 140 days. Fly-ash samples from five different sources were used in the study.	Exposure to fly-ash did not enhance oxidation of SO <sub>2</sub> to sulfates. Mineral oxides in fly ash contributed to sulphation of CaCO <sub>3</sub> .	Hutchinson et al. (1992)
Lime mortar Pozzolan mortar Cement mortar	Samples exposed to 7,856 µg/m <sup>3</sup> (3 ppm) SO <sub>2</sub> at 100% RH and 25 °C for 30, 60, or 90 days; samples sprayed with bidistilled water every 7 days to simulate rainfall.	Exposure to SO <sub>2</sub> produced significant quantities of calcium sulfite and calcium sulfate on specimens; however, the amount produced was dependent of the porosity, specific surface, and alkalinity of the sample.	Zappia et al. (1994)
Limestone Travertine marble	Samples exposed under actual ambient air conditions at two locations in Rome. Monitoring data obtained for SO <sub>2</sub> , NO, NO <sub>2</sub> , and total suspended particulates (TSP) but not reported. Exposure was for four seasons.	TSP exposure increased the cleaning frequency for stone monuments. Monuments are soiled proportionately overtime, based on brightness values. Horizontal surfaces showed higher graying values because of particle sediment.	Lorusso et al. (1997)

**TABLE 4-19 (cont'd). CORROSIVE EFFECTS OF PARTICULATE MATTER AND SULFUR DIOXIDE ON STONE**

Stone	Exposure Conditions	Comments	Source
Limestone Quartz-cemented sandstone Calcite-cemented sandstone Granite Brick	Samples from structures exposed for varying periods of time under ambient air conditions. Samples selected because of black layer on surface.	Black layers were found to be primarily comprised of iron compounds, quartz, silicate, soot, and dirt.	Nord and Ericsson (1993)
Carrara marble	Samples from structures taken from monuments in Venice Italy. Samples included those shielded from running water (unwashed), areas at the interface of the washed and unwashed areas, and washed areas. Samples of fog and rain near the monument were also taken for analysis.	Sulfate was higher in fog compared to other ions. The average concentration of chlorides and sulfates were 7 to 16 times higher in fog than rain. The degree of sulphonation on stone samples from areas shielded from running water was < 40%. At the interface between washed and unwashed surfaces and the washed surfaces, sulphonation is > 40%. Dendrite shaped crust from the transformation of calcium carbonate into gypsum was found on samples shielded from rain. Samples from the washed areas displayed superficial granular disaggregation, a natural process of deterioration ascribed to natural agents; however, the process was accelerated due to the ambient air sulfates.	Fassina et al. (2001)
Limestone Sandstone	Samples of ancient grey crust formed between 1180 and 1636 on the Church of Saint Trophime in Arks and formed between 1530 and 1187 on the Palazz d' Accursio in Bologna.	Crust samples contained calcite, soil dust, carbonaceous particles, and gypsum crystals.	Ausset et al. (1998)
Carrara marble Travertine marble Trani limestone Portland limestone Lime mortar Pozzolan mortar Cement mortar	Samples of the stones and mortars were representative of those used in the past and currently for new construction and restorations. Samples were exposed for 6, 12, and 24 mo under ambient conditions in Milan.	Mortars were more reactive than the stones. Of the mortars, cement and pozzolan mortar were more reactive than the lime mortar. Carrara marble was the least reactive of the stones. The maximum amount of degradation was found in areas sheltered from rain.	Zappia et al. (1998)
Lime mortar	Sample of black crust taken from Zamboni Tower Gate.	Exposure to environmental pollutants caused the formation of two separate layers on the mortar: An outer thin surface black crust composed of gypsum and carbonaceous particles and the inner composed of products from the dissolution and sulphation of the carbonate matrix in the mortar.	Sabbioni et al. (1998)
Carrara marble	Samples of crust removed from Milan General Hospital, built around 1937.	Gypsum main component of crust followed by carbonaceous particles and iron oxides. Estimated rate of crust formation was 2-5 $\mu\text{m}/\text{year}$ . Total amount of gypsum formed over the lifetime of exposure was 5 to 13 $\text{mg}/\text{cm}^2$ , an estimated 0.2 $\text{mg}/\text{cm}^2/\text{year}$ .	Bugini et al. (2000)

1           The dark colored gypsum is caused by surface deposition of carbonaceous particles  
2 (noncarbonate carbon) from combustion processes occurring in the area (Sabbioni, 1995;  
3 Saiz-Jimenez, 1993; Ausset et al., 1998; Hermosin and Saiz-Jimenez, 2000), trace metals  
4 contained in the stone, dust, and numerous other anthropogenic pollutants. After analyzing  
5 damaged layers of several stone monuments, Zappia et al. (1993) found that the dark-colored  
6 damaged surfaces contained 70% gypsum and 20% noncarbonate carbon. The lighter colored,  
7 damaged layers were exposed to rain and contained 1% gypsum and 4% noncarbonate carbon. It  
8 is assumed that rain removes reaction products, permitting further pollutant attack of the stone  
9 monument and likely redeposits some of the reaction products at rain runoff sites on the stone.  
10 Following sulfur compounds, carbon was reported to be the next highest element in dark crust on  
11 historical monuments in Rome. Elemental carbon and organic carbon accounted for 8 and 39%  
12 of the total carbon in the black crust samples. The highest percentage of carbon, carbonate  
13 carbon, was caused by the carbonate matrix in the stones. The high ratio of organic carbon to  
14 elemental carbon indicates the presence of a carbon source other than combustion processes  
15 (Ghedini et al., 2000). Cooke and Gibbs (1994) suggested that stones damaged during times of  
16 higher ambient pollution exposure likely would continue to exhibit a higher rate of decay,  
17 termed the “memory effect,” than newer stones exposed under lower pollution conditions.  
18 Increased stone damage also has been associated with the presence of sulfur-oxidizing bacteria  
19 and fungi on stone surfaces (Garcia-Vallès et al., 1998; Young, 1996; Saiz-Jimenez, 1993;  
20 Diakumaku et al., 1995).

21           Dissolution of gypsum on the stone’s surface initiates structural changes in the crust layer.  
22 Garcia-Vallès et al. (1998) proposed a double mechanism: the dissolution of the gypsum, in the  
23 presence of sufficient moisture, followed by recrystallization inside fissures or pores. In the  
24 event of limited moisture, the gypsum is dissolved and recrystallizes at its original location.  
25 According to the authors, this would explain the gypsum-rich crustal materials on stone surfaces  
26 sheltered from precipitation.

27           Moisture was found to be the dominant factor in stone deterioration for several sandstones  
28 (Petuskey et al., 1995). Dolske (1995) reported that the deteriorative effects of sulfur-containing  
29 rain events, sulfates, and SO<sub>2</sub> on marble were largely dependent on the shape of the monument  
30 or structure rather than the type of marble. The author attributed the increased fluid turbulence  
31 over a non-flat vertical surface versus a flat surface to the increased erosion. Sulfur-containing

1 particles also have been reported to enhance the reactivity of Carrara marble and Travertine and  
2 Trani stone to SO<sub>2</sub> (Sabbioni et al., 1992). Particles with the highest carbon content had the  
3 lowest reactivity.

4 The rate of stone deterioration is determined by the pollutant and the pollutant  
5 concentration, the stone's permeability and moisture content, and the pollutant deposition  
6 velocity. Dry deposition of SO<sub>2</sub> between rain events has also been reported to be a major  
7 causative factor in pollutant-related erosion of calcareous stones (Baedecker et al., 1991; Dolske,  
8 1995; Cooke and Gibbs, 1994; Schuster et al., 1994; Hamilton et al., 1995; Webb et al., 1992).  
9 Sulfur dioxide deposition increases with increasing relative humidity (Spiker et al., 1992), but  
10 the pollutant deposition velocity is dependent on the stone type (Wittenburg and Dannecker,  
11 1992), the porosity of the stone, and the presence of hygroscopic contaminants.

12 Although it is clear from the available information that gaseous pollutants (dry deposition  
13 of SO<sub>2</sub> in particular) will promote the decay of some types of stones under the specific  
14 conditions, carbonaceous particles (noncarbonate carbon) may help to promote the decay process  
15 by aiding in SO<sub>2</sub> transformation to a more acidic species (Del Monte and Vittori, 1985). Several  
16 authors have reported enhanced sulfation of calcareous material by SO<sub>2</sub> in the presence of  
17 particles containing metal oxides (Sabbioni et al., 1996; Hutchinson et al., 1992).

#### 19 **4.4.2 Soiling and Discoloration of Man-Made Surfaces**

20 Ambient particles can cause soiling of man-made surfaces. Soiling has been defined as  
21 the deposition of particles of less than 10 μm on surfaces by impingement. Soiling generally is  
22 considered an optical effect, that is, soiling changes the reflectance from opaque materials and  
23 reduces the transmission of light through transparent materials. Soiling can represent a  
24 significant detrimental effect requiring increased frequency of cleaning of glass windows and  
25 concrete structures, washing and repainting of structures, and, in some cases, reduction in the  
26 useful life of the object. Particles, in particular carbon, also may help catalyze chemical  
27 reactions that result in the deterioration of materials during exposure.

28 It is difficult to determine the accumulated particle levels that cause an increase in soiling.  
29 Soiling is dependent on the particle concentration in the ambient environment, particle size  
30 distribution, the deposition rate, and the horizontal or vertical orientation and texture of the  
31 surface being exposed (Haynie, 1986). The chemical composition and morphology of the

1 particles and the optical properties of the surface being soiled will determine the time at which  
2 soiling is perceived (Nazaroff and Cass, 1991). Carey (1959) reported that the average observer  
3 could observe a 0.2% surface coverage of black particles on a white background. Work by  
4 Bellan et al. (2000) indicates that it would take a 12% surface coverage by black particles before  
5 there is 100% accuracy in identifying soiling. Sharples et al. (2001) studied the effect of air  
6 pollution, moisture, and the function of the room/building on glazing daylight transmittance for a  
7 number of building windows. They found that the direct soiling load to a window was  
8 dependent on the immediate external and internal environment. For instance, there was only a  
9 10% reduction in daylight transmittance for windows from an office building that had not been  
10 cleaned for 5 years compared to clean windows. The reduction in transmittance for windows in  
11 a swimming pool complex was in excess of 20% due to soiling of the interior surface. For most  
12 office buildings, there was a reduction of glazing transmittance ranging from 3 to 10%, with  
13 most windows showing about a 3% reduction. The rate at which an object is soiled increases  
14 linearly with time; however, as the soiling level increases, the rate of soiling decreases. The  
15 buildup of particles on a horizontal surface is counterbalanced by an equal and opposite  
16 depletion process. The depletion process is based on the scouring and washing effect of wind  
17 and rain (Schwar, 1998).

#### 19 **4.4.2.1 Stones and Concrete**

20 Most of the research evaluating the effects of air pollutants on stone structures has  
21 concentrated on gaseous pollutants. The deposition of the sulfur-containing pollutants is  
22 associated with the formation of gypsum on the stone (see Section 4.5.1.3). The dark color of  
23 gypsum is attributed to soiling by carbonaceous particles from nearby combustion processes.  
24 A lighter gray colored crust is attributed to soil dust and metal deposits (Ausset et al., 1998;  
25 Camuffo, 1995; Moropoulou et al., 1998). Realini et al. (1995) recorded the formation of a dark  
26 gypsum layer and a loss of luminous reflection in Carrara marble structures exposed for 1 year  
27 under ambient air conditions. Dark areas of gypsum were found by McGee and Mossitti (1992)  
28 on limestone and marble specimens exposed under ambient air conditions for several years. The  
29 black layers of gypsum were located in areas shielded from rainfall; whereas particles of dirt  
30 were concentrated around the edges of the gypsum formations. Lorusso et al. (1997) attributed  
31 the need for frequent cleaning and restoration of historic monuments in Rome to exposure to

1 total suspended particulates. They also concluded that, based on a decrease in brightness  
2 (graying), surfaces are soiled proportionately over time; however, graying is higher on horizontal  
3 surfaces because of sedimented particles. Davidson et al. (2000) evaluated the effects of air  
4 pollution exposure on a limestone structure on the University of Pittsburgh campus using  
5 estimated average TSP levels in the 1930s and 1940s and actual values for the years 1957 to  
6 1997. Monitored levels of SO<sub>2</sub> were available for the years 1980 to 1998. Based on the  
7 available data concerning pollutant levels and photographs, it was thought that soiling began  
8 while the structure was under construction. With decreasing levels of pollution, the soiled areas  
9 have been slowly washed away, the process taking several decades, leaving a white, eroded  
10 surface.

#### 11 12 **4.4.2.2 Household and Industrial Paints**

13 Few studies are available that evaluate the soiling effects of particles on painted surfaces.  
14 Particles composed of elemental carbon, tarry acids, and various other constituents are  
15 responsible for soiling of structural painted surfaces. Coarse-mode particles (> 2.5 µm) initially  
16 contribute more soiling of horizontal and vertical painted surfaces than do fine-mode particles (<  
17 2.5 µm), but are more easily removed by rain (Haynie and Lemmons, 1990). The accumulation  
18 of fine particles likely promotes remedial action (i.e., cleaning of the painted surfaces); whereas  
19 coarse-mode particles are primarily responsible for soiling of horizontal surfaces. Rain interacts  
20 with coarse particles, dissolving the particle and leaving stains on the painted surface (Creighton  
21 et al., 1990; Haynie and Lemmons, 1990). Haynie and Lemmons (1990) proposed empirical  
22 predictive equations for changes in surface reflectance of gloss-painted surfaces that were  
23 exposed protected and unprotected from rain while oriented horizontally or vertically.

24 Early studies by Parker (1955) and Spence and Haynie (1972) demonstrated an association  
25 between particle exposure and increased frequency of cleaning of painted surfaces. Particle  
26 exposures also caused physical damage to the painted surface (Parker, 1955). Unsheltered  
27 painted surfaces are initially more soiled by particles than sheltered surfaces but the effect is  
28 reduced by rain washing. Reflectivity is decreased more rapidly on glossy paint than on flat  
29 paint (Haynie and Lemmons, 1990). However, surface chalking of the flat paint was reported  
30 during the exposure. The chalking interfered with the reflectance measurements for particle  
31 soiling. Particle composition measurements that were taken during exposure of the painted

1 surfaces indicated sulfates to be a large fraction of the fine mode and only a small fraction of the  
2 coarse mode. Although no direct measurements were taken, fine mode particles likely also  
3 contained large amounts of carbon and possibly nitrogen or hydrogen (Haynie and Lemmons,  
4 1990).

#### 7 **4.5 ATMOSPHERIC PARTICULATE MATTER, CLIMATE CHANGE,** 8 **AND EFFECTS ON SOLAR UVB RADIATION TRANSMISSION**

9 Atmospheric particles alter the amount of solar radiation transmitted through the Earth's  
10 atmosphere. The absorption of solar radiation by atmospheric particles, together with trapping  
11 of infrared radiation emitted by the Earth's surface by certain gases, enhances heating of the  
12 Earth's surface and lower atmosphere (i.e., the widely-known "greenhouse effect") potentially  
13 leading to "global warming" impacts on human health and the environment. Lesser impacts of  
14 airborne particles include alterations in the amount of ultraviolet solar radiation (especially  
15 UV-B) penetrating through the Earth's atmosphere and reaching its surface where UV radiation  
16 can exert various effects on human health, plant and animal biota, and other environmental  
17 components.

18 The effects of atmospheric PM on the transmission of electromagnetic radiation emitted  
19 by the sun at ultraviolet and visible wavelengths and by the Earth at infrared wavelengths depend  
20 on radiative properties (extinction efficiency, single scattering albedo, and asymmetry  
21 parameter) of the particles, which depend, in turn, on the size and shape of the particles, the  
22 composition of the particles, and the distribution of components within individual particles.  
23 In general, the radiative properties of particles are size- and wavelength-dependent. In addition,  
24 the extinction cross-section tends to be at a maximum when the particle radius is similar to the  
25 wavelength of the incident radiation. Thus, fine particles present mainly in the accumulation  
26 mode would be expected to exert a greater influence on the transmission of electromagnetic  
27 radiation than would coarse particles. The composition of particles can be crudely summarized  
28 in terms of the broad classes identified in Chapter 2 of this document. These include fine  
29 particles consisting mainly of (a) nitrate, sulfate, mineral dust, elemental carbon, organic carbon  
30 compounds (e.g., PAHs), and (b) metals derived from high temperature combustion or smelting  
31 processes. The major sources of these components are shown in Table 3-9 of Chapter 3 in this  
32 document.

1 Knowledge of the effects of PM on the transfer of radiation in the visible and infrared  
2 spectral regions is needed for assessing relationships between particles and global warming  
3 processes and associated environmental and biological changes. Knowledge of the factors  
4 controlling the transfer of solar radiation in the ultraviolet spectral range is needed to assess  
5 potential the biological and environmental effects associated with exposure to UV-B radiation  
6 (290 to 315 nm). Climate change processes, their potential to affect human and environmental  
7 health, and their potential relationships to atmospheric PM are discussed below. Subsequently,  
8 aspects related to solar ultraviolet radiation processes and effects are summarized and the roles  
9 of atmospheric PM are discussed.

## 11 **4.5.1 Atmospheric Particle Interactions with Solar and Terrestrial Radiation** 12 **Related to Climate Change**

### 13 **4.5.1.1 The Projected Impacts of Global Climate Change**

14 The study of atmospheric processes involved in mediating global climate change and its  
15 potential consequences for human health and global ecosystems is an area of active research.  
16 The most thorough evaluation of current scientific understanding of climate change available at  
17 this time is the Third Assessment Report (TAR) of the Intergovernmental Panel on Climate  
18 Change (IPCC, 2001a). Earlier assessments include those conducted by the United Nations  
19 Environment Program (UNEP, 1986), the World Meteorological Organization (WHO1988), the  
20 U.S. Environmental Protection Agency (U.S. Environmental Protection Agency, 1987), and  
21 others (e.g., Patz et al., 2000a,b). The reader is referred to these documents for a complete  
22 discussion of climate change science. An abbreviated list of the IPCC conclusions, to date, and a  
23 short discussion of the potential impacts of climate change on human health and welfare is  
24 provided here to serve as the context for the discussion of the role of particulate matter in  
25 climate.

26 The IPCC TAR (2001a) notes that the increasing body of observations indicates that the  
27 Earth is warming and that other climate changes are underway. These observations include the  
28 global surface temperature record assembled since the year 1860, the satellite temperature record  
29 begun in 1979, recorded changes in snow and ice cover since the 1950's, sea level measurements  
30 taken throughout the 20<sup>th</sup> century, and sea surface temperature observations since the 1950's.  
31 Other evidence includes a marked increase over the past 100 years in the frequency, intensity  
32 and persistence of the zonal atmospheric circulation shifts known as the El Nino-Southern

1 Oscillation (ENSO). ENSO events occur when the tropical ocean has accumulated a large,  
2 localized mass of warm water which interrupts cold surface currents along South America,  
3 altering precipitation and temperature patterns in the tropics, sub-tropics and the mid-latitudes.

4 Atmospheric concentrations of greenhouse gases (GHGs) which trap solar energy within  
5 the climate system, are continuing to increase due to human activities. These activities will  
6 continue to result changes in the composition of the atmosphere throughout the 21<sup>st</sup> century. The  
7 IPCC TAR describes the scientific evidence that ties this increase in GHGs over the past 50  
8 years to human activities (IPCC 2001b).

9 The IPCC (1998, 2001b) reports also describe the results of general circulation model  
10 (GCM) studies that indicate that human activities will alter the climate system in a manner that  
11 will likely to lead to marked global and regional changes in temperature, precipitation and other  
12 climate properties. This is expected to increase global mean sea level; increase the number of  
13 extreme weather events including floods, and droughts; and induce changes in soil moisture.  
14 These changes will directly impact human health, ecosystems, and global economic sectors, e.g.,  
15 hydrology and water resources, food and fiber production, etc., (IPCC 1998, 2001b). Table 4-20  
16 summarizes these projected impacts. Wide variations in the course and net impacts of climate  
17 change in different geographic areas can be expected. In general, projected climate change  
18 impacts can be expected to represent additional stresses on those natural ecosystems and human  
19 societal systems already impacted by increasing resource demands, unsustainable resource  
20 management practices, and pollution — with wide variation likely across regions and nations in  
21 their ability to cope with consequent alterations in ecological balances, in availability of  
22 adequate food, water, and clean air, and in human health and safety. However, although many  
23 regions are likely to experience severe adverse impacts (some possibly irreversible) of climate  
24 change, some climate change impacts may be locally beneficial in some regions. For example,  
25 sectors or subregions may benefit from warmer temperatures or increased CO<sub>2</sub> fertilization (e.g.,  
26 west coast coniferous forests; some western rangelands; reduced energy costs for heating in  
27 northern latitudes; reduced road salting and snow-clearance costs; longer open-water seasons in  
28 northern channels and ports; and agriculture in the northern latitudes, the interior West, and the  
29 west coast). The IPCC report, “The Regional Impacts of Climate Change” (IPCC, 1998),  
30 describes the projected effects of human-induced climate change on the different regions of the  
31 globe, including Africa, the Arctic and Antarctic, the Middle East and arid Asia, Australasia,

**TABLE 4-20. EXAMPLES OF IMPACTS RESULTING FROM PROJECTED CHANGES IN EXTREME CLIMATE EVENTS**

Projected changes during the 21 <sup>st</sup> Century in Extreme Climate Phenomena and their Likelihood <sup>a</sup>	Representative Examples of Projected Impacts <sup>b</sup> (all high confidence of occurrence in some areas <sup>c</sup> )
<i>Simple Extremes</i>	
Higher maximum temperatures; more hot days and heat waves <sup>d</sup> over nearly all land areas ( <i>very likely</i> <sup>a</sup> )	<ul style="list-style-type: none"> <li>• Increased incidence of death and serious illness in older age groups and urban poor</li> <li>• Increased heat stress in livestock and wildlife</li> <li>• Shift in tourist destinations</li> <li>• Increased risk of damage to a number of crops</li> <li>• Increased electric cooling demand and reduced energy supply reliability</li> </ul>
Higher (increasing) minimum temperatures; fewer cold days, frost days, and cold waves <sup>d</sup> over nearly all land areas ( <i>very likely</i> <sup>a</sup> )	<ul style="list-style-type: none"> <li>• Decreased cold-related human morbidity and mortality</li> <li>• Decreased risk of damage to a number of crops, and increased risk to others</li> <li>• Extended range and activity of some pest and disease vectors</li> <li>• Reduced heating energy demand</li> </ul>
More intense precipitation events ( <i>very likely</i> <sup>a</sup> over many years)	<ul style="list-style-type: none"> <li>• Increased flood, landslide, avalanche, and mudslide damage</li> <li>• Increased soil erosion</li> <li>• Increased flood runoff could increase recharge of some floodplain aquifers</li> <li>• Increased pressure on government and private flood insurance systems and disaster relief</li> </ul>
<i>Complex Extremes</i>	
Increased summer drying over most mid-latitude continental interiors and associated risk of drought ( <i>likely</i> <sup>a</sup> )	<ul style="list-style-type: none"> <li>• Decreased crop yields</li> <li>• Increased damage to building foundations caused by ground shrinkage</li> <li>• Decreased water resource quantity and quality</li> <li>• Increased risk of forest fire</li> </ul>
Increase in tropical cyclone peak wind intensities, mean and peak precipitation intensities ( <i>likely</i> <sup>a</sup> over some areas) <sup>e</sup>	<ul style="list-style-type: none"> <li>• Increased risk to human life, risk of infections, disease epidemics, and many other risks</li> <li>• Increased coastal erosion and damage to coastal buildings and infrastructure</li> <li>• Increased damage to coastal ecosystems such as coral reefs and mangroves</li> </ul>
Intensified droughts and floods associated with El Niño events in many different regions ( <i>likely</i> <sup>a</sup> ) (see also under droughts and intense precipitation events)	<ul style="list-style-type: none"> <li>• Decreased agricultural and rangeland productivity in drought- and flood-prone regions</li> <li>• Decreased hydro-power potential in drought-prone regions</li> </ul>
Increased Asian summer monsoon precipitation variability ( <i>likely</i> <sup>a</sup> )	<ul style="list-style-type: none"> <li>• Increased flood and drought magnitude and damages in temperate and tropical Asia</li> </ul>
Increased intensity of mid-latitude storms (little agreement between current models) <sup>d</sup>	<ul style="list-style-type: none"> <li>• Increased risks to human life and health</li> <li>• Increased property and infrastructure losses</li> <li>• Increased damage to coastal ecosystems</li> </ul>

<sup>a</sup>Likelihood refers to judgmental estimates of confidence used by TAR WGI: *very likely* (90-99% chance); *likely* (66-90% chance). Unless otherwise stated, information on climate phenomena is taken from the Summary for Policymakers, TAR WGI. TAR WGI = Third Assessment Report of Working Group I (IPCC, 2001a).

<sup>b</sup>These impacts can be lessened by appropriate response measures.

<sup>c</sup>High confidence refers to probabilities between 67 and 95%.

<sup>d</sup>Information from TAR WGI, Technical Summary.

<sup>e</sup>Changes in regional distribution of tropical cyclones are possible but have not been established.

Source: IPCC (2001b).

1 Europe, Latin America, North America, the small island nations, temperate Asia, and tropical  
2 Asia. For further details about the projected effects of climate change on a US-regional scale,  
3 the reader is also referred to several regionally-focused reports (MARAT, 2000; Yarnal et al.,  
4 2000; NERAG, 2001; GLRAG, 2000), as well as a report on potential impacts upon human  
5 health due to climate change (Bernard et al., 2001).

6 It must be borne in mind that while current climate models are successful in simulating  
7 present annual mean climate and the seasonal cycle on continental scales, they are less  
8 successful at regional scales. Clouds and humidity, essential factors in defining local and  
9 regional (“sub-grid”) climate, are significantly uncertain (IPCC 2001a). Due to modeling  
10 uncertainties, both in reproducing regional climate and in predicting future economic activity,  
11 the projected impacts discussed above are also uncertain.

12 Findings from the IPCC TAR (2001a), Regional Impacts Assessment (1998) and other  
13 regional assessments cited above illustrate well the considerable uncertainties and difficulties in  
14 projecting likely climate change impacts on regional or local scales. The findings also reflect the  
15 mixed nature of projected potential climate change impacts (combinations of mostly deleterious,  
16 but other possible beneficial effects) for U.S. regions and their variation across the different  
17 regions. Difficulties in projecting region-specific climate change impacts are complicated by the  
18 need to evaluate potential effects of local- or regional-scale changes in key air pollutants not  
19 only on global scale temperature trends but also in terms of potentially more local- or regional-  
20 scale impacts on temperature and precipitation patterns.

#### 21 22 **4.5.1.2 Airborne Particle Relationships to Global Warming and Climate Change**

23 Atmospheric particles both scatter and absorb incoming solar radiation. Visibility  
24 reduction is caused by particle scattering in all directions; whereas climate effects result mainly  
25 from scattering in the upward direction. Upward scattering of solar radiation reduces the total  
26 amount of energy received by the Earth system, leading to surface cooling. The effect on  
27 climate due to upward scattering and to absorption of radiation by aerosol can be roughly  
28 quantified as a “radiative forcing” (Houghton et al., 1990). Global and regional climate (at  
29 equilibrium) is defined by the balance between a large number of “positive” and “negative”  
30 forcings induced by different components of the Earth system. The Earth system responds to  
31 these forcings in a potentially complex way due to feedback mechanisms that are theorized but

1 very difficult to define. In the absence of information about climate feedbacks, radiative forcing  
2 values for the many components of the climate system are estimated as a tool for comparing, to  
3 first order, their relative importance in climate change. Forcing estimates for various classes of  
4 atmospheric particles are derived on the basis of climate modeling studies and reported by the  
5 IPCC (IPCC 2001b).

6 Particulate matter appears to play a significant role in defining climate on both a global and  
7 regional scale. Haywood et al. (1999) found that the inclusion of anthropogenic aerosols results  
8 in a significant improvement between calculations of reflected sunlight at the top of the  
9 atmosphere and satellite observations in oceanic regions close to sources of anthropogenic PM.  
10 Significant reductions over the past 50 years in solar radiation received at the Earth's surface on  
11 a globally averaged basis correlate with increases in atmospheric aerosol (Stanhill and Cohen,  
12 2001). While this correlation seems clear, quantifying the cooling and warming effects of  
13 aerosol in relation to greenhouse gas-related warming is difficult. Aerosol complicates the  
14 interpretation of climate change due to its spatial and temporal inhomogeneities and uncertain  
15 radiative properties. However, to first order, inclusion of modeled atmospheric sulfate  
16 concentrations substantially improved the agreement between modeled and observed surface  
17 temperatures (Kiehl and Briegleb, 1993). On a regional scale, the suspected influence of  
18 aerosols upon climate relates to regional hydrological cycles. Evidence is accumulating that  
19 pollution aerosols reduce precipitation frequency by clouds, potentially leading to drought in  
20 some parts of the world (Ramanathan et al, 2001).

## 21 22 **Greenhouse Gases, Particulate Matter and the Earth's Radiative Equilibrium**

23 According to simple radiative transfer theory, at thermal equilibrium, the Earth's surface  
24 should be near -15 °C. This is the temperature of a theoretical "black body" that is receiving and  
25 then re-emitting  $342.5 \text{ Wm}^{-2}$  (i.e., the globally averaged amount of solar radiation absorbed and  
26 then re-emitted by the Earth as infrared terrestrial radiation). In fact, satellite observations  
27 indicate that the Earth's average planetary temperature is remarkably close to the theoretical  
28 black body value at -18 °C, a temperature at which liquid water ordinarily does not exist.

29 At its surface, however, the Earth's average temperature is + 15 °C. The 33 °C  
30 temperature differential between Earth's planetary temperature and its surface temperature is due  
31 to the existence of infrared radiation-absorbing components in the atmosphere, i.e. GHGs,

1 including carbon dioxide, methane, several other trace gases and some types of particles and  
2 clouds. The phenomenon of planetary surface warming due to atmospheric absorption and re-  
3 emission of infrared radiation is popularly known as the “greenhouse effect” (Arrhenius, 1896;  
4 Schneider, 1992). Radiation trapped by the Earth’s atmosphere is reflected back to its surface,  
5 with some small fraction absorbed by dark atmospheric particles. The fraction of this radiation  
6 that is not directly re-emitted as long-wave terrestrial radiation transforms into heat energy that  
7 drives the atmospheric processes that form the basis of weather and climate. Eventually this  
8 energy is transformed a second time, to terrestrial radiation, and is re-emitted as part of the  
9 process that maintains Earth’s radiative equilibrium.

10 Satellite measurements of the Earth’s radiation budget suggest that the Earth is, however,  
11 out of equilibrium. These measurements indicate that from 1985 through 1990, the Earth  
12 absorbed  $238 \text{ W/m}^2$  and emitted  $235 \text{ Wm}^{-2}$  – an imbalance of  $3 \text{ Wm}^{-2}$ . If these measurements are  
13 correct, they suggest that continuously changing atmospheric concentrations of radiatively active  
14 species along with other alterations to the climate system due to human activities may be  
15 responsible for preventing the re-establishment of the Earth’s radiative equilibrium.

16 Radiatively active gases in the atmosphere are largely responsible for the greenhouse  
17 effect, although some light absorbing particles and clouds contribute to atmospheric and surface  
18 warming (IPCC 2001a). The majority of clouds and particles play a role in counteracting the  
19 greenhouse effect by increasing the degree to which the Earth is able to reflect solar radiation,  
20 i.e., its “albedo.” Successful modeling of the Earth’s climate and, therefore, assessment of the  
21 degree of human-induced climate change and development of appropriate policy depends on the  
22 high quality information on the relative efficiencies, amounts, spatial and temporal distributions  
23 of the various radiatively active components of the atmosphere at absorbing and/or reflecting  
24 solar and terrestrial radiation.

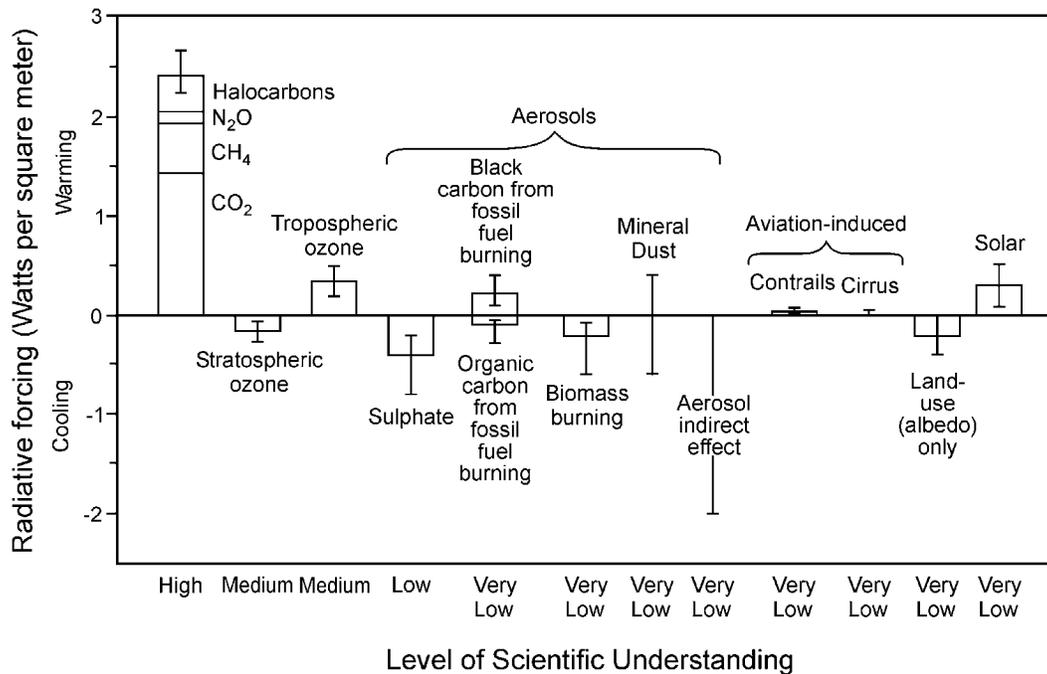

## 25 26 **“Forcing” and the Earth’s Radiative Balance**

27 A measure of the relative influence of a given component of the climate system on the  
28 Earth’s radiative balance is its “radiative forcing.” Radiative forcing, in  $\text{Wm}^{-2}$ , is a quantity that  
29 was developed by the climate modeling community as a first order-only means of estimating  
30 relative effects of anthropogenic and natural processes on the surface-troposphere system. No  
31 more precise metric has yet been found to replace radiative forcing as a measure of impact of

1 upon climate (IPCC, 2001). The convention for this quantity assigns a negative forcing to  
2 climate system components that reflect solar radiation back into space and positive forcing for  
3 those which enhance the greenhouse effect, or otherwise act to enhance the heating absorbing  
4 capacity of the Earth system. Purely reflective atmospheric aerosol, snow-covered land surfaces  
5 and dense sea ice provide a negative forcing, while highly absorbing atmospheric aerosol,  
6 greenhouse gases and dark ocean surfaces positively force the climate system.

7 The IPCC reports estimated values for forcing by the individual radiatively active gas and  
8 particle-phase components of the atmosphere. These estimates are derived primarily through  
9 expert judgment incorporating the results of peer-reviewed modeling studies. Uncertainty  
10 ranges are assigned that reflect the range of modeled values reported in these studies. According  
11 to the available research on climate forcing by aerosol, the panel has provided estimates for  
12 sulfate, organic, black carbon, biomass burning, and mineral dust aerosol. The current estimate  
13 of forcing due to long-lived, well-mixed, greenhouse gases accumulated in the atmosphere from  
14 the pre-industrial era (ca., 1750) through the year 2000 is + 2.4 Wm<sup>-2</sup> (IPCC, 2001). In contrast,  
15 forcing due to a sulfate aerosol-related increase in planetary albedo has been assigned a value of  
16 – 0.4 Wm<sup>-2</sup>. Biomass burning and fossil-fuel-related organic aerosol also increase the Earth's  
17 reflectivity and are estimated to contribute a –0.2 Wm<sup>-2</sup> and –0.1 Wm<sup>-2</sup> forcing, respectively.  
18 Fossil-fuel black carbon is expected to warm the atmosphere, resulting in an estimated  
19 + 0.2 Wm<sup>-2</sup> forcing. No estimate for forcing by nitrate aerosol has been proposed due to wide  
20 discrepancies in current global modeling results and the difficulties associated with obtaining  
21 accurate ambient samples of nitrate concentrations and size distributions. Likewise, no specific  
22 estimate has been offered for forcing by mineral dust aerosol introduced into the atmosphere due  
23 to human activities beyond the assignment of a tentative range of – 0.6 to + 0.4 Wm<sup>-2</sup>. The  
24 estimated forcing and associated uncertainty for each aerosol type is shown in relation to forcing  
25 estimates for the known greenhouse gases along with an indication of the level of confidence in  
26 each of these estimates in Figure 4-42.

27 The relationship between perturbations to the Earth's radiative balance and climate is  
28 complicated by various feedbacks within the climate system. An example would be the positive  
29 feedback associated with melting sea ice. As sea ice melts with increasing surface temperatures,  
30 the dark ocean surface is revealed which absorbs, rather than reflects, solar radiation. Such a  
31 feedback increases the rate of surface warming. The role of feedbacks in determining the

**Figure 4-42. Estimated global mean radiative forcing exerted by gas and various particle phase species for the year 2000, relative to 1750.**

Source: IPCC (2001a).

1 sensitivity of climate to changes in radiative forcing is described in detail by the IPCC in its third  
 2 assessment report (IPCC, 2001a).

3 One possible feedback of interest in the discussion of the role of aerosols in determining  
 4 climate may result from the possible sensitivity of aerosol number and mass to atmospheric  
 5 temperature (Hemming and Seinfeld, 2001). Increasing atmospheric temperatures may result in  
 6 a reduction of aerosol as semivolatile organic and inorganic aerosol constituents evaporate,  
 7 leading to a change in aerosol forcing. As described in Chapter 2 of this document, and further  
 8 discussed below, ambient aerosols are known to contain complex chemical mixtures of both  
 9 scattering and absorbing materials. The feedback that may result from this phenomenon will  
 10 depend upon whether the aerosols become more absorbing or more reflective upon the loss of  
 11 semivolatile material. Research is presently underway to evaluate both the role of temperature in  
 12 determining aerosol mass and in defining the link between air quality and climate, but no  
 13 literature presently exists to support an assessment of these effects. The following discussion,

1 therefore, will focus solely on the relative forcing properties of aerosols, for which a body of  
2 scientific research is available for consideration.

3 The physical and chemical properties of atmospheric aerosols, and their regional  
4 distribution and temporal nature, all play a role in determining the degree to which they force  
5 climate. These details are described, below, followed by a description of the “indirect” effect of  
6 aerosols due to changes in cloud properties; and brief discussions of the sources of uncertainty in  
7 determining aerosol-related climate forcing and of the link to human health and the environment  
8 then follow.

### 10 **The Physics of PM and Its Climate Effects**

11 Four wavelength-dependent physical properties of ambient aerosols are needed to calculate  
12 optical depth and thus their radiative properties: the mass light-scattering efficiency ( $a_{sp}$ ), the  
13 functional dependence of light-scattering on relative humidity  $f(RH)$ , the single-scattering albedo  
14 ( $\omega_0$ ), and the scattering asymmetry parameter ( $g$ ); (Charlson et al., 1992; Penner et al., 1994a).  
15 Direct forcing by aerosols is especially sensitive to single scattering albedo. Depending on the  
16 color of the underlying surface, small changes in  $\omega_0$  can change the sign of the calculated aerosol  
17 forcing (Hansen et al., 1997).

18 The wavelength-dependent phase function and scattering and absorption coefficients are  
19 calculated using Mie scattering theory. These values are then used to calculate mass light-  
20 scattering efficiency, single-scattering albedo, and the asymmetry factor. Mie calculations  
21 require the ratio of particle size versus wavelength and the complex refractive index of the  
22 particle – a composition-dependent property (Salby, 1996). The relationship between light-  
23 scattering and relative humidity likewise depends upon composition as water absorption depends  
24 upon the presence of hygroscopic material within the particle. Therefore, according to the  
25 current understanding of aerosol optics, good information about composition and size  
26 distribution is needed to successfully predict aerosol-related forcing.

### 28 **The Chemistry of PM and Its Climate Effects**

29 Although forcing estimates are reported for specific aerosol classes (i.e., sulfate, black  
30 carbon, dust, etc.) it is understood that shortly after emission, primary aerosols undergo chemical  
31 transformation in the atmosphere. These transformations occur through partitioning of gas phase

1 compounds, by coagulation with other aerosol or a combination of both processes (Pandis and  
2 Seinfeld, 1998). While the radiative properties of non-absorbing aerosol, such as sulfates or  
3 nitrates, are primarily sensitive to particle size, the radiative properties of aerosols containing  
4 absorbing constituents (i.e., black carbon and mineral aerosols) are also sensitive to chemical  
5 composition and mixing state. Studies of refractive index changes as a function of composition  
6 have shown that the type of mixing present both in the population of aerosols (i.e., “internal”  
7 versus “external” mixtures) and the extent of mixing within individual aerosols influence aerosol  
8 optical properties when absorbing material is present (Fuller et al., 1999). Modeled estimates for  
9 radiative forcing by black-carbon-containing aerosols do, in fact, range widely depending on  
10 whether the aerosol population is assumed to be internally or externally mixed and whether the  
11 absorbing carbon is uniformly distributed in the particle or whether it exists as a core surrounded  
12 by non-absorbing material. The IPCC Third Assessment report (2001) provides a tabulation of  
13 studies and their forcing estimates for black carbon existing in different mixing states. For  
14 example, Haywood and Shine (1997) calculated that externally mixed fossil-fuel black carbon  
15 forces climate by + 0.2 W/m<sup>2</sup>. Jacobson (2000) assumed that if black carbon exists as a solid  
16 core contained within an otherwise non-absorbing droplet, the global forcing will be + 0.54  
17 W/m<sup>2</sup>.

18 Chemically and physically detailed models at high spatial resolution are required to  
19 accurately represent the chemical transformation and size evolution of aerosol within the  
20 ambient atmosphere. Such models, however, are impractical for global scale climate modeling.  
21 Parameterizations are formulated to represent processes occurring at spatial and temporal scales  
22 that are too fine for climate models (i.e., “sub-grid” processes). Several important fundamental  
23 chemical and physical processes, however, are not yet well-enough defined to assure reasonable  
24 parameterization in large scale climate models. Prediction of the organic and black carbon  
25 content of ambient aerosols and their associated radiative properties, as described above, and the  
26 aerosol-induced changes in cloud properties, remain especially weak.

27 Modeling of the effect of black carbon aerosol on climate, to date, has been done on the  
28 basis of limited and poor quality data regarding total global emissions, aerosol composition, and  
29 the mixing state of ambient aerosols. Appendix 2B.2 of Chapter 2 in this document describes  
30 the many problems associated with the most commonly used organic carbon/elemental carbon  
31 measurement method (thermal optical reflectance and transmittance). For example, elemental

1 carbon comprises a relatively small fraction of total carbon in biomass burning-related aerosol  
2 which is, nevertheless, an important source of black carbon in the atmosphere due to the  
3 extensive use of biofuels in developing countries and to the prevalence of natural and  
4 agriculture-related open biomass burning (Ludwig et al., 2003). The concentrations of elemental  
5 carbon in these aerosols are close to the detection limits of thermal optical measurement  
6 systems, adding a high degree of uncertainty to the reported values. Thermal optical  
7 measurements also do not provide information about the specific chemical composition of  
8 carbonaceous aerosol that is needed to calculate refractive indices. Furthermore, the technique is  
9 based on filter collection, which only provides an average concentration of organic and  
10 elemental carbon and no information about mixing states.

11 The magnitude of the errors introduced into estimates of black carbon-related radiative  
12 forcing due to the lack of detailed information about optical properties of ambient black carbon  
13 aerosol cannot, yet, be estimated. The forcing estimate of + 0.2 Wm<sup>-2</sup> provided by the IPCC is  
14 based upon a summary of the available modeling estimates, some of which are founded on  
15 simplistic assumptions about the composition and mixing state of ambient BC aerosol.

16 New methods, such as photo-acoustic spectroscopy, hold promise for detecting quantities  
17 of light absorbing materials in streams of ambient aerosol (Arnott et al., 1999; Moosmuller et al.,  
18 2001). The photo-acoustic method is capable of identifying the absolute fraction of a given  
19 ambient aerosol sample that absorbs radiation at a given wavelength at high temporal resolution.  
20 The method does not alter the composition of the aerosol sample through heating and oxidation,  
21 thus eliminating chemical artifacts. Present photo-acoustic instruments detect absorption at  
22 wavelengths of interest for visibility studies, but the measurement principle can be adapted to  
23 climate studies through the selection of climate-forcing relevant wavelengths. Specific chemical  
24 speciation at the organic and inorganic compound level coupled with photo-acoustic  
25 measurements of the light absorbing properties of ambient aerosol would provide the best  
26 available test of atmospheric chemistry models attempting to simulate the evolution in aerosol  
27 radiative properties between emission and atmospheric removal.

## 28 **The Regional and Temporal Dependence of Aerosol Forcing**

29 In addition to information about the composition and size distributions of ambient aerosol,  
30 details regarding atmospheric concentrations on a spatial and temporal basis are needed for  
31

1 estimating climate forcing. Unlike the long-lived greenhouse gases, aerosols have lifetimes  
2 averaging only a week or less, leading to inhomogeneity in regional and global scale  
3 concentrations. Industrial processes and other human activities that produce air pollution  
4 aerosols also vary on a seasonal, monthly, weekly and diurnal basis, introducing other  
5 complications into forcing estimates (IPCC, 2001). Peak aerosol concentrations, along with the  
6 greatest temporal variation, exist near emissions sources.

7       Deviations from global mean forcing estimates can be very large on the regional scale.  
8 For instance, Tegen et al. (1996) found that local radiative forcing exerted by dust raised from  
9 disturbed lands ranges from  $-2.1 \text{ W m}^{-2}$  to  $5.5 \text{ W m}^{-2}$  over desert areas and their adjacent seas.  
10 The largest regional values of radiative forcing caused by anthropogenic sulfate are about  
11  $-3 \text{ W m}^{-2}$  in the eastern United States, south central Europe, and eastern China (Kiehl and  
12 Briegleb, 1993). These regional maxima in aerosol forcing are at least a factor of 10 greater than  
13 their global mean values shown in Figure 4-41. By comparison, regional maxima in forcing by  
14 the well-mixed greenhouse gases are only about 50% greater than their global mean value (Kiehl  
15 and Briegleb, 1993). Thus, the estimates of local radiative forcing by particles also are large  
16 enough to completely cancel the effects of greenhouse gases in many regions and to cause a  
17 number of changes in the dynamic structure of the atmosphere that still need to be evaluated.  
18 A number of anthropogenic pollutants whose distributions are highly variable are also effective  
19 greenhouse absorbers. These gases include  $\text{O}_3$  and, possibly,  $\text{HNO}_3$ ,  $\text{C}_2\text{H}_4$ ,  $\text{NH}_3$ , and  $\text{SO}_2$ , all of  
20 which are not commonly considered in radiative forcing calculations (Wang et al., 1976). High  
21 ozone values are found downwind of urban areas and areas where there is biomass burning.  
22 However, Van Dorland et al. (1997) found that there may not be much cancellation between the  
23 radiative effects for ozone and for sulfate because both species have different seasonal cycles  
24 and show significant differences in their spatial distribution.

### 25 26 **“Indirect” Effects of PM on Climate**

27       Aerosols directly affect climate by scattering and absorbing solar and terrestrial radiation.  
28 Depending on chemical composition, they can also nucleate new cloud droplets. For a given  
29 total liquid water content (LWC), increasing cloud droplet number means smaller droplets that  
30 both scatter solar radiation more effectively, reduce the amount of precipitation from the cloud,  
31 and consequently increase cloud lifetime – and the cloud’s ability to scatter solar radiation.

1 Observational evidence exists of this impact of hygroscopic aerosol on both warm and ice cloud  
2 properties. Increased albedo and increased cloud lifetime effects are treated separately by the  
3 climate modeling community. Particle-induced increases in cloud albedo are referred to as the  
4 “first” indirect effect, and changes to the cloud lifetime due to reduced precipitation are referred  
5 to as the “second” indirect effect. The highly uncertain estimated forcing due to the effects of  
6 particles on cloud albedo is given as a range from 0 to + 2.0 W m<sup>-2</sup> (IPCC, 2001a). A further  
7 effect, referred to as the “semi-indirect effect” is the reduction in cloud reflectivity due to the  
8 inclusion of black carbon-containing aerosol within the cloud drops themselves or as interstitial  
9 aerosol (Hansen et al., 2000).

10 Sulfate aerosols, especially those larger than 50 nm in diameter, are believed to alter clouds  
11 to the largest extent due to their efficient nucleation of cloud drops and ice crystals (Twomey,  
12 1974). Organic aerosols that contain highly oxidized carbon compounds may be similarly  
13 efficient in nucleating cloud droplets (Novakov and Penner, 1993). Both satellite and in-situ  
14 aircraft observations reinforce the hypothesis that pollutant aerosols increase cloud reflectivity  
15 and lifetime (Ramanathan et al., 2001).

16 An important consequence of this property of aerosols on regional climate includes  
17 suppression of rain over polluted regions. Satellite observations show that precipitation occurs  
18 only outside of pollution tracks, while clouds within pollution tracks show a reduction in  
19 effective cloud drop radius to below the precipitation threshold (D. Rosenfeld, 1999). Desert  
20 dust also appears to alter the microphysical properties of clouds, suppressing precipitation from  
21 warm clouds while nucleating ice crystals in cold clouds.

22 While climate models are not yet equipped for modeling the effect of aerosols on regional  
23 and global hydrological cycles, it has been proposed that aerosols will reduce precipitation  
24 efficiency over land where anthropogenic activities provide a major source of cloud  
25 condensation nuclei. Several studies using coupled ocean-atmosphere general circulation  
26 models support the possibility of a “spin down” effect upon hydrological cycles due only to a  
27 reduction in surface radiation receipts from sulfate aerosol scattering. When indirect effects are  
28 included, the reduction in precipitation rates from clouds was large enough to reverse the effect  
29 of greenhouse gas-related forcing (Ramanathan et al., 2001).

## 1 **Sources of Uncertainty in Aerosol Forcing Estimates**

2       Uncertainties in calculating the direct effect of airborne particles arise from a lack of  
3 knowledge of their vertical and horizontal variability, their size distribution, chemical  
4 composition, and the distribution of components within individual particles. For instance,  
5 gas-phase sulfur species may be oxidized to form a layer of sulfate around existing particles in  
6 continental environments or they may be incorporated in sea-salt particles (e.g., Li-Jones and  
7 Prospero, 1998). In either case, the radiative effects of a given mass of the sulfate will be much  
8 lower than if pure sulfate particles were formed. It also must be stressed that the overall  
9 radiative effect of particles at a given location is not simply determined by the sum of effects  
10 caused by individual classes of particles because of radiative interactions between particles with  
11 different radiative characteristics and with gases.

12       Calculations of the indirect effects of particles on climate are subject to much larger  
13 uncertainties than are calculations of their direct effects, reflecting uncertainties in a large  
14 number of chemical and microphysical processes that determine aerosol chemistry, size  
15 distribution, and the number of droplets within a cloud. A complete assessment of the radiative  
16 effects of PM will require computationally intensive calculations that incorporate the spatial and  
17 temporal behavior of particles of varying composition that have been emitted from (or formed  
18 from precursors emitted from) different sources. Refining values of model input parameters  
19 (such as improving emissions estimates) may be as important as improving the models per se in  
20 calculations of direct radiative forcing (Pan et al., 1997) and indirect radiative forcing (Pan et al.,  
21 1998). However, uncertainties associated with the calculation of radiative effects of particles  
22 will likely remain much larger than those associated with well-mixed greenhouse gases.

## 23 **Aerosol-Related Climate Effects, Human Health and the Environment**

24       Given the present difficulty in accurately modeling aerosol physical, chemical and  
25 temporal properties, its regionally-dependent atmospheric concentration levels, combined with  
26 difficulties in projecting location-specific increases or decreases in anthropogenic emissions of  
27 atmospheric particles (or their precursors), the specific impacts on human health and the  
28 environment due to aerosol effects on the climate system can not be calculated with confidence.  
29 However, substantial qualitative information, from observation and modeling, indicates that  
30 aerosol forces climate both positively and negatively, both globally and regionally, and may be  
31

1 negatively impacting hydrological cycles on a regional scale. The global and other regional  
2 scale impacts are suspected, on the basis of current, though uncertain, modeling studies suggest  
3 that climate change in general can have positive and negative effects on human health, human  
4 welfare and the environment.

## 6 **4.5.2 Atmospheric Particulate Matter Effects on the Transmission of Solar** 7 **Ultraviolet Radiation Transmission: Impacts on Human Health and** 8 **the Environment**

### 9 **4.5.2.1 Potential Effects of Increased Ultraviolet Radiation Transmission**

10 The transmission of solar UV-B radiation through the Earth's atmosphere is controlled by  
11 ozone, clouds, and particles. The depletion of stratospheric ozone caused by the release of  
12 anthropogenically produced chlorine (Cl)- and bromine (Br)-containing compounds has resulted  
13 in heightened concern about potentially serious increases in the amount of solar UV-B radiation  
14 (SUVB) reaching the Earth's surface. SUVB is also responsible for initiating the production of  
15 OH radicals that oxidize a wide variety of volatile organic compounds, some of which can  
16 deplete stratospheric ozone (e.g.,  $\text{CH}_3\text{Cl}$ ,  $\text{CH}_3\text{Br}$ ), absorb terrestrial infrared radiation (e.g.,  $\text{CH}_4$ ),  
17 and contribute to photochemical smog formation (e.g.,  $\text{C}_2\text{H}_4$ ,  $\text{C}_5\text{H}_8$ ).

18 Increased penetration of SUVB to the Earth's surface as the result of stratospheric ozone  
19 depletion continues to be of much concern because of projections of consequent increased  
20 surface-level SUVB exposure and associated potential negative impacts on human health, plant  
21 and animal biota, and man-made materials. Several summary overviews (Kripke, 1989; Grant,  
22 1989; Kodama and Lee, 1994; Van der Leun et al., 1995, 1998) of salient points related to  
23 stratospheric ozone depletion and bases for concern provide a concise introduction to the subject.  
24 Only a brief summary will be given here. Stratospheric ozone depletion results from  
25 (a) anthropogenic emissions of certain trace gases having long atmospheric residence times, e.g.,  
26 chlorofluorocarbons (CFCs), carbon tetrachloride ( $\text{CCl}_4$ ), and Halon 1211 ( $\text{CF}_2\text{Cl Br}$ ) and 1301  
27 ( $\text{CF}_3\text{Br}$ ) — which have atmospheric residence times of 75 to 100 years, 50 years, 25 years, and  
28 110 years, respectively; (b) their tropospheric accumulation and gradual transport, over decades,  
29 up to the stratosphere, where (c) they photolyze to release Cl and Br that catalyze ozone  
30 destruction; leading to (d) stratospheric ozone depletion. Such ozone depletion is most marked  
31 over Antarctica during spring in the Southern Hemisphere, to a less marked but still significant  
32 extent over the Arctic Polar Region during late winter and spring in the Northern Hemisphere,

1 and to a lesser extent, over mid-latitude regions during any season. Given the long time frame  
2 involved in transport of such gases to the stratosphere and their long residence times there, any  
3 effects already seen on stratospheric ozone are likely caused by the atmospheric loadings of trace  
4 gases from anthropogenic emissions over the past few decades. Ozone-depleting gases already  
5 in the atmosphere will continue to affect stratospheric ozone concentrations well into the 21st  
6 century. Shorter-lived gases, such as CH<sub>3</sub>Br, also exert significant ozone depletion effects.

7 The main types of deleterious effects hypothesized as likely to result from stratospheric  
8 ozone depletion and consequent increased SUVB penetration through the Earth's atmosphere  
9 include the following:

10 (1) *Direct Human Health Effects*, such as skin damage (sunburn), leading to more rapid  
aging and increased incidence of skin cancer; ocular effects (retinal damage and  
increased cataract formation possibly leading to blindness); and suppression of some  
immune system components (contributing to skin cancer induction and spread to  
nonirradiated skin areas, as well as possibly increasing susceptibility to certain  
infectious diseases).

11 (2) *Agricultural/Ecological Effects*, mediated largely through altered biogeochemical  
cycling resulting in consequent damaging impacts on terrestrial plants (leading to  
possible reduced yields of rice, other food crops, and commercially important trees, as  
well as to biodiversity shifts in natural terrestrial ecosystems); and deleterious effects  
on aquatic life (including reduced ocean zooplankton and phytoplankton, as important  
base components of marine food-chains supporting the existence of commercially  
important, edible fish and other seafood, as well as to other aquatic ecosystem shifts).

12 (3) *Indirect Human Health and Ecological Effects*, mediated through increased  
tropospheric ozone formation (and consequent exacerbation of surface-level, ozone-  
related health and ecological impacts) and alterations in the concentrations of other  
important trace species, most notably the hydroxyl radical and acidic aerosols.

13 (4) *Other Types of Effects*, such as faster rates of polymer weathering because of  
increased UV-B radiation and other effects on man-made commercial materials and  
cultural artifacts, secondary to climate change or exacerbation of air pollution  
problems.

1 Extensive qualitative and quantitative characterizations of stratospheric ozone depletion  
2 processes and projections of their likely potential impacts on human health and the environment  
3 have been the subjects of periodic (1988, 1989, 1991, 1994, 1998) international assessments  
4 carried out under WMO and UNEP auspices since the 1987 signing of the Montreal Protocol on  
5 Substances that Deplete the Ozone Layer. For more detailed up-to-date information, the reader  
6 is referred to recent international assessments of (a) processes contributing to stratospheric ozone  
7 depletion and the status of progress towards ameliorating the problem (WMO, 1999) and  
8 (b) revised qualitative and quantitative projections of potential consequent human health and  
9 environmental effects (UNEP, 1998, 2000).

10 Of considerable importance is the growing recognition, as reflected in these newer  
11 assessments, of impacts of enhanced solar radiation on biogeochemical cycles (see, for example,  
12 Zepp et al., 1998). As noted in that paper, the effects of UV-B radiation (both in magnitude and  
13 direction) on trace gas (e.g., CO) emissions and mineral nutrient cycling are species specific and  
14 can affect a variety of processes. These include, for example, changes in the chemical  
15 composition of living plant tissue, photodegradation of dead plant matter (e.g., ground litter),  
16 release of CO from vegetation previously charred by fire, changes in microbial decomposer  
17 communities, and effects on nitrogen-fixing microorganisms and plants. In addition, changes in  
18 the amount and composition of organic matter, caused by enhanced UV-B penetration, affect the  
19 transmission of solar ultraviolet and visible radiation through the water column. These changes  
20 in light quality broadly impact the effects of UV-B on aquatic biogeochemical cycles. Enhanced  
21 UV-B levels cause both positive and negative effects on microbial activities in aquatic  
22 ecosystems that can affect nutrient cycling and the uptake or release of greenhouse gases. Thus,  
23 there are emerging complex issues regarding interactions and feedbacks between climate change  
24 and changes in terrestrial and marine biogeochemical cycles because of increased UV-B  
25 penetration to the Earth's surface.

26 In contrast to the above types of negative impacts projected as likely to be associated with  
27 increased UV-B penetration to Earth's surface, some research results are suggestive of possible  
28 beneficial effects of increased UV-B radiation. For example, a number of U.S. and international  
29 studies have focused on the protective effects of UV-B radiation with regard to non-skin cancer  
30 incidence. One of the first of these studies investigated potential relationships between sunlight,  
31 vitamin D, and colon cancer (Garland and Garland, 1980). More recent studies continue to

1 provide suggestive evidence that UV-B radiation may be protective against several types of  
2 cancer and some other diseases. For example, Grant (2002) conducted a number of ecologic-  
3 type epidemiologic studies, which suggest that UV-B radiation, acting through the production of  
4 vitamin D, is a risk-reduction factor for mortality due to several types of cancer, including cancer  
5 of the breast, colon, ovary, and prostate, as well as non-Hodgkin lymphoma. Other related  
6 studies that provide evidence for protective effects of UV-B radiation include Gorham et al.  
7 (1989); Gorham et al. (1990); Garland et al. (1990); Hanchette and Schwartz (1992); Ainsleigh  
8 (1993); Lefkowitz and Garland (1994); Hartge et al. (1996); and Freedman et al. (1997).

9 As noted in the above detailed international assessments, since the signing of the Montreal  
10 Protocol, much progress has been made in reducing emissions of ozone depleting gases, leading  
11 to estimates that the maximum extent of stratospheric ozone depletion has likely leveled off  
12 during recent years, and this is expected to be followed by gradual lessening of the problem and  
13 its impacts during the next half-century. However, the assessments also note that the modeled  
14 projections are subject to considerable uncertainty (see, for example, UNEP, 2000). Varying  
15 potential roles of atmospheric particles, discussed below, are among salient factors complicating  
16 predictive modeling efforts.

#### 18 **4.5.2.2 Airborne Particle Effects on Atmospheric Transmission of Solar Ultraviolet** 19 **Radiation**

20 A given amount of ozone in the lower troposphere has been shown to absorb more solar  
21 radiation than an equal amount of ozone in the stratosphere because of the increase in its  
22 effective optical path produced by Rayleigh scattering in the lower atmosphere (Brühl and  
23 Crutzen, 1988). The effects of particles are more complex. The impact of particles on the  
24 SUVB flux throughout the boundary layer are highly sensitive to the altitude of the particles and  
25 to their single scattering albedo. Even the sign of the effect can reverse as the composition of the  
26 particle mix changes from scattering to absorbing types (e.g., from sulfate to elemental carbon or  
27 PAHs; Dickerson et al., 1997). In addition, scattering by particles also may increase the  
28 effective optical path of absorbing molecules, such as ozone, in the lower atmosphere.

29 The effects of particles present in the lower troposphere on the transmission of SUVB have  
30 been examined both by field measurements and by radiative transfer model calculations. The  
31 presence of particles in urban areas modifies the spectral distribution of solar irradiance at the  
32 surface. Shorter wavelength radiation (i.e., in the ultraviolet) is attenuated more than visible

1 radiation (e.g., Peterson et al., 1978; Jacobson, 1999). Wenny et al. (1998) also found greater  
2 attenuation of SUVB than SUVA (315 to 400 nm). However, this effect depends on the nature  
3 of the specific particles involved and, therefore, is expected to depend strongly on location.  
4 Lorente et al. (1994) observed an attenuation of SUVB ranging from 14 to 37%, for solar zenith  
5 angles ranging from about 30° to about 60°, in the total (direct and diffuse) SUVB reaching the  
6 surface in Barcelona during cloudless conditions on very polluted days (aerosol scattering  
7 optical depth at 500 nm,  $0.46 \lesssim \tau_{500 \text{ nm}} \lesssim 1.15$ ) compared to days on which the turbidity of urban  
8 air was similar to that for rural air ( $\tau_{500 \text{ nm}} \lesssim 0.23$ ).

9 Particle concentrations that can account for these observations can be estimated roughly by  
10 combining Koschmieder's relation for expressing visual range in terms of extinction coefficient  
11 with one for expressing the mass of PM<sub>2.5</sub> particles in terms of visual range (Stevens et al.,  
12 1984). By assuming a scale height (i.e., the height at which the concentration of a substance  
13 falls off to 1/e of its value at the surface) of 1 km for PM<sub>2.5</sub>, an upper limit of 30 µg/ m<sup>3</sup> can be  
14 derived for the clear case and between 60 and 150 µg/m<sup>3</sup> for the polluted case. Estupiñán et al.  
15 (1996) found that summertime haze under clear sky conditions attenuates SUVB between 5 and  
16 23% for a solar zenith angle of 34° compared to a clear sky day in autumn. Mims (1996)  
17 measured a decrease in SUVB by about 80% downwind of major biomass burning areas in  
18 Amazonia in 1995. This decrease in transmission corresponded to optical depths at 340 nm  
19 ranging from three to four. Justus and Murphey (1994) found that SUVB reaching the surface  
20 decreased by about 10% because of changes in aerosol loading in Atlanta, GA, from 1980 to  
21 1984. In addition, higher particle levels in Germany (48 °N) may be responsible for greater  
22 attenuation of SUVB than in New Zealand (Seckmeyer and McKenzie, 1992).

23 In a study of the effects of nonurban haze on SUVB transmission, Wenny et al. (1998)  
24 derived a very simple regression relation between the measured aerosol optical depth at 312 nm,  
25

$$26 \quad \ln(\text{SUVB transmission at solar noon}) = -0.1422 \tau_{312 \text{ nm}} - 0.138, R^2 = 0.90, \quad (4-14)$$

27  
28 and the transmission of SUVB to the surface. In principle, values of  $\tau_{312 \text{ nm}}$  could be found from  
29 knowledge of the aerosol optical properties and visual range values. Wenny et al. (1998) also  
30 found that absorption by particles accounted for 7 to 25% of the total (scattering + absorption)  
31 extinction. Relations such as the above one are strongly dependent on local conditions and

1 should not be used in other areas without knowledge of the differences in aerosol properties.  
2 Although all of the above studies reinforce the idea that particles play a major role in modulating  
3 the attenuation of SUVB, none included measurements of ambient PM concentrations, so direct  
4 relations between PM levels and SUVB transmission could not be determined.

5 Vuilleumier et al. (2001) concluded that variations in aerosol scattering and absorption  
6 were responsible for 97% of the variability in the optical depth measured at seven wavelengths  
7 from 300 to 360 nm at Riverside, CA, from 1 July to 1 November, 1997. Similar measurements  
8 made at nearby Mt. Wilson, located above the main surface haze layer, showed that 80% of the  
9 variations in optical depth were still driven by variations in aerosol scattering and absorption.  
10 The remainder of the variability in optical depth was attributed mainly to variability in ozone  
11 under clear-sky conditions. However, these results cannot be extrapolated to other locations  
12 because these effects are coupled and non-linear and are not straightforward. They depend on  
13 the concentrations of these species and on the physical and chemical characteristics of the  
14 particles. Hence, any quantitative statements regarding the relative importance of particles and  
15 ozone will be location-specific.

16 Liu et al. (1991) roughly estimated the overall effects on atmospheric transmission of  
17 SUVB of increases of anthropogenic airborne particles that have occurred since the beginning of  
18 the industrial revolution. Based on (a) estimates of the reduction in visibility from about 95 km  
19 to about 20 km over nonurban areas in the eastern United States and in Europe, (b) calculations  
20 of optical properties of airborne particles found in rural areas to extrapolate the increase in  
21 extinction at 550 to 310 nm, and (c) radiative transfer model calculations, Liu et al. concluded  
22 that the amount of SUVB reaching Earth's surface likely has decreased from 5 to 18% since the  
23 beginning of the industrial revolution. This was attributed mainly to scattering of SUVB back to  
24 space by sulfate-containing particles. Radiative transfer model calculations have not been done  
25 for urban particles.

26 Although aerosols are expected to decrease the flux of SUVB reaching the surface,  
27 scattering by particles is expected to result in an increase in the actinic flux within and above the  
28 aerosol layer. However, when the particles significantly absorb SUVB, a decrease in the actinic  
29 flux is expected. Actinic flux is the radiant energy integrated over all directions at a given  
30 wavelength incident on a point in the atmosphere and is the quantity needed to calculate rates of  
31 photolytic reactions in the atmosphere. Blackburn et al. (1992) measured attenuation of the

1 photolysis rate of ozone and found that aerosol optical depths near unity at 500 nm reduced  
2 ozone photolysis rate by as much as a factor of two. Dickerson et al. (1997) showed that the  
3 photolysis rate for  $\text{NO}_2$ , a key parameter for calculating the overall intensity of photochemical  
4 activity, could be increased within and above a scattering aerosol layer extending from the  
5 surface although it would be decreased at the surface. This effect is qualitatively similar to what  
6 is seen in clouds, where photolysis rates are increased in the upper layers of a cloud and above  
7 the cloud (Madronich, 1987). For a simulation of an ozone episode that occurred during July  
8 1995 in the Mid-Atlantic region, Dickerson et al. (1997) calculated ozone increases of up to  
9 20 ppb compared to cases that did not include the radiative effects of particles in urban airshed  
10 model (UAM-IV) simulations. In contrast, Jacobson (1998) found that particles may have  
11 caused a 5 to 8% decrease in  $\text{O}_3$  levels during the Southern California Air Quality Study in 1987.  
12 Absorption by organic compounds and nitrated inorganic compounds was hypothesized to  
13 account for the reductions in UV radiation intensity.

14 The photolysis of ozone in the Hartley bands also leads to production of electronically  
15 excited oxygen atoms,  $\text{O}(^1\text{D})$  that then react with water vapor to form OH radicals. Thus,  
16 enhanced photochemical production of ozone is accompanied by the scavenging of species  
17 involved in greenhouse warming and stratospheric depletion. However, these effects may be  
18 neutralized or even reversed by the presence of absorbing material in the particles. Any  
19 evaluation of the effects of particles on photochemical activity therefore will depend on the  
20 composition of the particles and will also be location-specific.

21 Further complicating any straightforward evaluation of UV-B penetration to specific areas  
22 of the Earth's surface are the influences of clouds, as discussed by Erlick et al. (1998), Frederick  
23 et al. (1998), and Soulen and Fredrick (1999). The transmission of solar UV and visible  
24 radiation is highly sensitive to cloud type, cloud amount, and the extent of their external or  
25 internal mixing with cloud droplets. Even in situations of very low atmospheric PM (e.g., over  
26 Antarctica), interannual variations in cloudiness over specific areas can be as important as ozone  
27 levels in determining UV surface irradiation, with net impacts varying from a month or season to  
28 another (Soulen and Fredrick, 1999). Evaluations of the effects of changes in the transmission of  
29 solar UV-B radiation to the surface have been performed usually for cloud-free or constant  
30 cloudiness conditions.

1           Given the above considerations, quantification of projected effects of variations in  
2 atmospheric PM on human health or the environment because of the effects of particles on the  
3 transmission of solar UV-B radiation would require location-specific evaluations, that take into  
4 account (a) composition, concentration, and internal structure of the particles; (b) temporal  
5 variations in atmospheric mixing height and depths of layers containing the particles; and (c) the  
6 abundance of ozone and other absorbers within the planetary boundary layer and the free  
7 troposphere. The outcome of such modeling effects would likely vary from location to location  
8 in terms of increased or decreased surface level UV-B exposures because of location-specific  
9 changes in atmospheric PM concentrations or composition. For example, to the extent that any  
10 location-specific scattering by airborne PM were to affect the directional characteristics of UV  
11 radiation at ground level, and thereby enhance radiation incident from low angles (Dickerson,  
12 1997), the biological effectiveness (whether deleterious or beneficial) of resulting ground-level  
13 UV-B exposures could be enhanced. Airborne PM also can reduce the ground-level ratio of  
14 photorepairing radiation (UV-A and short-wavelength visible) to damaging UV-B radiation.  
15 Lastly, PM deposition is a major source of PAHs in certain freshwater lakes and coastal areas,  
16 and the adverse effects of solar UV are enhanced by the uptake of PAHs by aquatic organisms.  
17 Thus, although airborne PM may, in general, tend to reduce ground-level UV-B, its net effect in  
18 some locations may be to increase UV damage to certain aquatic and terrestrial organisms, as  
19 discussed by Cullen and Neale (1997).

## 22 **4.6 SUMMARY AND KEY CONCLUSIONS**

### 23 **4.6.1 Particulate Matter Effects on Vegetation and Ecosystems**

24           The first section of this chapter assesses and characterizes the overall ecological integrity  
25 and indicate the status of ecosystems within the United States affected by the deposition of the  
26 anthropogenic stressors associated with PM. There are six Essential Ecological Attributes  
27 (EEAs) — Landscape Condition, Biotic Condition, and Chemical/ Physical Characteristics, and  
28 Ecological Processes, Hydrology/Geomorphology, and Natural Disturbance Regimes that can be  
29 used to provide a hierarchical framework for determining ecosystem status. The first three can  
30 be separated into “patterns” and the last three into “processes.” The ecological processes create  
31 and maintain the ecosystem elements in patterns. The patterns in turn affect how the ecosystem

1 processes are expressed. Patterns at the higher level of biological organization emerge from the  
2 interactions and selection processes at localized levels. Changes in patterns or processes result  
3 in changes in the status and functioning of an ecosystem. The relationships among the EEAs are  
4 complex because all are interrelated (i.e., changes in one EEA may affect, directly or indirectly,  
5 every other EEA).

6 Human existence on Earth depends on the life-support services provided by the interaction  
7 of the different EEAs. Ecosystem processes and patterns provide the functions that maintain  
8 clean water, clean air, a vegetated earth, and a balance of organisms that enable humans to  
9 survive. The benefits they impart include the absorption and breakdown of pollutants, cycling of  
10 nutrients, binding of soil, degradation of organic waste, maintenance of a balance of gases in the  
11 air, regulation of radiation balance, climate, and fixation of solar energy. Concern has arisen in  
12 recent years regarding biodiversity and the integrity of ecosystems. There are few ecosystems  
13 on Earth today whose activities are not influenced by humans. For this reason, understanding  
14 the changes in biodiversity and nutrient cycling resulting from PM deposition are of great  
15 importance.

16 The PM whose effects on vegetation and ecosystems is discussed in this section is not a  
17 single pollutant but represents a heterogeneous mixture of particles differing in origin, size and  
18 chemical constituents. The effects of exposure to a given mass concentration of PM of particular  
19 size may, depending on the particular mix of deposited particles, lead to widely differing  
20 phytotoxic responses.

21 The deposition of PM onto vegetation and soil, depending on its chemical composition  
22 (acid/base, trace metal, or nutrients, e.g., nitrates or sulfates), can produce direct or indirect  
23 responses within an ecosystem. Ecosystem response to pollutant deposition is a direct function  
24 of the level of sensitivity of the ecosystem and its ability to ameliorate resulting change.  
25 Changes in ecosystem structural patterns and the functioning of ecological processes, must be  
26 scaled in both time and space and propagated to the more complex levels of community  
27 interaction to produce observable ecosystem changes.

28 The nitrates and sulfates deposited in PM whose indirect effects occur via the soil are the  
29 stressors of greatest environmental significance. Upon entering the soil environment, they can  
30 alter the ecological processes of energy flow and nutrient cycling, inhibit nutrient uptake, change  
31 ecosystem structure, and affect ecosystem biodiversity. The soil environment is one of the most

1 dynamic sites of biological interaction in nature. It is inhabited by microbial communities of  
2 bacteria, fungi and actinomycetes. Bacteria are essential participants in the nitrogen and sulfur  
3 cycles that make these elements available for plant uptake. Fungi in association with plant roots  
4 form mycorrhizae, a mutualistic symbiotic relationship that is integral in mediating plant uptake  
5 of mineral nutrients. Changes in the soil environment that influence the role of the bacteria in  
6 nutrient cycling and fungi in making minerals available for plant utilization, determine plant and  
7 ultimately ecosystem response.

8 The affects on the growth of plants resulting from the deposition of nitrates and sulfates  
9 and the acidifying effect of the associated  $H^+$  ion in wet and dry deposition in PM are the most  
10 important environmentally. Nitrogen is of overriding importance in plant metabolism and, to a  
11 large extent governs the utilization of phosphorus, potassium, and other nutrients. Typically, the  
12 availability of nitrogen via nitrogen cycle controls net primary productivity, and possibly, the  
13 decomposition rate of plant litter. Plants usually obtain nitrogen directly from the soil by  
14 absorbing  $NH_4^+$  or  $NO_3^-$  through their roots, or it is formed by symbiotic organisms in their roots.  
15 Plants vary in their ability to absorb ammonium and nitrate from the soil.

16 Although nitrogen as molecular nitrogen ( $N_2$ ) is the most abundant element in the  
17 atmosphere, it only becomes available to support the growth of plants after it is converted into  
18 reactive forms. In nature, nitrogen may be divided into two groups: reactive (Nr) and  
19 nonreactive ( $N_2$ ). Reactive Nr includes the inorganic reduced forms of nitrogen (e.g., ammonia  
20 [ $NH_3$ ] and ammonium [ $NH_4^+$ ]), inorganic oxidized forms (e.g., nitrogen oxides [ $NO_x$ ], nitric acid  
21 [ $HNO_3$ ], nitrous oxide [ $N_2O$ ], and nitrate [ $NO_3^-$ ]), and organic compounds (e.g., urea, amine,  
22 proteins, and nucleic acids).

23 Reactive nitrogen is now accumulating in the environment on all spatial scales – local,  
24 regional and global. The three main causes of the increase in global Nr is the result of the (1)  
25 widespread cultivation of legumes, rice and other crops that promote conversion of  $N_2$  to organic  
26 nitrogen through biological nitrogen fixation; (2) combustion of fossil fuels, which converts both  
27 atmospheric  $N_2$  and fossil nitrogen to reactive  $NO_x$ ; and the (3) Haber-Bosch process, which  
28 converts nonreactive  $NH_3$  to sustain food production and some industrial activities. The major  
29 changes in the nitrogen cycle due to the cited causes can be both beneficial and detrimental to  
30 the health and welfare of humans and ecosystems.

1           Reactive nitrogen can be widely dispersed and accumulate in the environment when the  
2 rates of its formation exceed the rates of removal via denitrification. Nr creation and  
3 accumulation is projected to increase as per capita use of resources by human populations  
4 increases. The cascade of environmental effects of increases in Nr include the following:  
5 (1) production of tropospheric ozone and aerosols that induce human health problems;  
6 (2) increases in the productivity in forests and grasslands followed by decreases wherever  
7 deposition increases significantly and exceeds critical thresholds; Nr additions probably also  
8 decrease biodiversity in many natural habitats; (3) in association with sulfur is responsible for  
9 acidification and loss of biodiversity in lakes and streams in many regions of the world;  
10 (4) eutrophication, hypoxia, loss of biodiversity, and habitat degradation in coastal ecosystems.  
11 [Eutrophication is now considered the biggest pollution problem in coastal waters.]  
12 (5) contributes to global climate change and stratospheric ozone depletion, which can in turn  
13 affect ecosystems and human health (See Table 4-21).

14           Changes in nitrogen supply can have a considerable effect on an ecosystem's nutrient  
15 balance. Large chronic additions of nitrogen influence normal nutrient cycling and alter many  
16 plant and soil processes involved in nitrogen cycling. "Nitrogen saturation" results when Nr  
17 concentrations exceed the capacity of a system to utilize it. Saturation implies that some  
18 resource other than nitrogen is limiting biotic function. Water and phosphorus for plants and  
19 carbon for microorganisms are most likely to be the secondary limiting factors. The appearance  
20 of nitrogen in soil solution is an early symptom of excess nitrogen. In the final stage, disruption  
21 of ecosystem structure becomes visible.

22           Possible ecosystem responses to nitrogen saturation include (1) a permanent increase in  
23 foliar nitrogen and reduced foliar phosphorus and lignin caused by the lower availability of  
24 carbon, phosphorus, and water; (2) reduced productivity in conifer stands because of disruptions  
25 of physiological function; (3) decreased root biomass and increased nitrification and nitrate  
26 leaching; and (4) reduced soil fertility, resulting from increased cation leaching, increased nitrate  
27 and aluminum concentrations in streams, (5) decreased water quality and (6) changes in soil  
28 microbial communities from predominantly fungal (mycorrhizal) communities to those  
29 dominated by bacteria during saturation.

30           Although soils of most North American forest ecosystems are nitrogen limited, there are  
31 some that exhibit severe symptoms of nitrogen saturation (See Table 4-14). They include the

**TABLE 4-21. EFFECTS OF REACTIVE NITROGEN**

---

*Direct effects of Nr on ecosystems include:*

---

Increased productivity of Nr-limited natural ecosystems.  
Ozone-induced injury to crop, forest, and natural ecosystems and predisposition to attack by pathogens and insects.  
Acidification and eutrophication effects on forests, soils, and freshwater aquatic ecosystems.  
Eutrophication and hypoxia in coastal ecosystems.  
N saturation of soils in forests and other natural ecosystems.  
Biodiversity losses in terrestrial and aquatic ecosystems and invasions by N-loving weeds.  
Changes in abundance of beneficial soil organisms that alter ecosystem functions.

---

*Indirect effects of Nr on other societal values include:*

---

Increased wealth and well being of human populations in many parts of the world.  
Significant changes in patterns of land use.  
Regional hazes that decrease visibility at scenic vistas and airports.  
Depletion of stratospheric ozone by N<sub>2</sub>O emissions.  
Global climate change induced by emissions of N<sub>2</sub>O and formation of tropospheric ozone.  
Damage to useful materials and cultural artifacts by ozone, other oxidants, and acid deposition.  
Long-distance transport of Nr which causes harmful effects in countries distant from emission sources and/or increased background concentrations of ozone and fine particulate matter.

---

*In addition to these effects, it is important to recognize that:*

---

The magnitude of Nr flux often determines whether effects are beneficial or detrimental.  
All of these effects are linked by biogeochemical circulation pathways of Nr.  
Nr is easily transformed among reduced and oxidized forms in many systems. Nr is easily distributed by hydrologic and atmospheric transport processes.

---

---

1 high-elevation, non-aggrading spruce-fir ecosystems in the Appalachian Mountains; the eastern  
2 hardwood watersheds at the Fernow Experimental Forest near Parsons, WV; forests in southern  
3 California, the southwestern Sierra Nevada in Central California; and the Front Range in  
4 northern Colorado. The mixed conifer forest and chaparral watershed with high smog exposure  
5 in the Los Angeles Air Basin exhibit the highest stream water NO<sub>3</sub><sup>-</sup> concentrations for wild-lands  
6 in North America;

7 Increases in soil nitrogen play a selective role in ecosystems. Plants adapted to living in an  
8 environment of low nitrogen availability will be replaced by nitrophilic plants capable of using  
9 increased nitrogen because they have a competitive advantage when nitrogen becomes more  
10 readily available. Plant succession patterns and biodiversity are affected significantly by chronic  
11 nitrogen additions in some North American ecosystems. Long-term nitrogen fertilization studies  
12 in both New England and Europe suggest that some forests receiving chronic inputs of nitrogen  
13 may decline in productivity and experience greater mortality. Declining coniferous forest stands

1 with slow nitrogen cycling may be replaced by deciduous fast-growing forests that cycle  
2 nitrogen.

3 Linked to the nitrogen cascade is the deposition of Nr and sulfates and the associated  
4 hydrogen ion is acidic precipitation, a critical environmental stress that affects forest landscapes  
5 and aquatic ecosystems in North America, Europe, and Asia. Composed of ions, gases, and  
6 particles derived from gaseous emissions of sulfur dioxide (SO<sub>2</sub>), nitrogen oxides (NO<sub>x</sub>),  
7 ammonia (NH<sub>3</sub>) and particulate emissions of acidifying and neutralizing compounds, acidic  
8 precipitation is highly variable across time and space. Its deposition and the resulting soil  
9 acidity can lead to nutrient deficiencies and to high aluminum-to-nutrient ratios that limit uptake  
10 of calcium and magnesium and create a nutrient deficiency. Aluminum accumulation in root  
11 tissue can reduce calcium uptake and causes Ca<sup>2+</sup> deficiencies. Tree species can be adversely  
12 affected if altered Ca/Al ratios impair calcium or magnesiums uptake. Calcium is essential in  
13 the formation of wood and the maintenance of the primary plant tissues necessary for tree  
14 growth. Studies suggest that the decline of red spruce stands in Vermont may be related to the  
15 Ca/Al ratio (Johnson and Lindberg, 1992b).

16 The evidence of the effects of wet and dry particulate deposition SO<sub>4</sub><sup>-</sup> and Nr species on  
17 nutrient cycling in forest ecosystems is provided by the Integrated Forest Study (IFS). The  
18 deposition data from the study illustrates several important aspects of the atmospheric exposure  
19 characteristics across a wide elevational gradient and over a wide spatial scale. Atmospheric  
20 deposition plays a significant role in the biogeochemical cycles at all IFS sites, but is most  
21 important in the east at high-elevation sites. The flux of the sulfate ion, Nr compounds, and H<sup>+</sup>  
22 ions in throughfall at all sites is dominated by atmospheric deposition. Atmospheric deposition  
23 may have significantly affected the nutrient status of some IFS sites through the mobilization of  
24 aluminum by impeding cation uptake. Nitrates and sulfate are the dominant anions in the  
25 Smokies and pulses of nitrates are the major causes of aluminum pulses in soil solutions.  
26 However, the connection between aluminum mobilization and forest decline is not clear, hence,  
27 aluminum mobilization presents a situation worthy of further study.

28 Notable impacts of excess nitrogen deposition also have been observed with regard to  
29 aquatic systems. For example, atmospheric nitrogen deposition into soils in watershed areas  
30 feeding into estuarine sound complexes (e.g., the Pamlico Sound of North Carolina) appear to  
31 contribute to excess nitrogen flows in runoff (especially during and after heavy rainfall events

1 such as hurricanes) from agricultural practices or other uses (e.g., fertilization of lawns or  
2 gardens), massive influxes of such nitrogen into watersheds and sounds can lead to dramatic  
3 decreases in water oxygen and increases in algae blooms that can cause extensive fish kills and  
4 damage to commercial fish and sea food harvesting.

5 The critical loads concept is useful for estimating the amounts of pollutants (e.g., Nr and  
6 acidic precipitation) that sensitive ecosystems can absorb on a sustained basis without  
7 experiencing measurable degradation. The estimation of ecosystem critical loads requires an  
8 understanding of how an ecosystem will respond to different loading rates in the long term and  
9 can be of special value for ecosystems receiving chronic deposition of Nr and sulfur  
10 independently and as acidic deposition when in combination.

11 Changes in the soil can result from the deposition of heavy metals. Exposures to heavy  
12 metals are highly variable depending whether deposition is by wet or dry processes. Few (e.g.,  
13 copper, nickel, zinc) have been documented to have direct phytotoxicity under field conditions.  
14 Exposure to coarse particles of natural origin and elements such as iron and manganese are more  
15 likely to occur via dry deposition while fine particles of atmospheric origin and elements such as  
16 cadmium, chromium, lead nickel, and vanadium. Ecosystems immediately downwind of major  
17 emissions sources such as power generating, industrial, or urban complexes can receive locally  
18 heavy inputs. Heavy metal accumulation by affecting litter decomposition presents the greatest  
19 potential for influencing nutrient cycling. Microbial populations decreased and logarithmic rates  
20 of microbial increase were prolonged as a result of cadmium toxicity. Additionally, the presence  
21 of cadmium, copper and nickel were observed to affect the symbiotic activity of fungi, bacteria,  
22 and actinomycetes.

23 Phytochelatins produced by plants as a response to sublethal concentrations of heavy  
24 metals, are indicators of metal stress and can be used to indicate that heavy metals are involved  
25 in forest decline. Increasing concentrations of phytochelatins with increase in altitude and their  
26 increase across regions showing increased levels of forest injury implicated them in forest  
27 decline.

28 The ambient concentration of particles, the parameter for which there is most data (Chapter  
29 3), is at best an indicator of exposure. The amount of PM entering the immediate plant  
30 environment, deposited onto the plant surfaces or soil in the vicinity of the roots, determines the  
31 biological effect. Three major routes are involved during the wet and dry deposition processes:

1 (1) precipitation scavenging in which particles are deposited in rain and snow; (2) occult (fog,  
2 cloud water, and mist interception); and (3) dry deposition, a much slower, yet more continuous  
3 removal to place surfaces.

4 Deposition of PM on above-ground plant parts can have either a physical and/or chemical  
5 effect. Particles transferred from the atmosphere to plant surfaces may cause direct effects if  
6 they (1) reside on the leaf, twig, or bark surface for an extended period; (2) are taken up through  
7 the leaf surface; or (3) are removed from the plant via resuspension to the atmosphere, washing  
8 by rainfall, or litter-fall with subsequent transfer to the soil. Ecosystem effects have been  
9 observed only in the neighborhood limestone quarries.

10 Secondary organics formed in the atmosphere have been variously subsumed under the  
11 following terms: toxic substances, pesticides, hazardous air pollutants (HAPS), air toxics,  
12 semivolatile organic compounds (SOCs), and persistent organic pollutants (POPS). The  
13 substances alluded to under the above headings are controlled under CAA Sect.112, Hazardous  
14 Air Pollutants not as criteria pollutants controlled by NAAQS under CAA Sections 108 and 109  
15 (U.S. Code, 1991). Their possible effects on humans and ecosystems are discussed in many  
16 other government documents and publications. They are noted in this chapter because, in the  
17 atmosphere, many of the chemical compounds are partitioned between gas and particle phases  
18 and are deposited as particulate matter. As particles, they become airborne and can be  
19 distributed over a wide area and affect remote ecosystems. Some of the chemical compounds  
20 are of concern to humans because they may reach toxic levels in food chains of both animals and  
21 humans; whereas others tend to decrease or maintain the same toxicity as they move through the  
22 food chain.

23 An important characteristic of fine particles is their ability to affect flux of solar radiation  
24 passing through the atmosphere directly, by scattering and absorbing solar radiation, and  
25 indirectly, by acting as cloud condensation nuclei that, in turn, influence the optical properties of  
26 clouds. Regional haze has been estimated to diminish surface solar visible radiation by  
27 approximately 8%. Crop yield have been reported as being sensitive to the amount of sunlight  
28 receive, and crop losses have been attributed to increased airborne particle levels in some area of  
29 the world.

30 From among all of the various effects of PM on ecosystems discussed above, the effects of  
31 excess nitrogen added to the environment via emissions to the atmosphere and especially

1 increases in Nr due to food production has resulted in the accumulation in the environmental at  
2 all spatial scales, local, regional and global. The results of the nitrogen cascade as Nr moves  
3 through the different environmental compartments has effects both beneficial and detrimental to  
4 humans and ecosystems. Table 4-21 summarizes a variety of effects (both and indirect)  
5 associated with the presence of Nr as it circulates through the various environmental  
6 compartments. These effects are associated with the long-term chronic deposition of Nr on the  
7 terrestrial and aquatic ecosystems.

#### 9 **4.6.2 Particulate Matter-Related Effects on Visibility**

10 Visibility is defined as the degree to which the atmosphere is transparent to visible light  
11 and the clarity and color fidelity of the atmosphere. Visual range is the farthest distance a black  
12 object can be distinguished against the horizontal sky. Visibility impairment is any humanly  
13 perceptible change in visibility. For regulatory purposes, visibility impairment, characterized by  
14 light extinction, visual range, contrast, and coloration, is classified into two principal forms:  
15 (1) “reasonably attributable” impairment, attributable to a single source or small group of  
16 sources, and (2) regional haze, any perceivable change in visibility caused by a combination of  
17 many sources over a wide geographical area.

18 Visibility is measured by human observation, light scattering by particles, the light  
19 extinction-coefficient, and parameters related to the light-extinction coefficient (visual range and  
20 deciview scale), and fine PM mass concentrations.

21 The air quality within a sight path will affect the illumination of the sight path by scattering  
22 or absorbing solar radiation before it reaches the Earth’s surface. The rate of energy loss with  
23 distance from a beam of light is the light extinction coefficient. The light extinction coefficient  
24 is the sum of the coefficients for light absorption by gases ( $\sigma_{ag}$ ), light scattering by gases ( $\sigma_{sg}$ ),  
25 light absorption by particles ( $\sigma_{ap}$ ), and light scattering by particles ( $\sigma_{sp}$ ). Corresponding  
26 coefficients for light scattering and absorption by fine and coarse particles are  $\sigma_{sfp}$  and  $\sigma_{afp}$  and  
27  $\sigma_{scp}$  and  $\sigma_{acp}$ , respectively. Visibility within a sight path longer than approximately 100 km (60  
28 mi) is affected by the change in the optical properties of the atmosphere over the length of the  
29 sight path.

30 Visual range was developed for and continues to be used as an aid in military operations  
31 and to a lesser degree in transportation safety. Visual range is commonly taken to be the greatest

1 distance a dark object can be seen against the background sky. The deciview is an index of  
2 haziness. A change of 1 or 2 deciviews is seen as a noticeable change in the appearance of a  
3 scene.

4 Under certain conditions, fine particle mass concentrations may be used as a visibility  
5 indicator. However, the relationship may differ between locations and for different times of the  
6 year. Also, measurement should be made under dry conditions.

7 Visibility impairment is associated with airborne particle properties, including size  
8 distributions (i.e., fine particles in the 0.1- to 1.0- $\mu\text{m}$  size range) and aerosol chemical  
9 composition, and with relative humidity. With increasing relative humidity, the amount of  
10 moisture available for absorption by particles increases, thus causing the particles to increase in  
11 both size and volume. As the particles increase in size and volume, the light scattering potential  
12 of the particles also generally increases. Visibility impairment is greatest in the eastern United  
13 States and Southern California. In the eastern United States, visibility impairment is caused  
14 primarily by light scattering by sulfate aerosols and, to a lesser extent, by nitrate particles and  
15 organic aerosols, carbon soot, and crustal dust. Up to 86% of the haziness in the eastern United  
16 States is caused by atmospheric sulfate. Further West, scattering contributions to visibility  
17 impairment decrease to from 25 to 50%. Light scattering by nitrate aerosols is the major cause  
18 of visibility impairment in southern California. Nitrates contribute about 45% to the total light  
19 extinction in the West and up to 17% of the total extinction in the East. Organic particles are the  
20 second largest contributors to light extinction in most U.S. areas. Organic carbon is the greatest  
21 cause of light extinction in the West, accounting for up to 40% of the total extinction and up to  
22 18% of the visibility impairment in the East. Coarse mass and soil, primarily considered  
23 “natural extinction,” is responsible for some of the visibility impairment in the West, accounting  
24 for up to 25% of the light extinction.

### 25 26 **4.6.3 Particulate Matter-Related Effects on Materials**

27 Building materials (metals, stones, cements, and paints) undergo natural weathering  
28 processes from exposure to environmental elements (wind, moisture, temperature fluctuations,  
29 sun light, etc.). Metals form a protective film of oxidized metal (e.g., rust) that slows  
30 environmentally induced corrosion. On the other hand, the natural process of metal corrosion

1 from exposure to natural environmental elements is enhanced by exposure to anthropogenic  
2 pollutants, in particular SO<sub>2</sub>, that render the protective film less effective.

3 Dry deposition of SO<sub>2</sub> enhances the effects of environmental elements on calcereous stones  
4 (limestone, marble, and cement) by converting calcium carbonate (calcite) to calcium sulfate  
5 dihydrate (gypsum). The rate of deterioration is determined by the SO<sub>2</sub> concentration, the  
6 stone's permeability and moisture content, and the deposition rate; however, the extent of the  
7 damage to stones produced by the pollutant species apart from the natural weathering processes  
8 is uncertain. Sulfur dioxide also has been found to limit the life expectancy of paints by causing  
9 discoloration and loss of gloss and thickness of the paint film layer.

10 A significant detrimental effect of particle pollution is the soiling of painted surfaces and  
11 other building materials. Soiling changes the reflectance of a material from opaque and reduces  
12 the transmission of light through transparent materials. Soiling is a degradation process that  
13 requires remediation by cleaning or washing, and, depending on the soiled surface, repainting.  
14 Available data on pollution exposure indicates that particles can result in increased cleaning  
15 frequency of the exposed surface and may reduce the usefulness of the soiled material. Attempts  
16 have been made to quantify the pollutants exposure levels at which materials damage and soiling  
17 have been perceived. However, to date, insufficient data are available to advance our knowledge  
18 regarding perception thresholds with respect to pollutant concentration, particle size, and  
19 chemical composition.

#### 21 **4.6.4 Effects of Atmospheric Particulate Matter on Global Warming** 22 **Processes and Transmission of Solar Ultraviolet Radiation**

23 The physical processes (i.e., scattering and absorption) responsible for airborne particle  
24 effects on transmission of solar visible and ultraviolet radiation are the same as those responsible  
25 for visibility degradation. Scattering of solar radiation back to space and absorption of solar  
26 radiation determine the effects of an aerosol layer on solar radiation.

27 Atmospheric particles greatly complicate projections of future trends in global warming  
28 processes because of emissions of greenhouse gases; consequent increases in global mean  
29 temperature; resulting changes in regional and local weather patterns; and mainly deleterious  
30 (but some beneficial) location-specific human health and environmental effects. The body of  
31 available evidence, ranging from satellite to in situ measurements of aerosol effects on radiation  
32 receipts and cloud properties, is strongly indicative of an important role in climate for aerosols.

1 This role, however, is poorly quantified. No significant advances have been made in reducing  
2 the uncertainties assigned to forcing estimates provided by the IPCC for aerosol-related forcing,  
3 especially for black carbon-containing aerosol. The IPCC characterizes the scientific  
4 understanding of greenhouse gas-related forcing as “high” in contrast to that for aerosol, which it  
5 describes as “low” to “very low.”

6 Quantification of the effect of anthropogenic aerosol on hydrological cycles requires more  
7 information than is presently available regarding ecosystems responses to reduced solar radiation  
8 and other changes occurring in the climate system. However, several global scale studies  
9 indicate that aerosol cooling alone can slow down the hydrological cycle, while cooling plus the  
10 nucleation of additional cloud droplets can dramatically reduce precipitation rates.

11 In addition to direct climate effects through the scattering and absorption of solar radiation,  
12 particles also exert indirect effects on climate by serving as cloud condensation nuclei, thus  
13 affecting the abundance and vertical distribution of clouds. The direct and indirect effects of  
14 particles appear to have significantly offset global warming effects caused by the buildup of  
15 greenhouse gases on a globally-averaged basis. However, because the lifetime of particles is  
16 much shorter than that required for complete mixing within the Northern Hemisphere, the  
17 climate effects of particles generally are felt much less homogeneously than are the effects of  
18 long-lived greenhouse gases.

19 Any effort to model the impacts of local alterations in particle concentrations on projected  
20 global climate change or consequent local and regional weather patterns would be subject to  
21 considerable uncertainty.

22 Atmospheric particles also complicate estimation of potential future impacts on human  
23 health and the environment projected as possible to occur because of increased transmission of  
24 solar ultraviolet radiation (UV-B) through the Earth’s atmosphere, secondary to stratospheric  
25 ozone depletion due to anthropogenic emissions of chlorofluorocarbons (CFCs), halons, and  
26 certain other gases. The transmission of solar UV-B radiation is affected strongly by  
27 atmospheric particles. Measured attenuations of UV-B under hazy conditions range up to 37%  
28 of the incoming solar radiation. Measurements relating variations in PM mass directly to UV-B  
29 transmission are lacking. Particles also can affect the rates of photochemical reactions occurring  
30 in the atmosphere, e.g., those involved in catalyzing tropospheric ozone formation. Depending  
31 on the amount of absorbing substances in the particles, photolysis rates either can be increased or

1 decreased. Thus, atmospheric particle effects on UV-B radiation, which vary depending on size  
2 and composition of particles, can differ substantially over different geographic areas and from  
3 season to season over the same area. Any projection of effects of location-specific airborne PM  
4 alterations on increased atmospheric transmission of solar UV radiation (and associated potential  
5 human health or environmental effects) due to stratospheric ozone-depletion would, therefore,  
6 also be subject to considerable uncertainty.

## Appendix 4A

### Colloquial and Latin Names

Alder, hazel	<i>Alnus serrulata</i> (Aiton) Willdenow
Alder, red	<i>Alnus rubra</i> Bong.
Bean, common	<i>Phaseolus vulgaris</i> L.
Beech	<i>Fagus sylvatica</i> L.
Birch, yellow	<i>Betula alleghaniensis</i> Britt.
Blackhaw	<i>Viburnum prunifolium</i> L.
Brush box	<i>Lophostemon confertus</i> (R. BR.) P.G. Wilson & Waterhouse
Ceanothus, hoaryleaf	<i>Ceanothus crassifolius</i> Torrey
Chaparral	<i>Ceanothus crassifolius</i>
Coachwood	<i>Ceratopetalum apetalum</i> , D. Don
Corn	<i>Zea mays</i> L.
Dogwood, flowering	<i>Cornus florida</i> L.
Elm	<i>Ulmus</i> spp.
Fir, balsam	<i>Abies balsamea</i> (L.) Mill.
Fir, Douglas	<i>Pseudotsuga menziesii</i> (Mirb.) Franco.
Fir, fraser	<i>Abies fraseri</i> (Pursh.) Poir
Grape	<i>Vitis</i> spp.
Grass, red brome	<i>Bromus rubens</i> L.
Grass, purple moor	<i>Molina caerulea</i> (L.) Moench.
Greenbriar	<i>Smilax</i> spp.
Gum, sweet	<i>Liquidambar styraciflua</i> L.
Haw, black	<i>Viburnum prunifolium</i> L.
Heather, Scottish	<i>Calluna vulgaris</i> Salisb.

Hickory	<i>Carya</i> spp.
Hophornbeam	<i>Ostrya virginiana</i> (Mill.) Koch
Ivy, English	<i>Hedera helix</i> L.
Laurel, mountain	<i>Kalmia latifolia</i> L.
Lichen, monks hood	<i>Hypogymnia physiodes</i>
Maize	<i>Zea mays</i> L.
Maple, red	<i>Acer rubrum</i> L.
Maple	<i>Acer</i> spp.
Maple, sugar	<i>Acer saccharum</i> Marsh.
Mustard, small podded	<i>Brassica geniculata</i> L.
Nettle, stinging	<i>Urtica dioica</i> L.
Oak, bur	<i>Quercus macrocarpa</i> Michx.
Oak, English	<i>Quercus rober</i> L.
Oak, chestnut	<i>Quercus prinus</i> = <i>Q. montana</i> Willd.
Oak, live	<i>Quercus virginiana</i> Mill.
Oak, northern red	<i>Quercus rubra</i> L.
Oak, turkey	<i>Quercus laevis</i> Walt.
Oak, white	<i>Quercus alba</i> L.
Oak	<i>Quercus</i> spp.
Oats, domestic	<i>Avena sativa</i> L.
Oats, wild	<i>Avena fatua</i> L.
Persimmon, common	<i>Diosporos virginiana</i> L.
Pine, eastern white	<i>Pinus strobus</i> L.
Pine, jack pine	<i>Pinus banksiana</i> Lamb.
Pine, loblolly	<i>Pinus taeda</i> L.
Pine, lodgepole	<i>Pinus contorta</i> Loud.
Pine, Scots (Scotch)	<i>Pinus sylvestris</i> L.
Pine, slash	<i>Pinus elliotti</i> Englem.

Pine, lodgepole x jack pine	<i>Pinus contorta</i> (Douglas ex Loud) x <i>P. banksiana</i> Lamb.
Poplar, black	<i>Populus nigra</i> L.
Poplar, white	<i>Populus alba</i> L.
Poplar, yellow or tulip	<i>Liriodendron tulipifera</i> L.
Privet	<i>Ligustrum</i> spp.
Purple Moor Grass	<i>Molina caerulea</i> (L.) Moench.
Ragweed	<i>Ambrosia</i> spp.
Rhododendron, Catawba	<i>Rhododendron catawbiense</i> Michx.
Rhododendron, rosebay	<i>Rhododendron maximum</i> L.
Sage, coastal	<i>Artemisia californica</i> Less.
Scottish Heather	<i>Calluna vulgaris</i> Salisb.
Soybean	<i>Glycine max</i> (L.) Merr.
Spruce, Norway	<i>Picea abies</i> (L.) Karst.
Spruce, red	<i>Picea rubens</i> Sarg.
Spruce, sitka	<i>Picea sitchensis</i> (Bong.) Carr.
Spruce, white	<i>Picea glauca</i> (Moench.) Voss.
Sunflower	<i>Helianthus annuus</i> L.
Sweetgum	<i>Liquidambar styraciflua</i> L.
Tulip poplar	<i>Liriodendron tulipifera</i> L.

# 5. HUMAN EXPOSURE TO PARTICULATE MATTER AND ITS CONSTITUENTS

## 5.1 INTRODUCTION

### 5.1.1 Purpose

The U.S. Environmental Protection Agency's (EPA's) regulatory authority for PM applies primarily to ambient air and those sources that contribute to ambient air PM concentrations. Most of the epidemiological studies, discussed in Chapter 8, relate measured community levels of airborne pollutants to population-based health statistics. Of necessity, these studies have to rely on some simplifying assumptions regarding exposures, usually that air pollutant concentrations measured at community (or population-oriented) monitoring sites (or the average concentration of several such sites) can serve as surrogate indices for the average personal exposure to ambient PM for the population. However, total personal exposure to PM includes both ambient and nonambient components, and both components may contribute to adverse health effects. Thus, a major emphasis must be to develop an understanding of exposure to PM from sources that contribute to ambient air pollution. Ultimately, it will be necessary to account for both ambient and nonambient components of personal exposure in order to fully understand the relationship between PM and health effects. In addition, an individual's personal exposure to ambient, nonambient, and total PM would provide useful information for studies where health outcomes are tracked individually.

Exposure has many definitions. However, for airborne particulate matter (PM), an individual's exposure is ideally based on measurements of the PM concentrations in the air in the individual's breathing zone as the individual moves through space and time. However, epidemiological studies frequently use the ambient concentration as a surrogate for exposure. Therefore, understanding exposure is important because it is the individual who experiences adverse health effects associated with elevated PM concentrations. Human exposure data and models provide the link between ambient concentrations (from monitoring data or estimated with atmospheric transport models) and lung deposition and clearance models to enable estimates of the source-air concentration-exposure-dose relationship for input into dose-response

1 assessments for PM from ambient sources. Personal exposure includes contributions from many  
2 different types of particles, from many sources, and in many different environments.

3 The goal of this chapter is to provide current information on the development of human  
4 exposure data and models. This includes information on (a) relationships between PM measured  
5 at ambient sites and personal exposures to PM from both ambient and nonambient sources, and  
6 (b) factors that affect these relationships. Human exposure data and models presented in this  
7 chapter provide critical links between ambient monitoring data and PM dosimetry and between  
8 toxicological studies and epidemiologic studies which are presented in other chapters. Specific  
9 objectives of this chapter are fourfold:

- 10 (1) To provide an overall conceptual framework of exposure science as applied to PM,  
including the identification and evaluation of factors that determine personal PM  
exposure;
- 11 (2) To provide a concise summary and review of recent data (since 1996) and findings from  
pertinent PM exposure studies;
- 12 (3) To characterize quantitative relationships between ambient air quality measurements  
(mass, chemical components, number, etc.) as determined by a community monitoring  
site and total personal PM exposure as well as its ambient and nonambient components;  
and
- 13 (4) To evaluate the implications of using ambient PM concentrations as a surrogate for  
personal exposure in epidemiologic studies of PM health effects.

### 14 15 **5.1.2 Particulate Matter Mass and Constituents**

16 Current EPA PM regulations are based on mass as a function of aerodynamic size.  
17 However, EPA also measures the chemical composition of PM in both monitoring and research  
18 studies. The composition of PM is variable and, as discussed in Chapters 7 and 8, health effects  
19 may be related to PM characteristics other than mass. Since PM from ambient air and other  
20 microenvironments may have different physical and chemical characteristics, PM from such  
21 different sources may also have different health effects. Ultimately, to understand and control  
22 health effects caused by PM exposures from all sources, it is important to quantify and  
23 understand exposure to those chemical constituents from various sources that are responsible for  
24 adverse health effects.

1           The National Research Council (NRC) recognized the distinction between measuring  
2 exposure to PM mass and to chemical constituents when setting *Research Priorities for Airborne*  
3 *Particulate Matter I: Immediate Priorities and a Long-range Research Portfolio* (NRC, 1998).  
4 Specifically, in Research Topic 1, Outdoor Measures versus Actual Human Exposures, NRC  
5 recommends evaluating “the relationships between concentrations of particulate matter and  
6 gaseous co-pollutants measured at stationary outdoor air monitoring sites and the contributions  
7 of these concentrations to actual personal exposures . . .” for PM mass. The NRC Research  
8 Topic 2 recommends evaluating exposures to biologically important constituents and specific  
9 characteristics of PM that cause responses in potentially susceptible subpopulations and the  
10 general population. It also was recognized by the NRC that “a more targeted set of studies under  
11 this research topic (#2) should await a better understanding of the physical, chemical, and  
12 biological properties of airborne particles associated with the reported mortality and morbidity  
13 outcomes” (NRC, 1999). The NRC also stated that the later studies “should be designed to  
14 determine the extent to which members of the population contact these biologically important  
15 constituents and size fractions of concern in outdoor air, outdoor air that has penetrated indoors,  
16 and air pollutants generated indoors” (NRC, 1999). Thus, exposure studies should include  
17 contributions from all sources. The emphasis in this chapter on PM mass reflects the current  
18 state of the science. Where available, data also have been provided on chemical constituents  
19 although in most cases the data are limited. As recognized by the NRC, a better understanding  
20 of exposures to PM chemical constituents from multiple sources will be required to more fully  
21 identify, understand, and control those sources of PM contributing to adverse health effects and  
22 to accurately define the relationship between PM exposure and health outcomes due to either  
23 short-term or chronic exposures.

### 24 25 **5.1.3 Relationship to Past Documents**

26           Early versions of PM criteria documents did not emphasize total human exposure, but  
27 rather focused almost exclusively on outdoor air concentrations. For instance, the 1969 Air  
28 Quality Criteria for Particulate Matter (National Air Pollution Control Administration, 1969) did  
29 not discuss either *exposure* or *indoor concentrations*. The 1982 EPA PM Air Quality Criteria  
30 Document (1982 PM AQCD), however, provided some discussion of indoor PM concentrations  
31 reflecting an increase in microenvironmental and personal exposure studies (U.S. Environmental

1 Protection Agency, 1982). The new data indicated that personal activities along with PM  
2 generated by personal and indoor sources (e.g., cigarette smoking) could lead to high indoor  
3 levels and high personal exposures to total PM. Some studies reported indoor concentrations  
4 that exceeded PM concentrations found in the air outside the monitored microenvironments or at  
5 nearby monitoring sites. Between 1982 and 1996, many more studies of personal and indoor PM  
6 exposure demonstrated that in most inhabited domestic environments indoor PM mass  
7 concentrations and personal PM exposures of the residents were greater than ambient PM mass  
8 concentrations measured simultaneously (e.g., Sexton et al., 1984; Spengler et al., 1985; Clayton  
9 et al., 1993). As a result, the NRC (1991) recognized the potential importance of indoor sources  
10 of contaminants (including PM) in causing adverse health outcomes.

11 The 1996 AQCD (U.S. Environmental Protection Agency, 1996) reviewed the human PM  
12 exposure literature through early 1996 mainly to evaluate the use of ambient air monitors as  
13 surrogates for PM exposure in epidemiological studies. Many of the studies cited showed poor  
14 correlations between personal exposure or indoor measurements of PM mass and outdoor or  
15 ambient site measurements. Conversely, Janssen et al. (1995) and Tamura et al. (1996a) showed  
16 that in the absence of major nonambient sources, total PM exposures to individuals tracked  
17 through time were highly correlated with ambient PM concentrations. Analyses of these latter  
18 two studies led to consideration of ambient and nonambient exposures as separate components of  
19 total personal exposure. As a result, the 1996 PM AQCD (U.S. Environmental Protection  
20 Agency, 1996) distinguished between ambient and nonambient PM personal exposure for the  
21 first time. This chapter builds on the work of the 1996 PM AQCD by further evaluating the  
22 ambient and nonambient components of PM and by reporting research that evaluates the  
23 relationship between ambient concentrations and total, ambient, and nonambient personal  
24 exposure.

#### 25 26 **5.1.4 Chapter Structure**

27 The chapter is organized to provide information on the principles of exposure, review the  
28 existing literature, and summarize key findings and limitations in the information; the specific  
29 sections are described below.

- 30 • Section 5.2 discusses the basic concepts of exposure including definitions, methods for  
estimating exposure, and methods for estimating ambient air components of exposure.

- 1 • Section 5.3 presents PM mass data including a description of the key available studies, the relationship of PM exposures with ambient concentrations, and factors that affect the relationship.
- 2 • Section 5.4 presents data on PM constituents including a description of the key available studies, the relationship with ambient concentrations, and factors that affect the relationship.
- 3 • Section 5.5 discusses the implications of using ambient PM concentrations in epidemiologic studies of PM health effects.
- 4 • Section 5.6 summarizes key findings and limitations of the information.

## 5.2 BASIC CONCEPTS OF EXPOSURE

### 5.2.1 The Concept of Exposure

9 “There is reasonable agreement that human exposure [to a substance] means contact with  
10 the chemical or agent.” However, contact can be either with “(a) the visible exterior of the  
11 person (skin and openings into the body such as mouth and nostrils), or (b) the so-called  
12 exchange boundaries where absorption takes place (skin, lung, gastrointestinal tract)” (Federal  
13 Register, 1986). In its 1992 Guidelines for Exposure Assessment (U.S. EPA, 1992), EPA  
14 defined exposure as “taking place at the visible external boundary, as in (a) above, [concluding  
15 that this definition] is less ambiguous and more consistent with nomenclature in other scientific  
16 fields.” This was a change from the 1986 Guidelines (Federal Register, 1986).

17  
18 Under this definition, it is helpful to think of the human body as having a hypothetical outer  
19 boundary separating inside the body from outside the body. This outer boundary of the body  
20 is the skin and the openings into the body such as the mouth, the nostrils, and punctures and  
21 lesions in the skin. As used in these Guidelines, exposure to a chemical is the contact of that  
22 chemical with the outer boundary. An exposure assessment is the quantitative or qualitative  
23 evaluation of that contact; it describes the intensity, frequency, and duration of contact, and  
24 often evaluates the rates at which the chemical crosses the boundary (chemical intake or  
25 uptake rates), the route by which it crosses the boundary (exposure route; e.g., dermal, oral,  
26 or respiratory), and the resulting amount of the chemical that actually crosses the boundary  
27 (a dose) and the amount absorbed (internal dose) (U.S. EPA, 1992).

1           When applied to PM exposure by the inhalation route, the concentration of interest is that  
2 of PM in the air which enters the respiratory system, not the average concentration of inspired  
3 and exhaled air which exists at the mouth or nostrils. Therefore, a measurement of inhalation  
4 exposure to PM is based on measurements of the PM concentration near the breathing zone but  
5 not affected by exhaled air.  
6

## 7 **5.2.2 Components of Exposure**

8           The total exposure of an individual over a discrete period of time includes exposures to  
9 many different particles from various sources while in different microenvironments. Duan  
10 (1982) defined a microenvironment as “a [portion] of air space with homogeneous pollutant  
11 concentration.” It also has been defined as a volume in space for a specific time interval during  
12 which the variance of concentration within the volume is significantly less than the variance  
13 between that microenvironment and surrounding ones (Mage, 1985). In general, people pass  
14 through a series of microenvironments including outdoor, in-vehicle, and indoor  
15 microenvironments as they go through time and space. Thus, total *daily* exposure for a single  
16 individual to PM must be expressed as the sum of various exposures for the microenvironments  
17 that the person occupies in the day (modified from National Research Council, 1991).

18           In a given microenvironment, particles may originate from a wide variety of sources.  
19 For example, in an indoor microenvironment PM may be generated by (1) indoor activities,  
20 (2) outdoor PM entering indoors, (3) the chemical interaction of outdoor air pollutants and  
21 indoor air or indoor sources, (4) transport from another indoor microenvironment, or (5) personal  
22 activities. All of these disparate sources have to be accounted for when estimating total human  
23 exposure to PM.

24           An analysis of personal exposure to PM mass (or constituent compounds) requires  
25 definition and discussion of several classes of particles and exposure. In this chapter, PM  
26 metrics may be described in terms of exposure or as an air concentration. PM also may be  
27 described according to both its source (i.e., ambient, nonambient) and the microenvironment  
28 where exposure occurs. Table 5-1 provides a summary of the terms used in this chapter, the  
29 notation used for these terms, and their definition. These terms are used throughout this chapter  
30 and provide the terminology for evaluating personal exposure to total PM and to PM from  
31 ambient and nonambient sources.

**TABLE 5-1. TYPES OF PARTICULATE MATTER USED IN EXPOSURE AND CONCENTRATION VARIABLES**

Term	Notation	Definition
<b><i>General Definitions</i></b>		
Concentration	C	General term for the average air concentration over some specified time period, used with subscript to indicate concentration of a specific type of PM, usually expressed in $\mu\text{g}/\text{m}^3$ units.
Personal Exposure	E	General term for the average personal exposure over some specified time period, used with subscript to indicate exposure to a specific type of PM, quantified as the concentration at the oral/nasal contact boundary.
<b><i>Types of Particulate Matter</i></b>		
Term	Subscript	Definition
Ambient PM	a	PM in the atmosphere measured at a community ambient monitoring site either emitted into the atmosphere directly (primary PM) or formed in it (secondary PM). Major sources of PM species are industry, motor vehicles, commerce, domestic emissions such as wood smoke, and natural wind-blown dust or soil. (C without subscript is used for $C_a$ . $E_a$ is used for exposure to ambient PM while outdoors.)
Ambient-Outdoor PM	o	Ambient PM in an outdoor microenvironment. ( $C_o$ is frequently considered to be equal to, or at least represented by, C.)
Indoor PM	i	All PM found indoors.
Ambient-Indoor PM	ai	Ambient PM that has infiltrated indoors (i.e., has penetrated indoors and remains suspended). $E_{ai}$ is used for ambient exposure while indoors.
Indoor-generated PM	ig	PM generated indoors.
Indoor-reaction PM	ir	PM formed indoors by pollutants from outdoors reacting with indoor-generated pollutants.
Personal Cloud PM	pc	PM contributing to personal exposure but not contained in indoor or outdoor measurements of PM, usually related to personal activities.
Personal PM (of a subject)	s	PM at the oral/nasal contact zone as the subject moves through time and space.
<b><i>Concentration and Exposure Variable Used without Subscripts</i></b>		
Term	Notation	Definition
Ambient Concentration	C	Concentration measured at a community ambient air monitoring site (or the average of several such sites).
Total Personal Exposure	T	Total personal exposure as measured by a personal exposure monitor (PEM).
Ambient Exposure	A	Personal exposure to the ambient component of total personal exposure, i.e., personal exposure to that PM measured at an ambient air community monitoring site. Includes exposure to C and $C_{ai}$ but not to resuspended ambient PM previously deposited indoors.
Nonambient Exposure	N	Personal exposure to nonambient PM.

**TABLE 5-1 (cont'd). TYPES OF PARTICULATE MATTER USED IN EXPOSURE AND CONCENTRATION VARIABLES**

---

---

*Relationships among Concentration and Exposure Variables for a Two-Compartment Model (indoors and outdoors)*

---

$$T = A + N$$

$$A = E_a + E_{ai}$$

A = yC + (y-1) C<sub>ai</sub>, where y = fraction of time outside

$$N = E_{ig} + E_{ir} + E_{pc}$$

---

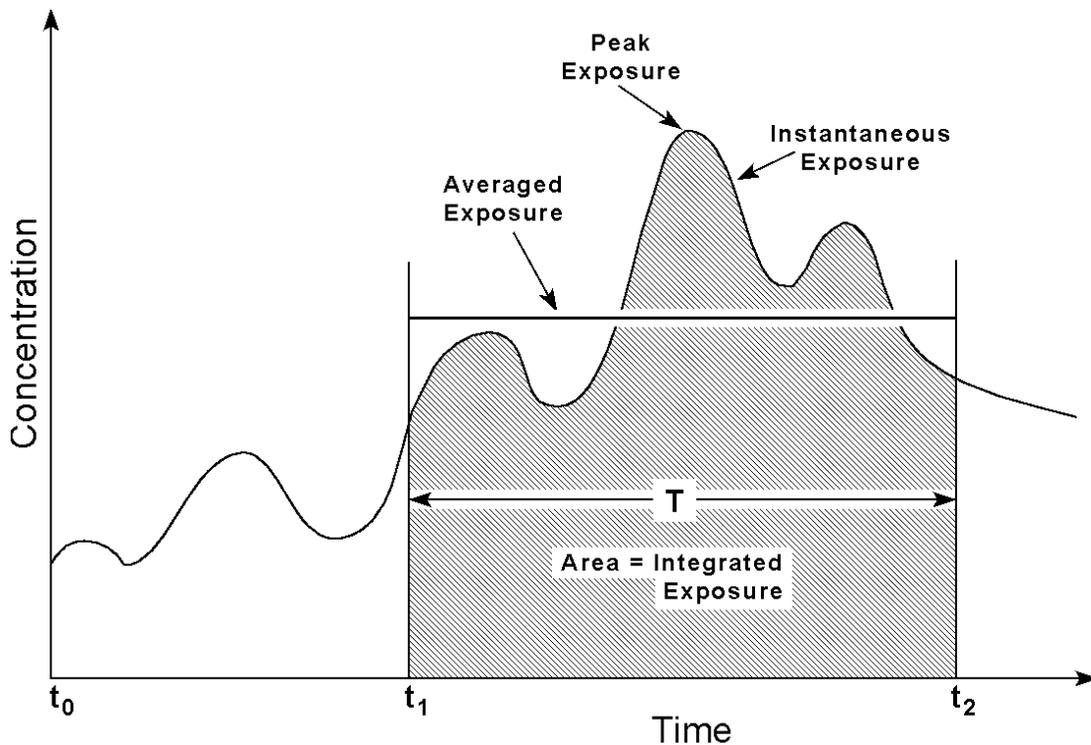

---

1           Exposures are significant only if they are associated with a biologically relevant duration  
2 of contact with a substance of concern. Application of this concept to PM exposure is  
3 complicated by a lack of understanding of the biological mechanisms of PM toxicity. It is not  
4 certain whether the relevant duration is the instantaneous exposure to a peak concentration, or  
5 hourly, daily, or long-term exposure for months or years (or possibly all of the above).  
6 Similarly, it is not certain how PM toxicity depends on particle size or particle composition;  
7 whether number, surface area, or mass is the appropriate metric; or how PM toxicity may be  
8 influenced by conditions that might increase susceptibility (age, pre-existing disease conditions  
9 [COPD, asthma, diabetes, etc.], exposure to infectious agents, exposure to heat or cold, stress,  
10 etc.). It should be clear that a person's exposure is influenced by the distribution of many  
11 variables and parameters. A measurement at a single point in space or time along each  
12 distribution cannot easily describe a person's exposure. Thus, it is important to think of  
13 exposure as a path function, the instantaneous exposure varying as the PM concentration and  
14 composition varies as the person moves through time and space.

15           The 1997 NAAQS were developed largely on the basis of evidence from epidemiologic  
16 studies that found relatively consistent associations between outdoor PM mass concentrations  
17 and observed health effects. Thus, an emphasis in this chapter is on the relationship between the  
18 PM concentrations measured at ambient sites and personal exposures to the PM measured at  
19 those ambient sites (NRC, 1998), i.e., ambient PM exposure. Although this is an emphasis,  
20 it should be kept in mind that every particle that deposits in the lung becomes part of a dose  
21 delivered to the individual. It is likely that the nonambient component of total exposure also has  
22 health effects which would not necessarily be detected using community time-series  
23 epidemiological studies.

### 5.2.3 Quantification of Exposure

Quantification of inhalation exposure to PM or any other air pollutant starts with the concept of the variation in the concentration of the air pollutant in the breathing zone (but unperturbed by exhaled breath) as measured by a personal exposure monitor as a person moves through time and space. The relationships among the various types of exposure quantities can easily be seen in the hypothetical exposure time profile shown in Figure 5-1. The peak exposure, instantaneous exposure, and average exposure have units of concentration, for PM, usually  $\mu\text{g}/\text{m}^3$ . The integrated exposure has units of concentration  $\times$  time.

**Figure 5-1. Hypothetical exposure time profile: Pollutant exposure as a function of time showing how the averaged exposure, integrated exposure, and peak exposure relate to the instantaneous exposure. ( $t_2 - t_1 = T$ )**

Source: Adapted from Duan et al. (1989); Zartarian et al. (1997).

1 The integrated exposure may be written as

$$\mathcal{E}(t_1, t_2) = \int_{t=t_1}^{t=t_2} C_s(t) dt, \quad (5-1)$$

2

3 where  $\mathcal{E}$  is the integrated personal exposure during the time period  $t_1$  to  $t_2$  and  $C_s$  is the  
4 instantaneous exposure of the subject as the subject moves through space and time (Lioy, 1990;  
5 NRC, 1991; Georgopoulos and Lioy, 1994).  $C_s$  is a function of both time and space so in general  
6 it cannot be correctly approximated by a measurement at a single time or at a single point in  
7 space.

8 For most of the discussion in this chapter we will be interested in the average exposure  
9 given as

$$E(t_1, t_2) = \frac{1}{t_2 - t_1} \int_{t=t_1}^{t=t_2} C_s(t) dt, \quad (5-2)$$

10 where  $E$  is the average exposure over the time period  $t_2-t_1$ . Most studies report 24-hour averages  
11 although some studies measure 12-hour or 2 or 3 day averages.

12 Equations 5-1 and 5-2 apply to a specific individual moving through time and space on a  
13 specific path. When treating populations it is necessary to consider the distribution of values of  
14 the variables and parameters. Georgopoulos and Lioy (1994) show how these equations can be  
15 modified to consider the probability distributions.

16

#### 17 **5.2.4 Methods To Estimate Personal Exposure**

18 Personal exposure may be estimated using either direct or indirect approaches. *Direct*  
19 *approaches* measure the contact of the person with the chemical concentration in the exposure  
20 media over an identified period of time. Direct measurement methods include personal exposure  
21 monitors (PEMs) for PM that are worn continuously by individuals as they encounter various  
22 microenvironments while performing their daily activities. *Indirect approaches* use models and  
23 available information on concentrations of chemicals in microenvironments, the time individuals  
24 spend in those microenvironments, and personal PM generating activities to estimate personal

1 exposure. This section describes the methods to directly measure personal exposures and  
2 microenvironmental concentrations as well as the models used to estimate exposure. Several  
3 approaches to estimate personal exposure to ambient PM also are described.

#### 4 5 **5.2.4.1 Direct Measurement Methods**

##### 6 ***5.2.4.1.1 Personal Exposure Monitoring Methods***

7 In theory, personal exposure to total PM is measured by sampling the concentration of PM  
8 in inhaled air entering the nose or mouth. Practically, it is defined as that PM collected by a  
9 PEM worn by a person and sampling from a point near the breathing zone (but not affected by  
10 exhaled breath). PEMs for PM use measurement techniques similar to those used for ambient  
11 PM. Most PEMs rely on filter-based mass measurement of a particle size fraction (PM<sub>10</sub> or  
12 PM<sub>2.5</sub>) usually integrated over either a 24- or 12-h period at flow rates of 2 to 4 L/min using  
13 battery-operated pumps. PEMs must be worn by study participants; therefore, they must be  
14 quiet, compact, and battery-operated. These requirements limit the type of pumps and the total  
15 sample volume that can be collected. Generally, small sample volumes limit personal exposure  
16 measurements to PM mass and a few elements detected by XRF. In most studies, PM<sub>2.5</sub> and  
17 PM<sub>10</sub> have not been collected concurrently; thus, there are very few data available with which to  
18 estimate personal exposure to coarse thoracic PM (i.e., PM<sub>10-2.5</sub>) exposures.

19 Other methods used for ambient PM also have been adapted for use as a PEM.  
20 For example, a personal nephelometer that measures light scattering has been worn by subjects  
21 and used in personal exposure studies to obtain real-time measurements of PM (Quintana et al.,  
22 2000; Rea et al., 2001; Magari et al., 2002; Lanki et al., 2002). Light scattering instruments are  
23 most sensitive to particles in the accumulation mode size range. A portable condensation nuclei  
24 counter (with a lower size limit of 20 nm diameter) has also been used in exposure studies  
25 (Abraham et al., 2002).

##### 26 27 ***5.2.4.1.2 Microenvironmental Monitoring Methods***

28 Direct measurements of microenvironmental PM concentrations which are used with  
29 models to estimate personal exposure to PM also use methods similar to those for ambient PM.  
30 These methods differ from PEMs in that they are stationary with respect to the  
31 microenvironment (such as a stationary PEM). Microenvironmental monitoring methods include

1 filter-based mass measurements of particle size fractions ( $PM_{10}$ ,  $PM_{2.5}$ ) usually integrated over  
2 either a 24- or 12-h period. Flow rates vary between various devices from 4 to 20 L/min. Larger  
3 sample volumes allow more extensive chemical characterization to be conducted on  
4 microenvironmental samples. Because more than one pumping system can be used in a  
5 microenvironment,  $PM_{2.5}$  and  $PM_{10}$  can be collected simultaneously. Other continuous ambient  
6 PM measurement methods that have been utilized for microenvironmental monitoring are the  
7 Tapered Element Oscillating Microbalance (TEOM) and nephelometers. Various continuous  
8 techniques for counting particles by size (Climet, LASX, SMPS, APS) also have also been used.  
9 Measurement techniques are discussed in Chapter 2.

## 11 **5.2.4.2 Indirect or Modeling Methods**

### 12 **5.2.4.2.1 Personal Exposure Models**

13 Exposure modeling for PM mass ( $PM_{2.5}$  and  $PM_{10-2.5}$ ) and chemical constituents is a  
14 relatively new field facing significant methodological challenges and input data limitations.  
15 Exposure models typically use one of two general approaches: (1) a time-series approach that  
16 estimates microenvironmental exposures sequentially as individuals go through time or  
17 (2) a time-averaged approach that estimates microenvironmental exposures using average  
18 microenvironmental concentrations and the total time spent in each microenvironment.  
19 Although the time-series approach to modeling personal exposures provides the appropriate  
20 structure for accurately estimating personal exposures (Esmen and Hall, 2000; Mihlan et al.,  
21 2000), a time-averaged approach typically is used when the input data needed to support a time-  
22 series model are not available. However, the time-varying dose profile of an exposed individual  
23 can be modeled only by using the time-series approach (McCurdy, 1997, 2000).

24 Even though the processes that lead to exposure are nonlinear in nature, personal exposure  
25 models are often used to combine microenvironmental concentration data with human activity  
26 pattern data in order to estimate personal exposures. Time-averaged models can be used to  
27 estimate personal exposure for an individual or for a defined population. Total personal  
28 exposure models estimate exposures for all of the different microenvironments in which a person  
29 spends time, and total average personal exposure is calculated from the sum of these  
30 microenvironmental exposures:

$$E = \sum_j E_j = \frac{1}{T} \left( \sum_j C_j t_j \right), \quad (5-3)$$

1  
2 where  $E_j$  is the personal exposure in each microenvironment,  $j$  (Duan, 1982). Example  
3 microenvironments include outdoors, indoors at home, indoors at work, and in transit. Each  
4 microenvironmental exposure,  $E_j$ , is calculated from the average concentration in  
5 microenvironment  $j$ ,  $C_j$ , weighted by the time spent in microenvironment  $k$ ,  $t_j$ .  $T$  is the sum of  $t_j$   
6 over all  $j$ . This model has been applied to concentration data in a number of studies (Ott, 1984;  
7 Ott et al., 1988, 1992; Miller et al., 1998; Klepeis et al., 1994; Lachenmyer and Hidy, 2000).

8 Many exposure studies use 24-hour average measurements of concentration indoors and  
9 outdoors and use these concentrations with the time spent indoors and outdoors in Equation 5-3.  
10 It is important to note that although measurement data may be an average concentration over  
11 some time period (i.e., 24 h), significant variations in PM concentrations can occur during that  
12 time period. Thus, an error may be introduced if real-time concentrations are highly variable and  
13 an average concentration for a microenvironment is used to estimate exposure when the  
14 individual is in that microenvironment for only a fraction of the total time. This may create large  
15 errors if the indoor 24-hour average, e.g., in a house, includes significant time periods when  
16 there are no people in the house because the indoor concentrations are increased by the activities  
17 of people. In an effort to overcome these errors, the EXPOLIS study (Kousa et al., 2002) turned  
18 outdoor samplers off when the subject was indoors and the indoor sampler off with the subject  
19 was outdoors. This provides a better estimate of  $E_a$  and  $E_i$  to compare with the PEM  
20 measurement and allows a better calculation of  $E_{pc}$ . However, it does not provide data that can  
21 be used to regress  $C$  or  $C_o$  with  $C_i$ .

22 Microenvironmental concentrations used in the exposure models can be measured directly  
23 or estimated from one or more microenvironmental models. Microenvironmental models vary in  
24 complexity from a simple indoor/outdoor ratio to a multi-compartmental mass-balance model.  
25 A discussion of microenvironmental models is presented in Section 5.3.4.2.2.

26 On the individual level, the time spent in the various microenvironments is obtained from  
27 time/activity diaries that are completed by the individual. For population-based estimates, the  
28 time spent in various microenvironments is obtained from human activity databases. Many of

1 the largest human activity databases have been consolidated by EPA's National Exposure  
2 Research Laboratory (NERL) into one comprehensive database called the Consolidated Human  
3 Activity Database (CHAD). CHAD contains over 22,000 person-days of 24-h activity data from  
4 11 different human activity-pattern studies (McCurdy et al., 2000). Population cohorts with  
5 diverse characteristics can be constructed from the activity data in CHAD and used for exposure  
6 analysis and modeling (McCurdy, 2000). These databases can also be used to estimate  
7 inhalation rates based on activity levels, age, gender, and weight for dosimetry calculations.  
8 A human activity data base may contain information on location, activity, and other information  
9 such as presence of combustion sources (e.g., wood fireplaces, smokers) and the relative exertion  
10 rates. However, in exposure studies "activity" frequently refers to a person's location in space,  
11 i.e., in what microenvironment at what times. In dosimetry, "activity" is used as an indication of  
12 the level of physical exertion and is used to estimate breathing rate and extent of mouth, nose, or  
13 combined breathing. Table 5-2 is a summary of the human activity studies in CHAD.

14 Methodologically, personal exposure models can be divided into three general types:  
15 (1) statistical models based on empirical data obtained from one or more personal monitoring  
16 studies, (2) simulation models based upon known or assumed physical relationships, and  
17 (3) physical-stochastic models that include Monte Carlo or other techniques to explicitly address  
18 variability and uncertainty in model structure and input data (Ryan, 1991; MacIntosh et al.,  
19 1995). The attributes, strengths, and weaknesses of these model types are discussed by Ryan  
20 (1991), National Research Council (1991), Frey and Rhodes (1996), and Ramachandran and  
21 Vincent (1999). A review of the logic of exposure modeling is found in Klepeis (1999).

22 Personal exposure models that have been developed for PM are summarized in Table 5-3.  
23 The regression-based models (Johnson et al., 2000; Janssen et al., 1997; Janssen et al., 1998a)  
24 were developed for a specific purpose (i.e., to account for the observed difference between  
25 personal exposure and microenvironmental measurements) and are based on data from a single  
26 study, which limits their utility for broader purposes. Other types of models in Table 5-3 were  
27 limited by a lack of data for the various model inputs. For example, ambient PM monitoring  
28 data is not generally of adequate spatial and temporal resolution for these models. Lurmann and  
29 Korc (1994) assumed a constant relationship between coefficient of haze (COH) and  $PM_{10}$  and  
30 used site-specific COH information to stochastically develop a time series of 1-h  $PM_{10}$  data from  
31 every sixth day 24-h  $PM_{10}$  measurements. A mass-balance model typically was used for indoor

**TABLE 5-2. ACTIVITY PATTERN STUDIES INCLUDED IN THE CONSOLIDATED HUMAN ACTIVITY DATABASE (CHAD)**

Study Name	Calendar Time Period of the Study	Age <sup>1</sup>	Days <sup>2</sup>	Diary		Rate <sup>5</sup>	Documentation or Reference	Notes
				Type <sup>3</sup>	Time <sup>4</sup>			
Baltimore	Jan-Feb 1997 Jul-Aug 1998	65+	391	Diary; 15-min blocks	24h Standard	No	Williams et al. (2000a,b)	Multiple days, varying from 5-15; part of a PM <sub>2.5</sub> PEM study

Cincinnati (EPRI)	Mar-Apr and Aug 1985	0-86	2,614	Diary	24h; nominal 7 pm-7 am	Yes	Johnson (1989)	3 consecutive days; 186 P-D removed <sup>7</sup>
Denver (EPA)	Nov 1982-Feb 1983	18-70	805	Diary	24h; nominal 7 pm-7 am	No	Akland et al. (1985) Johnson (1984)	Part of CO PEM <sup>6</sup> study; 2 consec. days; 55 P-D removed <sup>7</sup>
Los Angeles: Elem. School Children	Oct 1989	10-12	51	Diary	24h Standard	Yes	Spier et al. (1992)	7 P-D removed <sup>7</sup>
Los Angeles: High School Adoles.	Sept-Oct 1990	13-17	43	Diary	24h Standard	Yes	Spier et al. (1992)	23 P-D removed <sup>7</sup>
National: NHAPS-A <sup>8</sup>	Sept 1992-Oct 1994	0-93	4,723	Retrospective	24h Standard	No <sup>9</sup>	Klepeis et al. (1995) Tsang and Klepeis (1996)	A national random-probability survey
National: NHAPS-B <sup>8</sup>	As above	0-93	4,663	Retrospective	24h Standard	No <sup>9</sup>	As above	As above
University of Michigan: Children	Feb-Dec1997	0-13	5,616	Retrospective	24h Standard	No	Institute for Social Research (1997)	2 days of data: one is a weekend day
Valdez, AK	Nov 1990-Oct 1991	11-71	401	Retrospective	Varying 24-h period	No	Goldstein et al. (1992)	4 P-D removed <sup>7</sup>
Washington, DC (EPA)	Nov 1982-Feb 1983	18-98	699	Diary	24h; nominal 7 pm-7 am	No	Akland et al. (1985) Hartwell et al. (1984)	Part of a CO PEM <sup>6</sup> study; 6 P-D removed <sup>7</sup>

<sup>1</sup> All studies included both genders. The age range depicted is for the subjects actually included; in most cases, there was not an upper limit for the adult studies. Ages are inclusive. Age 0 = babies < 1 year old.

<sup>2</sup> The actual number of person-days of data in CHAD after the "flagging" and removal of questionable data. See the text for a discussion of these procedures.

<sup>3</sup> Retrospective: a "what did you do yesterday" type of survey; also known as an ex post survey. Diary: a "real-time" paper diary that a subject carried as he or she went through the day.

<sup>4</sup> Standard = midnight-to-midnight.

<sup>5</sup> Was activity-specific breathing rate data collected?

<sup>6</sup> PEM = a personal monitoring study. In addition to the diary, a subject carried a small CO or PM<sub>2.5</sub> monitor throughout the sampling period.

<sup>7</sup> P-D removed = The number of person-days of activity pattern data removed from consolidated CHAD because of missing activity *and* location information; completeness criteria are listed in the text.

<sup>8</sup> National Human Activity Pattern Study; A = the air version; B = the water version. The activity data obtained on the two versions are identical.

<sup>9</sup> A question was asked regarding which activities (within each 6-h time block in the day) involved "heavy breathing," lifting heavy objects, and running hard.

(2001)	SHEDS-PM	Stochastic	Outdoors, indoors: residence, office, stores, school, in vehicle, restaurant/lounge,	PM <sub>2.5</sub> exposure distributions for population, by age, gender, smoking and employment status; PM <sub>2.5</sub> exposure uncertainty predictions. Percent contribution from PM of ambient origin to total personal exposures	A 2-stage Monte-Carlo simulation model for predicting population distribution of daily- average personal exposures to PM. Model has been applied to Philadelphia using spatially and temporally interpolated PM <sub>2.5</sub> ambient measurements from 1992-1993 and 1990 census data. Does not consider PM <sub>2.5</sub> exposure from active smoking or exposure in subways
Chao and Tung (2001)	None	Mass Balance with Empirical corrections	Indoors in unoccupied residences in Hong Kong	Predictions of ambient PM in indoor microenvironments	Model makes corrections for nonideal mixing (residence with multiple compartments with limited intermixing)

1 microenvironments when sufficient data were available, such as for a residence. For most other  
2 microenvironments, indoor/outdoor ratios were used because of the lack of data for a mass  
3 balance model. In addition, only the deterministic model, PMEX, included estimation of inhaled  
4 dose from activity-specific breathing rate information. Data from recent PM personal exposure  
5 and microenvironmental measurement studies should help in the future to facilitate the  
6 development of improved personal exposure models for PM.

7 An integrated human exposure source-to-dose modeling system that will include exposure  
8 models to predict population exposures to environmental pollutants, such as PM, currently is  
9 being developed by EPA/NERL. A first-generation population exposure model for PM, called  
10 the Stochastic Human Exposure and Dose Simulation (SHEDS-PM) model, recently has been  
11 developed. The SHEDS-PM model uses a 2-stage Monte Carlo sampling technique previously  
12 applied by MacIntosh et al. (1995) for benzene exposures. This technique allows for separate  
13 characterization of variability and uncertainty in the model predictions to predict the distribution  
14 of total exposure to PM for the population of an urban/metropolitan area and to estimate the  
15 contribution of ambient PM to total PM exposure. Results from a case study using data from  
16 Philadelphia have been reported (Burke et al., 2001). Work is underway to link exposure  
17 modeling with dosimetry so as to provide estimates of integrated PM doses for different regions  
18 of the lung. In the future, both exposure and dose metrics generated for various subgroups of  
19 concern should aid evaluation of PM health effects.

#### 21 **5.2.4.2.2 Microenvironmental Models**

22 The mass balance model has been used extensively in exposure analysis to estimate PM  
23 concentrations in indoor microenvironments (Calder, 1957; Sexton and Ryan, 1988; Duan, 1982,  
24 1991; McCurdy, 1995; Johnson, 1995; Klepeis et al., 1995; Dockery and Spengler, 1981; Ott,  
25 1984; Ott et al., 1988, 1992, 2000; Miller et al., 1998; Mage et al., 1999; Wilson et al., 2000).  
26 The mass balance model describes the infiltration of particles from outdoors into the indoor  
27 microenvironment, the removal of particles in indoor microenvironments, and the generation of  
28 particles from indoor sources:

$$30 \quad V \frac{dC_i}{dt} = v P C - v C_i - kVC_i + Q_i, \quad (5-4)$$

### 5.2.4.3 Methods for Estimating Personal Exposure to Ambient Particulate Matter

In keeping with the various components of PM exposure described in Section 5.3.2, personal exposure to PM can be expressed as the sum of exposure to particles from different sources summed over all microenvironments in which exposure occurs. Total personal exposure may be expressed as

$$T = E_a + E_{ai} + E_{ig} + E_{ir} + E_{pc} \quad (5-5)$$

or

$$T = A + N, \quad (5-6)$$

where T is the total personal exposure to ambient and nonambient PM,  $E_a$  is personal exposure to ambient PM while outdoors,  $E_{ai}$  is personal exposure to ambient PM that has infiltrated indoors while indoors,  $E_{ig}$  is personal exposure to indoor-generated PM,  $E_{ir}$  is exposure to indoor-reaction PM, and  $E_{pc}$  is personal exposure to PM from personal activity (personal cloud). T can also be expressed as A + N where A is ambient PM exposure ( $E_a + E_{ai}$ ) and N is nonambient PM exposure ( $E_{ig} + E_{ir} + E_{pc}$ ). Although personal exposure to ambient and nonambient PM cannot be measured directly, they can be calculated or estimated from other measurement data.

Approaches for estimating these components of PM exposure are described in the following section.

#### 5.2.4.3.1 Mass Balance Approach

##### Ambient-Indoor Concentrations of Particulate Matter

The mass balance model described above (Equation 5-4) has been used to estimate PM concentrations in indoor microenvironments. This model also may be used to estimate ambient-indoor ( $C_{ai}$ ) and indoor-generated ( $C_{ig}$ ) PM concentrations. The mass balance model can be solved for  $C_{ai}$  and  $C_{ig}$  assuming equilibrium conditions, i.e., all variables remain constant (Ott et al., 2000; Dockery and Spengler, 1981; Koutrakis et al., 1992) and no indoor reaction PM ( $C_{ir}$ ). By substituting  $a = v/V$ , where  $a$  = the number of air exchanges per hour substituting,  $dC_{ai} + dC_{ig}$  for  $dC_i$  in Equation 5-4, and assuming that  $dC_{ai} = 0$  and  $dC_{ig} = 0$ , i.e., ambient-indoor PM ( $C_{ai}$ ) and indoor-generated PM ( $C_{ig}$ ) are at equilibrium,  $C_{ai}$  and  $C_{ig}$  are given by Equations 5-7 and 5-8.

$$C_{ai} = C \left[ \frac{Pa}{(a + k)} \right] \quad (5-7)$$

$$C_{ig} = \frac{Q_i}{V(a + k)} \quad (5-8)$$

1

7

8

9

10

11

12

13

14

Equations 5-7 and 5-8 assume equilibrium conditions and, therefore, are valid only when the parameters  $P$ ,  $k$ ,  $a$ ,  $C$ , and  $Q_i$  are not changing rapidly and when the  $C$ s are averaged over several hours. It should be understood that equilibrium is a simplification of indoor microenvironments that are occupied by residents. This assumption of equilibrium may only represent a virtual set of individuals or populations at risk. Under certain conditions (e.g., air-conditioned homes, homes with HVAC or air cleaners that cycle on and off, or ambient pollutants with rapidly varying concentrations), nonequilibrium versions of the mass balance model (Ott et al., 2000; Freijer and Bloemen, 2000; Isukapalli and Georgopoulos, 2000) are likely to provide a more accurate estimate of  $C_{ai}$  and  $C_{ig}$ . However, the equilibrium model provides a useful, if simplified, example of the basic relationships (Ott et al., 2000).

Equation 5-7 may be rearranged further to give  $C_{ai}/C$ , the equilibrium fraction of ambient PM that is found indoors, defined as the infiltration factor ( $F_{INF}$ ) (Dockery and Spengler, 1981).

$$F_{INF} = \frac{C_{ai}}{C} = \frac{Pa}{a + k} \quad (5-9)$$

15

20

21

The penetration ratio ( $P$ ) and the decay rate ( $k$ ) can be estimated using a variety of techniques. A discussion of these variables and estimation techniques is given in Section 5.4.3.2.2. Both  $P$  and  $k$  are a function of particle aerodynamic diameter, air exchange rate, and housing characteristics.  $F_{INF}$  will also be a function of these parameters and as a result  $F_{INF}$  may vary substantially within a population. Distributions of this parameter should be estimated to understand the uncertainty and variability associated with estimating exposure to PM of ambient

1 origin. The distribution of daytime  $F_{INF}$ , as estimated from Particle Total Exposure Assessment  
2 Methodology (PTEAM) data, is shown in Figure 5-2a (Wilson et al., 2000).

### 4 **Personal Exposure to Ambient Particulate Matter**

5 Personal exposure to ambient PM (A) may be estimated using ambient-indoor PM  
6 concentration ( $C_{ai}$ ) from the mass balance model, ambient outdoor PM concentrations (C), and  
7 information on the time an individual spent in the various microenvironments. For a two-  
8 compartment model, A may be expressed as

$$\begin{aligned} A &= yC + (1 - y)C_{ai} \\ &= yC + (1 - y)C \left[ \frac{Pa}{(a + k)} \right], \end{aligned} \tag{5-10}$$

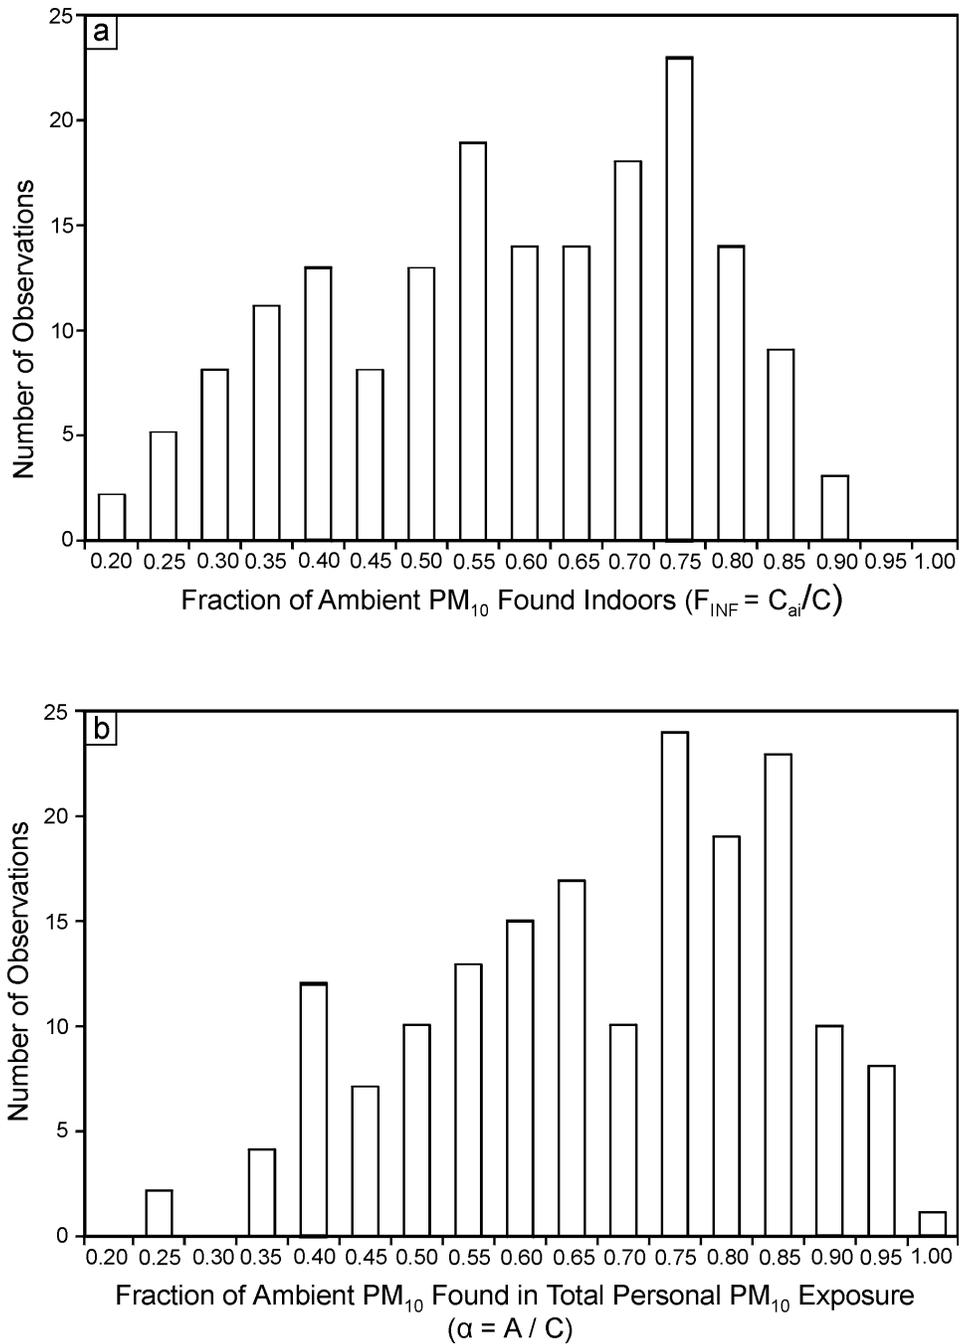

10 where  $y$  is the fraction of time that an individual spent outdoors, and  $(1 - y)$  is the fraction of  
11 time spent indoors.

12 It is convenient to express personal exposure to ambient PM (A) as the product of the  
13 ambient PM concentration (C) and a personal exposure or attenuation factor. Following the  
14 usage in several recent papers (Zeger et al., 2000; Dominici et al., 2000; Ott et al., 2000), the  
15 symbol  $\alpha$  will be used for this attenuation factor. Equation 5-10 can be rearranged to obtain an  
16 expression for  $\alpha$ :  
17

$$\alpha = \frac{T}{C} = y + (1 - y) \left[ \frac{Pa}{a + k} \right] \tag{5-11}$$

18 Substituting equation 5-9 in equation 5-11 gives a relationship for  $\alpha$  in terms of the infiltration  
19 factor  $F_{INF}$  and the fraction of time spent in the various microenvironments:  
20

$$a = y + (1 - y) F_{INF}. \tag{5-12}$$

**Figure 5-2. Distribution of  $F_{INF}$  (a) and  $\alpha$  (b) for daytime as estimated from PTEAM study data.**

Source: Wilson et al. (2000).

1 Thus, personal exposures to ambient PM (A) may be calculated from measurable quantities:

$$A = \alpha C. \quad (5-13)$$

2  
3  
4  
5 The factor  $\alpha$  can be measured directly or calculated from measured or estimated values of the  
6 parameters  $a$ ,  $k$ , and  $P$  and the time spent in various microenvironments from activity pattern  
7 diaries (Wilson et al., 2000). Because  $\alpha$  depends on housing factors and lifestyle factors, air  
8 exchange rate, and PM deposition rate, it could vary to a certain extent from region to region and  
9 from season to season. Consequently, predicted exposures based on these physical modeling  
10 concepts will provide exposure distributions derived conceptually as resulting from housing,  
11 lifestyles, and meteorological considerations. For any given population the coefficient  $\alpha$  may  
12 represent substantial intra- and inter-personal variability based on personal activities, housing  
13 characteristics, particle size, and composition. The distribution of daytime  $\alpha$  as estimated from  
14 PTEAM data is shown in Figure 5-2b. Note that the distribution of  $\alpha$  is shifted to higher values  
15 compared to  $F_{INF}$  because of the inclusion of time outdoors in  $\alpha$ . Distributions of  $\alpha$  should be  
16 determined using population studies in order to evaluate the uncertainty and variability  
17 associated with model exposures.

18 The mass balance model has been used to separate indoor concentrations into ambient and  
19 nonambient components. This approach, based on Equation 5-5 as given in Duan (1982) and  
20 called superposition of component concentrations, has been applied using multiple  
21 microenvironments to estimate exposures to carbon monoxide (Ott, 1984; Ott et al., 1988, 1992),  
22 volatile organic compounds (Miller et al., 1998), and particles (Koutrakis et al., 1992; Klepeis  
23 et al., 1994). However, in these studies and in most of the exposure literature, the ambient and  
24 nonambient components are added to yield a personal exposure from all sources of the pollutant.  
25 The use of the mass balance model, ambient concentrations, and exposure parameters to estimate  
26 exposure to ambient PM and exposure to indoor-generated PM separately as different classes of  
27 exposure has been discussed in Wilson and Suh (1997) and in Wilson et al. (2000).

#### 28 29 **5.2.4.3.2 The Sulfate Ratio Technique for Estimating Ambient PM Exposure**

30 The ratio of personal exposure to ambient concentration for sulfate has been recommended  
31 as a technique to estimate  $\alpha$  (Wilson et al., 2000). If sulfate has no indoor sources, then  $A^S = T^S$ .

1 (Superscript S refers to sulfate; superscript 2.5 to PM<sub>2.5</sub>.) As can be seen in Equation 5-11,  $P$  and  
2  $k$  depend on particle size, but  $a$  and  $y$  do not. Therefore, if sulfate and PM<sub>2.5</sub> have the same size  
3 distribution,  $T^S/C^S = A^{2.5}/C^{2.5} = \alpha^S = \alpha^{2.5}$ . Sulfate is formed in the ambient air via photochemical  
4 oxidation of gaseous sulfur dioxide arising from the primary emissions from the combustion of  
5 fossil fuels containing sulfur. It also arises from the direct emissions of sulfur-containing  
6 particles from nonanthropogenic sources (e.g., volcanic activity, wind-blown soil). It has been  
7 known since the mid-1970s that sulfate and accumulation mode mass have similar size  
8 distributions (Whitby, 1978). In the indoor environment, the only common sources of sulfate  
9 may be resuspension by human activity of deposited PM containing ammonium sulfates or soil  
10 sulfates that were tracked into the home. However, resuspended PM will be mostly larger than  
11 PM<sub>2.5</sub>. In some homes, an unvented kerosene heater using a high-sulfur fuel may be a major  
12 contributor during winter (Leaderer et al., 1999). Use of matches to light cigarettes or gas stoves  
13 can also be a source of sulfates.

14 Studies that have used the sulfate ratio technique to estimate  $\alpha$  and ambient PM exposures  
15 are discussed in Section 5.4.3.1. When there are no indoor sources of accumulation-mode  
16 sulfates, one may deduce that the ambient-to-personal relationship found for sulfates probably  
17 would be the same as that for other PM with the same size range and physical/chemical  
18 properties. This assumption has been validated for several homes in Boston (Sarnat et al., 2002).  
19 For particle sizes within the accumulation mode size range, the ratio  $C_{ai}/C$  was similar for sulfate  
20 and PM<sub>2.5</sub> as estimated from SMPS measurements. However, ambient PM with different  
21 physical or chemical characteristics than sulfate will not behave similarly to sulfate. Sulfate has  
22 been used as a marker of outdoor air in the indoor microenvironments (Jones et al., 2000; Ebel  
23 et al., 2000). However, the personal exposure of sulfate ( $T^S = A^S$ ) should not be taken as an  
24 indicator or surrogate for ambient PM<sub>2.5</sub> exposure ( $A^{2.5}$ ) unless it has been previously determined  
25 that PM<sub>2.5</sub> and sulfate concentrations are highly correlated. This may be the case in some air  
26 sheds with high sulfate concentrations but will not be true in general.

#### 27 28 **5.2.4.3.3 Source-Appportionment Techniques**

29 Source apportionment techniques provide a method for determining personal exposure to  
30 PM from specific sources. If a sufficient number of samples are analyzed with sufficient  
31 compositional detail, it is possible to use statistical techniques to derive source category

1 signatures, identify indoor and outdoor source categories, and estimate their contribution to  
2 indoor and personal PM. Daily contributions from sources that have no indoor component can  
3 be used as tracers to generate exposure to ambient PM of similar aerodynamic size or directly as  
4 exposure surrogates in epidemiological analyses. Studies that have used source-apportionment  
5 are discussed in Section 5.4.3.3 (i.e., Özkaynak and Thurston, 1987; Yakovleva et al., 1999; Mar  
6 et al. 2000; Laden et al., 2000).

## 7 8 9 **5.3 SUMMARY OF PARTICULATE MATTER MASS DATA**

### 10 **5.3.1 Types of Particulate Matter Exposure Measurement Studies**

11 A variety of field measurement studies have been conducted to quantify personal exposure  
12 to PM mass, to measure microenvironmental concentrations of PM, to evaluate relationships  
13 between personal exposure to PM and PM air concentrations measured at ambient sites, and to  
14 evaluate factors that affect exposure. In general, exposure measurement studies are of two types  
15 depending on how the participants are selected for the study. In a *probability* study, participants  
16 are selected using a probability sampling design where every member of the defined population  
17 has a known, positive probability of being included in the sample. Probability study results can  
18 be used to make statistical inferences about the target population. In a *purposeful* or  
19 *nonprobability* design, any convenient method may be used to enlist participants; and the  
20 probability of any individual in the population being included in the sample is unknown.  
21 Participants in purposeful samples may not have the same characteristics that would lead to  
22 exposure as the rest of the unsampled population. Thus, results of purposeful studies apply only  
23 to the subjects sampled on the days that they were sampled and not to other subjects or other  
24 periods of time. Although such studies may report significant differences, confidence intervals,  
25 and *p* values, they do not have inferential validity (Lessler and Kalsbeek, 1992). Purposeful  
26 studies, however, may have generalizability (external validity). The extent of generalizability is  
27 a matter of judgement based on study participant characteristics. Purposeful studies of PM  
28 personal exposure can provide data with which to develop relationships based on important  
29 exposure factors and can provide useful information for developing and evaluating either  
30 statistical or physical/chemical human exposure models.

1           Regardless of the sampling design (probability or purposeful), there are three general  
2 categories of study design that can be used to measure personal exposure to PM and evaluate the  
3 relationship between personal PM exposure levels and ambient PM concentrations measured  
4 simultaneously: (1) longitudinal, in which each subject is measured for many days; (2) pooled,  
5 in which each subject is measured for only one or two days, different days for different subjects;  
6 and (3) daily-average, in which many subjects are measured on the same day. Only one study, in  
7 which 14 subjects were measured for 14 days, provides sufficient data for a comparison of  
8 longitudinal and daily-average data (Lioy et al., 1990). Longitudinal and pooled studies are  
9 discussed in Section 5.4.3.1.1.

## 11 **5.3.2 Available Data**

### 12 **5.3.2.1 Personal Exposure Data**

13           Table 5-4 gives an overview of the personal exposure studies that have been reported since  
14 the 1996 PM AQCD. In addition, major studies that were reported before that time also have  
15 been included to provide a comprehensive evaluation of data in this area. Table 5-4 gives  
16 information on the sampling and study designs, the study population, the season, number of  
17 participants, PM exposure metric, and the PM size fraction measured.

18           Although there are a number of studies listed in the table, the data available with which to  
19 evaluate longitudinal relationships and the factors that influence these are limited. Few studies  
20 are based on probability sampling designs that allow study results to be inferred to the general  
21 population and to develop distributional data or exposures and the factors that affect exposure.  
22 Unfortunately, none of these probability studies used a longitudinal study design. This limits our  
23 ability to provide population estimates and distributional data on the relationship between  
24 personal PM exposures and ambient site measurements. In addition, most of the probability  
25 studies of PM exposure were conducted during a single season; thus, variations in ambient  
26 concentrations, air exchange rates, and personal activities are not accounted for across seasons.  
27 In these cases, study results are only applicable to a specific time period. Longitudinal studies,  
28 on the other hand, generally have small sample sizes and use a purposeful sampling design.  
29 Some studies did not include ambient site measurements to allow comparisons with the exposure  
30 data. Approximately half of these studies monitored PM<sub>2.5</sub>. Only one or two studies measured  
31 both PM<sub>10</sub> and PM<sub>2.5</sub> to provide information on PM<sub>10-2.5</sub>.

<sup>a</sup>All based on gravimetric measurements.

<sup>b</sup>P = personal, I = indoors, O = outdoors, A = ambient.

<sup>c</sup>pooled; data from many subjects with only a few days per subject.

<sup>d</sup>longitudinal; one subject measured for many days.

1 Four large-scale probability studies that quantify personal exposure to PM under normal  
2 ambient source conditions have been reported in the literature. These include the EPA's  
3 PTEAM study (Clayton et al., 1993; Özkaynak et al., 1996a,b); the Toronto, Ontario, study  
4 (Clayton et al., 1999a and Pellizzari et al., 1999); the Air Pollution Exposure Distribution within  
5 Adult Urban Populations in Europe (EXPOLIS) study (Jantunen et al., 1998, 2000; Oglesby,  
6 et al., 2000; Gotshi et al., 2002; Kousa et al., 2002); and a study of a small, highly polluted area  
7 in Mexico City (Santos-Burgoa et al., 1998). A fifth study conducted in Kuwait during the last  
8 days of the oil-well fires (Al-Raheem et al., 2000) is not reported here because the ambient PM  
9 levels were not representative of normal ambient source conditions.

10 Recent longitudinal exposure studies have focused on potentially susceptible  
11 subpopulations such as the young and elderly with preexisting respiratory and heart diseases  
12 (hypertension, chronic obstructive pulmonary disease, and congestive heart disease). This is in  
13 keeping with epidemiological studies that indicate mortality associated with high levels of  
14 ambient PM<sub>2.5</sub> is greatest for elderly people with cardiopulmonary disease (U.S. Environmental  
15 Protection Agency, 1996). Longitudinal studies were conducted in the Netherlands by Janssen  
16 (1998) and Janssen et al. (1997, 1998a,b, 1999b,c) on purposefully selected samples of adults  
17 (50 to 70 years old) and children (10 to 12 years old). School children have also been studied in  
18 Chile (Rojas-Bracho et al., 2002). Several additional studies have focused on nonsmoking  
19 elderly populations in Amsterdam and Helsinki (Janssen et al., 2000), Tokyo (Tamura et al.,  
20 1996a), Baltimore, MD (Liao et al., 1999; Williams et al., 2000a,b,c), and Fresno, CA (Evans  
21 et al., 2000). These cohorts were selected because of the low incidence of indoor sources of PM  
22 (such as combustion or cooking). This should allow an examination of the relationship between  
23 personal and ambient PM concentrations without the large influences caused by smoking,  
24 cooking, and other indoor particle-generating activities. The EPA has a research program  
25 focused on understanding PM exposure characteristics and relationships. Within the program,  
26 longitudinal studies are being conducted on elderly participants with underlying heart and lung  
27 disease (COPD, patients with cardiac defibrillator, and myocardial infarction), an elderly  
28 environmental justice cohort, and asthmatics. These studies are being conducted in several cities  
29 throughout the United States and over several seasons (Rodes et al., 2001; Conner et al., 2001;  
30 Landis et al., 2001; Rea et al., 2001).

1 A series of studies by Phillips et al. (1994, 1996, 1997a,b, 1998a,b, 1999) examined  
2 personal ETS exposure in several European cities. Participants varied by age and occupation.  
3 Respirable particulate matter (RSP) concentrations were reported. These studies are not  
4 included in Table 5-4 because of their focus on ETS exposure (which is not the focus of this  
5 chapter). A small personal exposure study in Zurich, Switzerland, was reported by Monn et al.,  
6 (1997) for PM<sub>10</sub>. This study also is not listed in Table 5-4 because indoor and outdoor  
7 measurements were not taken simultaneously with the personal measurements and other details  
8 of the study were not published.

### 10 **5.3.2.2 Microenvironmental Data**

11 Usually, personal PM monitoring is conducted using integrated measurements over a  
12 12- or 24-h period. As such, total PM exposure estimates based on PEM measurements do not  
13 capture data from individual microenvironments. Recent studies have examined PM  
14 concentrations in various microenvironments using a number of different types of instruments  
15 ranging from filter-based to continuous particle monitors. Details on the instruments used,  
16 measurements collected, and findings of these studies according to microenvironment  
17 (residential indoor, nonresidential indoor, and traffic-related) are summarized in Table 5-5.  
18 Those studies which collected microenvironmental data as part of a personal exposure  
19 monitoring study are summarized in Table 5-4. In general, the studies listed in Table 5-5 are  
20 relatively small, purposeful studies designed to provide specific data on the factors that affect  
21 microenvironmental concentration of PM from both ambient and nonambient sources.

22 Recently published studies have used various types of continuous monitors to examine  
23 particle concentrations in specific microenvironments and resulting from specific activities.  
24 Continuous particle monitors such as the scanning mobility particle sizer (SMPS), aerodynamic  
25 particle sizer (APS), and Climet have been used to measure particle size distributions in  
26 residential microenvironments (Abt et al., 2000a; Long et al., 2000a; Wallace et al., 1997;  
27 Wallace, 2000a; McBride et al., 1999; Vette et al., 2001; Wallace and Howard-Reed, 2002).  
28 These studies have been able to assess penetration efficiency for ambient particles to indoor  
29 microenvironments, as well as penetration factors and deposition rates. Continuous instruments  
30 are also a valuable tool for assessing the impact of particle resuspension caused by human  
31 activity. A semi-quantitative estimate of PM exposure can be obtained using personal

**TABLE 5-5. SUMMARY OF RECENT MICROENVIRONMENTAL PM MEASUREMENT STUDIES**

Reference	Study Description	Instrument(s)	Size Fraction ( $\mu\text{m}$ )	Summary of Measurements	Notes
<b>Residential Indoor: Nonsmoking Homes</b>					
Abt et al. (2000a) Boston, MA	2 homes, 2 seasons, 6 days	SMPS APS		Detailed indoor/outdoor traces of PM in various size classes for different air exchange rates (< $1\text{h}^{-1}$ to $> 2\text{h}^{-1}$ ).	Major indoor sources of PM: cooking, cleaning, human activity.
Long et al. (2000a) Boston, MA	9 homes, 2 seasons	SMPS APS	0.02-10 $\mu\text{m}$	Continuous PM distributions and size distributions obtained for indoor and outdoor air using SMPS and APS monitors.	Sources of fine particles: cooking and outdoor particles; Sources of coarse particles: cooking, cleaning, indoor activities. 50% of particles by volume generated by indoor events were ultrafine particles.
Anuszewski et al. (1998) Seattle, WA	9 homes, 18 days	Nephelometer (radiance)	$\text{PM}_{10}$	Simultaneous indoor and outdoor PM measured continuously; 1-h avg time, $I/O = 0.98$ ; air exchange rate: $0.7\text{-}1.7\text{h}^{-1}$ .	Homes contained asthmatic children, heavy wood burning. Dominant source of fine particles was outdoor air.
Leaderer et al. (1999) Southwest, VA	58 homes, summer		$\text{PM}_{10}$  $\text{PM}_{2.5}$	24 h mean: Regional air $26.0 \pm 11.5\ \mu\text{g}/\text{m}^3$ (n = 47); Outdoor homes $28.0 \pm 17.7\ \mu\text{g}/\text{m}^3$ (n = 43); Indoor w/ AC $28.9 \pm 18.7\ \mu\text{g}/\text{m}^3$ (n = 49); Indoor w/o AC $33.3 \pm 14.2\ \mu\text{g}/\text{m}^3$ (n = 8).  24 h mean: Regional air $20.2 \pm 9.9\ \mu\text{g}/\text{m}^3$ (n = 50); Outdoor homes $21.8 \pm 14.8\ \mu\text{g}/\text{m}^3$ (n = 43); Indoor w/ AC $18.7 \pm 13.2\ \mu\text{g}/\text{m}^3$ (n = 49); Indoor w/o AC $21.1 \pm 7.5\ \mu\text{g}/\text{m}^3$ (n = 9).	Epidemiologic study of maternal and infant health effects associated with indoor air pollution.  Indoor PM concentrations were lower for homes with air conditioning (AC) than non-air-conditioned homes.
Wallace et al. (1997); Wallace (2000b) Reston, VA	1 home, 4 years	SMPS Climet PAHs Black carbon	6 size bins; 100 size channels 0.01- 0.4 $\mu\text{m}$	Time activity data, whole-house air exchange rates. Continuous carbon monoxide; descriptive data for monitored pollutants; size profiles for six indoor particle sources.	0.3- to 0.5- $\mu\text{m}$ particles linked to outdoor concentrations, frying, broiling; 0.5- to 2.5- $\mu\text{m}$ particles related to cooking events; $> 2.5\text{-}\mu\text{m}$ particles influenced by physical movement.
Howard-Reed et al. (2000) Fresno, CA Baltimore, MD	15 participants	Nephelometer (personal MIE) PEM	0.1-10 $\mu\text{m}$  $\text{PM}_{2.5}$	Continuous (15-min avg) PM and time activity data; 24-h PM mass; participants from Baltimore and Fresno PM panel studies. Descriptive statistics from each study for five microenvironments.	Time-series plots of personal nephelometer data showed that each participant's PM exposure consisted of a series of short-term peaks, imposed on a background caused by ambient PM concentrations.

**TABLE 5-5 (cont'd). SUMMARY OF RECENT MICROENVIRONMENTAL PM MEASUREMENT STUDIES**

Reference	Study Description	Instrument(s)	Size Fraction ( $\mu\text{m}$ )	Summary of Measurements	Notes
<b>Residential Indoor: Nonsmoking Homes (cont'd)</b>					
Rea et al. (2001) Baltimore, MD Fresno, CA	15 participants	Nephelometer (personal MIE) PEM	0.1-10 $\mu\text{m}$  PM <sub>2.5</sub> and PM <sub>10</sub>	54 $\pm$ 31% of average daily PM <sub>2.5</sub> exposure occurred indoor residences, where participants spent 83 $\pm$ 10% of their time. A significant portion of PM <sub>2.5</sub> exposure occurred where participants spent 4-13% of their time.	Continuous (15-min avg) PM and time activity data; 24-h PM mass; modeled PM mass and time activity data to apportion time spent in a location. Good comparison with nephelometer mass (6-20%).
Quintana et al. (2000) San Diego, CA	Asthmatic children indoor and outdoor 9 homes	Nephelometer (personal MIE) Harvard impactors TEOM	0.1-10 $\mu\text{m}$  PM <sub>2.5</sub> and PM <sub>10</sub>	Nephelometer correlates best with PM <sub>2.5</sub> : vs. Indoor PM <sub>2.5</sub> r = 0.66, vs. indoor PM <sub>10</sub> r = 0.13, vs. outdoor PM <sub>2.5</sub> r = 0.42, vs. outdoor PM <sub>10</sub> r = 0.20.	Indoor and outdoor measurements collected using passive, active, and active heated nephelometers for comparison to PM mass measurements.
Chang et al. (2000) Baltimore, MD	1 person performing predetermined activities	"Roll around" monitor (RAS) (PM <sub>2.5</sub> , CO, VOC, O <sub>3</sub> , NO <sub>2</sub> , SO <sub>2</sub> )	PM <sub>2.5</sub>	1-h personal O <sub>3</sub> exposures were significantly lower in indoor than outdoor microenvironments. 1-h personal CO exposures were highest in vehicles. Personal and ambient PM <sub>2.5</sub> correlations were strongest for outdoor microenvironments and those with high air exchange rates (i.e., vehicles).	1-h personal exposures measured simultaneously. Personal and ambient concentrations were compared.
Liroy et al. (1999) NA	10 vacuum cleaners		0.3-0.5 $\mu\text{m}$	Vacuum cleaners ranged in collection efficiency from 29-99%. Substantial fine particle emissions from motors with emission rates from 0.028 - 128.8 $\mu\text{g}/\text{min}$ .	
Ezzati and Kammen (2001) Mpala, Kenya	55 Native huts 2- years	MiniRam (MIE)	Not specified. Optical device detects particles 1-10 $\mu\text{m}$ , but it is not PM <sub>10</sub>	Measured PM surrounding wood fires in unvented huts. PM measures were up to 8000 $\mu\text{g}/\text{m}^3$ , but uncalibrated against wood smoke.	Exposures were related to ARI.
Chao and Tung (2001) Hong Kong	5 unoccupied homes measured indoors and outdoors, along with air exchange rates	Dust-Trak (TSI)	PM <sub>2.5</sub> real time, calibrated against an Andersen Mark II	In the limit as air exchange goes to zero, there appears to be a residual source, perhaps from drafts or thermal effects. Above air exchange rates of 4.5/hr penetration goes to 1, but indoor turbulence resuspends previously settled PM <sub>2.5</sub> .	Developed an excellent model for ambient PM infiltration in the absence of anthropogenic indoor sources.

**TABLE 5-5 (cont'd). SUMMARY OF RECENT MICROENVIRONMENTAL PM MEASUREMENT STUDIES**

Reference	Study Description	Instrument(s)	Size Fraction ( $\mu\text{m}$ )	Summary of Measurements	Notes
<b>Residential Indoor: Nonsmoking Homes (cont'd)</b>					
Fischer et al. (2000) Amsterdam, NL	Measured traffic related differences of PM and VOCs, indoor/outdoor in 18 paired homes at varying distances from traffic	Harvard Impactors	PM <sub>2.5</sub> and PM <sub>10</sub> . EC was measured by reflectance of the PM <sub>2.5</sub> filters. PAH also measured as indicator of diesel traffic.	Outdoor PM <sub>10</sub> and PM <sub>2.5</sub> were approximately 15-20% higher at higher traffic streets than at the quiet streets on the same days. However, much larger differences were found for PAH and EC which are traffic specific.	"This [study] supports the use [of] traffic related pollution mapping as an exposure proxy in large-scale epidemiologic studies into health effects of motorized traffic emissions."
Kingham et al. (2000) Huddersfield, UK	Measured PM at ten homes of non-smokers, < 50 m and > 300 m from traffic	Harvard Impactors	PM <sub>2.5</sub> and PM <sub>10</sub> and PAH. EC measured by filter reflectance.	Median Indoor/outdoor ratio =1 (no indoor combustion sources).	Found an absence of a spatial gradient, perhaps due to wind direction effects (e.g. sometimes upwind and sometimes downwind of traffic).
Morawska et al. (2001) Brisbane, Australia	Measured PM indoors and outdoors at 16 homes while residents were absent. Air exchange rate estimated, not measured	Scanning mobility particle sizer, aerodynamic particle sizer, and a TSI dust-trak	Submicron PM, Supramicron PM, PM <sub>2.5</sub>	For supra and sub micron particles, indoor = outdoor for normal ventilation conditions of > 2 air changes/hour.	Average outdoor PM concentrations are good estimates of average indoor concentrations of PM of ambient origin for air exchange rates of > 0.5/h.
Abraham et al. (2002)	Measured ultrafine PM in various home and traffic microenvironments	TSI 8525	< 1 $\mu\text{m}$ optical diameter	1-second readings collected while noting presence of sources.	The TSI 8525 is a useful instrument for screening UFPM in microenvironments.
Geller et al. (2002)	Comparison of indoor and outdoor PM in homes in Coachella Valley, CA	USC Personal PM 5 Lpm	PM <sub>2.5</sub> and PM <sub>10-2.5</sub>	I2.5 = 4.3 + 0.74 O I10-2.5 = 3 + 0.3 O I EC = 0.84 O EC I OC > O OC.	13 volunteers had two to four 23-h measurements I and O analyzed for elemental carbon (EC) and organic carbon (OC). Some unoccupied homes measured.
Gotschi et al. (2002)	Measured Black Smoke (BS) by reflection from PM <sub>2.5</sub> filters for 4 European cities, indoor and outdoor.	XPOLIS PM monitor and EEL 43 reflectometer.	PM <sub>2.5</sub>	PM measured I and O for two nights while subject was home (5 pm - 8 am). 183 sampled PM <sub>2.5</sub> and BS were compared for these samples.	BS is a supplementary measurement that can be made on PM <sub>2.5</sub> filters as an indication of EC.
Sarnat et al. (2002)	Measured PM <sub>2.5</sub> for sulfate analysis in and out of 6 Boston homes	Harvard Impactors with SMPS and APS particle counters	PM <sub>2.5</sub>	The ratio of I/O PM <sub>2.5</sub> , sulfate and size sub-fractions are developed as a function of season and Air Exchange Rate.	Sulfur is primarily of outdoor origin and can be used to track ambient PM of similar (0.06-0.5 $\mu\text{m}$ ) AD, but different relations exist for ultrafine PM and coarse mode PM < 2.5 $\mu\text{m}$ AD.
Wallace and Howard-Reed (2002)	Measured ultrafine, fine and coarse PM in one Reston, VA tri-level home for 18 months with air exchange and meteorologic data	TSI 3071 SMPS TSI 3320 APS Climet 500-I MIE pDR-1000	10 nm to > 10 $\mu\text{m}$	Analysis of particle counts as a function of Air Exchange Rate and meteorological variables.	Wind speed has little influence on AER. The home sometimes acts as 1 compartment and sometimes multiple compartments.

**TABLE 5-5 (cont'd). SUMMARY OF RECENT MICROENVIRONMENTAL PM MEASUREMENT STUDIES**

Reference	Study Description	Instrument(s)	Size Fraction ( $\mu\text{m}$ )	Summary of Measurements	Notes
<b>Residential Indoor: Other Home Types</b>					
Brauer et al. (1996) Mexico	22 rural Mexican homes (smoking and nonsmoking)	Inertial impactor Radiance nephelometer	PM <sub>10</sub>  PM <sub>2.5</sub>	Indoor PM <sub>2.5</sub> : 132-555 $\mu\text{g}/\text{m}^3$ PM <sub>10</sub> : 282-768 $\mu\text{g}/\text{m}^3$ . Outdoor PM <sub>2.5</sub> : 37 $\mu\text{g}/\text{m}^3$ PM <sub>10</sub> : 68 $\mu\text{g}/\text{m}^3$ ; I/O PM <sub>2.5</sub> : 1.8-12.4; PM <sub>10</sub> : 4.7-10.0.	Variety of cooking fuels used Nephelometer data were highly correlated with PM <sub>2.5</sub> and PM <sub>10</sub> indoors ( $r = \approx 0.87$ -0.95).
Jenkins et al. (1996 a,b) 16 U.S. Cities	Smoking and nonsmoking homes	Fluoropore membrane filters	Particle phase ETS markers	Mean PM <sub>3.5</sub> concentrations were 17-20 $\mu\text{g}/\text{m}^3$ in smoking homes over nonsmoking homes.	
McBride et al. (1999) NA	Combustion source (incense) and walking (1 room, carpeted)	Met-One laser particle counter		Ratios of particle counts a 1.0 and 5.7 m from the combustion source/activity were obtained.	Proximity to source may help explain the existence of a personal cloud.
Vette et al. (2001) Fresno, CA	Detached semioccupied residence	SMPS LASX	0.01-2.5 $\mu\text{m}$	Temporal relationships between indoor and outdoor aerosol concentrations evaluated; penetration factors and deposition rates estimated. Fresno panel study empty residence.	Diurnally variable indoor/outdoor aerosol concentration ratios because of resuspension from daytime activities. Penetration factors ranged from 0.5 to 0.9.
Douce et al. (2001)	ETS measured by 4 methods in smokers homes and offices	37 mm filter and XAD-4 resin backup	PM <sub>5</sub>	Samples extracted and analyzed for UV absorption, fluorescence, solanesol, and scopoletin.	Solanesol is best method of 4, but needs study of solanesol stability on filter.
<b>Nonresidential Microenvironments</b>					
Bohadana et al. (2000)	Manufacturing plant, woodworkers		Not given	443 personal time-weighted average occupations samples of airborne dust.	
Donham et al. (2000) San Francisco, CA	34 poultry workers	NIOSH Method 0600 monitors probed respirators	PM <sub>5</sub>	Total dust sampled indoor respiratory masks. Personal monitoring: $630 \pm 980 \mu\text{g}/\text{m}^3$ (n = 210) ranging from 10-7,730 $\mu\text{g}/\text{m}^3$ .	Respirable dust constituted about 10% of total dust measured.
Klepeis et al. (1996) San Francisco, CA	Airport lounge, ETS	TSI 8510 piezobalance	PM <sub>3.5</sub>	Estimated cigarette emission rate of 1.43 mg/min/cigarette.	Personal exposures to ETS can be modeled in these types of microenvironments.
Nieuwenhuijsen et al. (1999)	Agricultural activities		PM <sub>4</sub>	Average respirable fraction: 4.5 mg/m <sup>3</sup> .	
Teschke et al. (1999)	Wood production, wood finishing, wood construction workers		PM $\approx$ 50	1,632 observations from 1979-1997. Arithmetic mean exposure: 7.93 mg/m <sup>3</sup> . Geometric mean exposure: 1.86 mg/m <sup>3</sup> .	

**TABLE 5-5 (cont'd). SUMMARY OF RECENT MICROENVIRONMENTAL PM MEASUREMENT STUDIES**

Reference	Study Description	Instrument(s)	Size Fraction ( $\mu\text{m}$ )	Summary of Measurements	Notes
<b>Nonresidential Microenvironments (cont'd)</b>					
Baek et al. (1997) Korea	Indoor and outdoor smoking restaurants		PM <sub>3,5</sub>	Indoor concentrations: 33-475 $\mu\text{g}/\text{m}^3$ Outdoor concentrations: 12-172 $\mu\text{g}/\text{m}^3$ I/O: 2.4.	No significant correlation between indoor and outdoor measurements.
Ott et al. (1996) California	Bar before and after smoking prohibited	Piezobalance	PM <sub>3,5</sub>	Smoking permitted: indoor 26.3-182 $\mu\text{g}/\text{m}^3$ ; outdoor < 5-67 $\mu\text{g}/\text{m}^3$ Smoking prohibited: indoor 4-82 $\mu\text{g}/\text{m}^3$ ; outdoor 2-67 $\mu\text{g}/\text{m}^3$ .	I/O nonsmoking: 2.2. I/O smoking: 3.4.
Houseman et al. (2002) Boston, MA	Indoor and outdoor restaurants, stores	TSI DusTrak		Indoor restaurants: 14-278 $\mu\text{g}/\text{m}^3$ Outdoor restaurants: 7-281 $\mu\text{g}/\text{m}^3$ Indoor stores: 12-206 $\mu\text{g}/\text{m}^3$ Outdoor stores: 7-281 $\mu\text{g}/\text{m}^3$ .	Avg I/O for restaurants: 2.3. Not known if the restaurants allowed smoking. In stores, indoor and outdoor measurements were correlated, avg I/O: 0.83.
Brauer and Mannetje (1998) Vancouver, BC	Indoor restaurants, various smoking policies		PM <sub>2,5</sub> PM <sub>10</sub>	Nonsmoking: PM <sub>2,5</sub> 7-65 $\mu\text{g}/\text{m}^3$ , PM <sub>10</sub> < 10-74 $\mu\text{g}/\text{m}^3$ Restricted smoking (> 40% nonsmoking) PM <sub>2,5</sub> 11-163 $\mu\text{g}/\text{m}^3$ ; PM <sub>10</sub> 24-89 $\mu\text{g}/\text{m}^3$ Unrestricted smoking: PM <sub>2,5</sub> 47-253 $\mu\text{g}/\text{m}^3$ ; PM <sub>10</sub> 51-268 $\mu\text{g}/\text{m}^3$ .	
Lee and Chang (1999) Hong Kong	Indoor and outdoor 5 classrooms		PM <sub>10</sub>	Indoor PM <sub>10</sub> : 30-470 $\mu\text{g}/\text{m}^3$ Outdoor PM <sub>10</sub> : 20-617 $\mu\text{g}/\text{m}^3$	
Chan (2002)	A Hong Kong Office monitored indoor and outdoor	TEOM 1400a	PM <sub>2,5</sub>	Daily 9 a.m - 6 p.m. weekday for 9 months.	Temp, RH and solar intensity influence In/Out. Wind speed has no effect.
Levy et al. (2002)	Arbitrary choice of one library, coffee shop, urban shopping mall, food court, apartment, hospital, subway, diesel bus in Boston, MA	TSI DustTrak 8520 TSI P-Trak 8525	PM counter calibrated to PM <sub>2,5</sub> < 1 $\mu\text{m}$ OD	Measured inside and outside the various microenvironments tested, weekdays morning and afternoon. At least 3 visits, several 10 min averages.	10 min outdoor averages are poor predictors of indoor values.

**TABLE 5-5 (cont'd). SUMMARY OF RECENT MICROENVIRONMENTAL PM MEASUREMENT STUDIES**

Reference	Study Description	Instrument(s)	Size Fraction ( $\mu\text{m}$ )	Summary of Measurements	Notes
<b>Traffic-Related Microenvironments (TRM)</b>					
Praml and Schierl (2000) Munich, Germany	Trams and buses, rural and urban	Continuous millipore polycarbonate filter	PM <sub>10</sub>	n = 201 4-h trips, mean concentration 155 $\mu\text{g}/\text{m}^3$ range: 13-686 $\mu\text{g}/\text{m}^3$ I/O: 2.8.	Tram > circular bus route > radial bus route Day > night
Monn et al. (1997) Switzerland	Spatial scale from a city street	Harvard microenvironment monitor	PM <sub>10</sub>	48- or 72-h avg times; horizontal distance from street: 0, 15, 50, and 80 m; vertical distance from street: 20 m. Mean PM <sub>10</sub> 27.3 $\pm$ 3.0 $\mu\text{g}/\text{m}^3$ .	No vertical gradient (0-20 m) and horizontal gradient (0-80 m) in distance from road, each about 13%. No significant differences between wet and dry periods.
Rodes et al. (1998) Saevanenso, Los Angeles, CA	In-vehicle, various road types, 2-h trips		PM <sub>2.5</sub> PM <sub>10</sub>	Vehicles in front of the monitored vehicle accounted for most of the in-vehicle commuting exposure; average I/O: 0.6-0.8 h <sup>-1</sup> for PM <sub>2.5</sub> ; carpool lane concentrations were 30-60% lower than noncarpool lane concentrations.	Air exchange rates measured at various ventilation settings and speeds. Monitoring vehicle followed a diesel bus or truck.
Roorda-Knappe et al. (1998) van Vliet et al. (1997) Netherlands	Gradient in distance from roadway	Harvard impactor	PM <sub>2.5</sub> PM <sub>10</sub> Black smoke	PM monitoring at 50, 100, 150, and 300 m from roadway; 1-week avg time.	No concentration gradient with increasing distance from the roadways for PM <sub>2.5</sub> and PM <sub>10</sub> ; concentration gradient did exist for black smoke, also found an effect with wind direction.
Houseman et al. (2002) Boston, MA	Indoor and outdoor vehicles buses, subways	TSI DusTrak	PM <sub>10</sub>	Vehicle concentrations ranged from 33-170 $\mu\text{g}/\text{m}^3$ . Outdoor vehicle concentrations ranged from 40-144 $\mu\text{g}/\text{m}^3$ . Bus concentrations: 17-268 $\mu\text{g}/\text{m}^3$ ; outdoor 10-203 $\mu\text{g}/\text{m}^3$ . Subway: 28-174 $\mu\text{g}/\text{m}^3$ ; outdoor 8-203 $\mu\text{g}/\text{m}^3$ .	The average in-vehicle to outdoor ratio was 0.99. Average I/O: 3; subway values were correlated with outdoor concentrations.
Brauer et al. (1999) Vancouver, BC	Commuting environments	APC-1000		PM < 5: greatest concentrations by combustion powered vehicles. PM > 5: greatest concentrations by bicycling and buses.	
Janssen et al. (1997) Netherlands	Background and roadway		PM <sub>2.5</sub> PM <sub>10</sub>	PM <sub>2.5</sub> background: 21-35 $\mu\text{g}/\text{m}^3$ ; roadway 23-43 $\mu\text{g}/\text{m}^3$ . PM <sub>10</sub> background: 13-32 and 29-62 $\mu\text{g}/\text{m}^3$ ; roadway 16-56 and 30-75 $\mu\text{g}/\text{m}^3$ .	Average roadway/background ratio: 3 for PM <sub>2.5</sub> and PM <sub>10</sub> . Average increase in concentration at the roadway 7.2-12.7 $\mu\text{g}/\text{m}^3$ .

**TABLE 5-5 (cont'd). SUMMARY OF RECENT MICROENVIRONMENTAL PM MEASUREMENT STUDIES**

Reference	Study Description	Instrument(s)	Size Fraction ( $\mu\text{m}$ )	Summary of Measurements	Notes
<b>Traffic-Related Microenvironments (TRM) (cont'd)</b>					
Adams et al. (2001)	PM by volunteers in TRM in London, UK	16 lpm personal monitor. Porous foam size selector	PM <sub>2.5</sub>	Volunteers rode/cycled along fixed routes repetitively.	Personal exposures were generally double those at fixed-site ambient station. Subway exposures are maximal.
Alm et al. (1999) Kuopio, Finland	9-km commuter route, rush hours 1/mo	Climet	6 channels	Windows closed, vents open air exchange rate 36-47 h <sup>-1</sup> .	Morning commutes were generally higher than afternoon commutes; relationships determined between PM and wind speed and vehicle speed.
Chan et al. (2002)	PM measured in TRM in Hong Kong	TSI 8520 DustTrac Calibrated to Partisol PM <sub>2.5</sub> HiVol PM <sub>10</sub>	PM <sub>2.5</sub> and PM <sub>10</sub>	Repetitive sampling over 8 fixed routes.	Highly variable by mode. Tram exposures are maximal.
Hoek et al. (2001) Hoek et al. (2002)	BS in Netherlands interpolated to outdoor locations relative to traffic at subject's homes	Black Smoke measured from filters	Not Recorded	GIS used to interpolate background and regional ambient BS with added increment for distance to traffic < 50 m and < 100 m.	May be useful technique. Estimates not validated with BS measurements at interpolated loci.
Jinsart et al. (2002)	PM Exposure of traffic police at intersection post in Bangkok, Thailand	Sibata personal single nozzle 2.5 lpm	PM <sub>2.5</sub> and PM <sub>10</sub>	Sampled 12-h while on duty at post at intersection.	Exposures of both PM <sub>2.5</sub> and PM <sub>10</sub> higher than ambient PM measured at station with $\beta$ gauge. Not comparable to U.S. conditions.
Lena et al. (2002)	PM <sub>2.5</sub> and EC in the Bronx, NY in area of high Diesel truck traffic	PM <sub>2.5</sub> @ 4 lpm 3 Lpm quartz filter for EC EEL for BS	PM <sub>2.5</sub>	Sampled 10-h at sidewalk locations while counting cars and trucks for 3-weeks in summer of 1999.	EC is a large component of Diesel PM <sub>2.5</sub> and varies with truck traffic.
Zhu et al. (2002)	Ultrafine near Interstate Highway in Los Angeles, CA with heavy Diesel traffic	CPC TSI 3022A SMPS TSI 3936 BC aethalometer	6 nm-220 nm	200 m upwind and 17, 20, 30, 90, 150 and 300 m downwind.	Ultrafine PM decreased exponentially from the freeway and was equal to upwind at 300 m.

1 nephelometers that measure PM using light-scattering techniques. Recent PM exposure studies  
2 have used condensation nuclei counters (1 s averaging time) and personal nephelometers (1 min  
3 averaging time) to measure PM continuously (Howard-Reed et al., 2000; Quintana et al., 2000;  
4 Magari et al., 2002; Lanki et al., 2002) in various microenvironments. These data have been  
5 used to identify the most important ambient and nonambient sources of PM, to provide an  
6 estimate of source strength, and to compare modeled time activity data and PEM 24-h mass data  
7 to nephelometer measurements (Rea et al., 2001).

### 9 **5.3.2.3 Traffic-Related Microenvironments**

10 There has been increasing interest in the possible role of traffic-related pollutants.  
11 Distance to roadways has been used as a surrogate for exposure to traffic-related pollutants  
12 (Hoek et al., 2001), and this exposure indicator was subsequently used in an epidemiological  
13 study (Hoek et al., 2002). A traffic model, using traffic volume, direct exhaust emissions rate,  
14 and a re-entrainment rate has been used to estimate concentrations of traffic-related emissions at  
15 several schools in East Los Angeles (Korenstein and Piazza, 2002). Personal exposure studies  
16 have been made in a variety of commuting situations including vehicle traffic (Adams et al.,  
17 2001; Chan et al., 2002). Other studies have measured various indicators of traffic near  
18 roadways (Lena et al., 2002), inside vehicles in traffic (Abraham et al., 2002), and in several  
19 types of traffic related microenvironments (Levy et al., 2002). Table 5-5 provides a brief  
20 description of these studies, instruments used, measurements made, and key findings.

### 22 **5.3.2.4 Reanalyses of Previously-Reported Particulate Matter Exposure Data**

23 Papers that have reanalyzed and interpreted the data collected in previous PM exposure  
24 studies are summarized in Table 5-6. These reanalyses are directed toward understanding the  
25 personal cloud, the variability in total PM exposure, and the personal exposure-to-ambient  
26 concentration relationships for PM. Brown and Paxton (1998) determined that the high  
27 variability in personal exposure to PM makes the personal-to-ambient PM relationship difficult  
28 to predict. Wallace (2000b) used data from a number of studies to test two hypotheses: elderly  
29 COPD patients have (1) smaller personal clouds and (2) higher correlations between personal  
30 exposure and ambient concentrations compared to healthy elderly, children, and the general  
31 population. The analysis by Wallace (2000a) and three subsequent longitudinal studies

**TABLE 5-6. PAPERS REPORTING REANALYSES OF PARTICULATE MATTER EXPOSURE STUDIES**

Reference	Study Cited	Objectives/Hypotheses	Findings
Wallace (2000a)	PTEAM (Özkaynak et al., 1990; Spengler et al., 1989; Wiener 1988, 1989; Wiener et al., 1990) THEES (Liroy et al., 1990) Nashville COPD (Bahadori et al., 2001) Amsterdam COPD (Janssen et al., 1997, 1998a) Boston COPD (Rojas-Bracho et al., 2000)	Examines the differences between pooled and longitudinal correlations in personal and ambient (or outdoor) data for PM <sub>2.5</sub> and PM <sub>10</sub> .  Discusses the personal cloud for PM <sub>2.5</sub> and PM <sub>10</sub> .  Hypothesizes that COPD patients have (1) smaller personal clouds (supported) and (2) higher correlations of personal exposure with outdoor concentrations because of reduced mobility (not supported).	Median longitudinal correlation coefficient is much higher than the pooled correlation coefficient for the same data sets. Personal cloud for PM <sub>10</sub> : 3-67 µg/m <sup>3</sup> ; PM <sub>2.5</sub> 6-27 µg/m <sup>3</sup> . Personal cloud for elderly COPD was much smaller (PM <sub>10</sub> : 6-11 µg/m <sup>3</sup> ; PM <sub>2.5</sub> ≈ 6 g/m <sup>3</sup> ) than for other healthy populations (PM <sub>10</sub> : 27-56 µg/m <sup>3</sup> ; PM <sub>2.5</sub> : 11-27 µg/m <sup>3</sup> ) of elderly, children, and the general population. However, correlations of personal exposure with ambient concentrations were not higher for elderly COPD than for other groups.
Özkaynak and Spengler (1996)	Dockery and Spengler, 1981  PTEAM (Özkaynak et al., 1996a,b)  Netherlands (Janssen et al., 1995)	Uses statistical modeling techniques to examine the relationship between ambient PM concentrations and personal exposures. Data analysis involves use of air exchange rates, penetration factors, and indoor/outdoor ratios, as well as examining exposure in various microenvironments (traveling, working, outdoors, indoors) activities (exposure to smoke, cooking), and source strengths.	The important components of personal exposures are received during contact with indoor sources, mainly in homes and work places.  Ambient aerosols contribute about 50% or more to the personal PM <sub>10</sub> exposures of the general population. The contribution of ambient aerosols to the total toxicity of inhaled particles is significant.
Brown and Paxton (1998)	THEES (Liroy et al., 1990) PTEAM pilot (Wallace, 1996) Boston and Nashville COPD (Rojas-Bracho et al., 2000); Bahadori et al., 2001)	Cross-sectional and longitudinal regression analysis on data sets.	Individual personal PM exposure is subject to high variability, which makes the personal-to-ambient PM relationship difficult to predict.
Wilson and Suh (1997)	Philadelphia (Burton et al., 1996; Suggs and Burton, 1983)  EPA AIRS database	Determines the utility of fine and coarse PM concentrations as indicators of time-series epidemiology with regard to day-to-day variability, area uniformity, and indoor/outdoor PM ratios.  Necessary to treat personal exposure to ambient PM and personal exposure to nonambient PM as separate components of total personal PM exposure.	Fine and coarse particles should be considered separate classes of pollutants.  Fixed-site ambient fine-particle measurements likely give a reasonable indication of the variability in the concentration of ambient fine particles across the community. Coarse-particle measurements most likely will not.
Wilson et al. (2000)	New Jersey (Liroy et al., 1990) Japan (Tamura et al., 1996a) PTEAM (Clayton et al., 1993; Özkaynak et al., 1996a,b) Netherlands (Janssen, 1998a; Suh et al., 1992)	Synoptic review of the “exposure paradox”: Low correlations between personal exposure and ambient PM concentrations in spite of the existence of statistical association between ambient PM and epidemiologic health effects.  Uses personal exposure equation, mass balance, regression analysis, and deductive logic.	Personal PM exposure needs to be divided into different classes according to source type: exposure to ambient PM (outdoor and indoors) and exposure to nonambient PM (indoor source and personal activity).  Correlations are higher between personal exposure and ambient PM concentrations when PM exposures from nonambient sources are removed.

**TABLE 5-6 (cont'd). PAPERS REPORTING REANALYSES OF PARTICULATE MATTER EXPOSURE STUDIES**

Reference	Study Cited	Objectives/Hypotheses	Findings
Mage et al. (1999)	Japan (Tamura et al., 1996a) State College (Suh et al., 1995) Netherlands (Janssen et al., 1997, 1998a, 1999a) New Jersey (Lioy et al., 1990) PTEAM (Clayton et al., 1993; Özkaynak et al., 1996a,b)	Examines the influence of nonambient PM on total PM concentrations and how it may confound the outdoor/personal PM relationship. Missing data and outlier values created using an algorithm. Linear regression analysis of subsequent data sets.	Variation in daily personal exposure for subjects with similar lifestyles and no ETS exposure are driven by variations in ambient PM concentrations.  Exposure to ambient PM is highly correlated in time with ambient PM concentrations measured at a community site. Indoor PM does not confound the relationship between daily mortality and ambient PM.
Mage (1998)	PTEAM (Clayton et al., 1993; Özkaynak et al., 1993, 1996a,b)	Uses a reduced-form mass-balance model to predict the average fraction of ambient PM to which the average person is exposed.	On average, a person is exposed to > 75% of ambient PM <sub>2.5</sub> and > 64% of ambient PM <sub>10</sub> measured by the community monitor.
Monn (2001)	Multiple Literature Review	To make an objective review of literature published since 1996 as an implicit update to the 1996 U.S. EPA PM AQCD. Emphasis on European studies.	“It is important to note that a personal measurement does not <i>a priori</i> provide more valid data than a stationary ambient measurement, i.e. a personal sample in a study investigating effects from outdoor combustion particles is often influenced by sources other than outdoor sources and may thus confound the exposure-effect outcome.”  “Despite some lack of correlation between personal (PM <sub>10</sub> ) and outdoor values, outdoor fine particle concentrations were strongly associated with mortality and morbidity indicating that outdoor sources (e.g. vehicular emissions) emit the toxic entity (Dockerey et al., 1993; Schwartz et al., 1996).”
Rotko et al. (2000a)	Jantunen et al. (1998) Carrer et al. (1997) Koistinen et al. (1999)	To make a comparison of exposure relationships between the six EXPOLIS European cities (Athens, Basel, Grenoble, Helsinki, Milan, Prague).	Demographic bias exists because women and more-educated individuals are more likely to respond to survey.  Socioeconomic bias exists in low SES subjects less likely to participate in diary keeping and exposure monitoring.  Weighting is required for inter-city comparisons.  Selection bias is not a problem for characterizing physical factors influencing personal exposure.
Rotko et al. (2000b)	Rotko et al. (2000a), Jantunen et al. (1998)	To determine sociodemographic influences of exposure in Helsinki.	Distinct male vs female differences: males had higher exposures to PM <sub>2.5</sub> , related to ETS, and a larger variance between sociodemographic groupings.  No sociodemographic differences existed in outdoor PM <sub>2.5</sub> concentrations.  Lower occupational status contributed to greater PM <sub>2.5</sub> exposures than higher (professional) occupational status.
Rodes et al. (2001)	EPA Baltimore and Fresno 1 and 2	To investigate relationships between the different retirement centers and identify most likely factors influencing personal and indoor concentrations.	Mean personal exposure PM <sub>2.5</sub> was higher than their apartment concentrations. Personal cloud of 3 µg/m <sup>3</sup> for PM <sub>2.5</sub> was negligible but cloud for PM <sub>10</sub> was 20 µg /m <sup>3</sup> . Indoor PM <sub>2.5</sub> data were less than ambient concentrations.

1 (Williams 2000a,b,c; Ebel et al., 2000; Sarnat et al., 2000) supported hypothesis 1 but not  
2 hypothesis 2. Özkaynak and Spengler (1996) showed that at least 50% of personal  $PM_{10}$   
3 exposure for the general population comes from ambient particles. Wilson and Suh (1997)  
4 concluded that fine and coarse particles should be treated as separate classes of pollutants  
5 because of differences in characteristics and potential health effects. Wilson et al. (2000) gave a  
6 review of what they call the “exposure paradox” and determine that personal PM needs to be  
7 divided into different classes according to source type and that correlations between personal and  
8 ambient PM will be higher when nonambient sources of PM are removed from the personal PM  
9 concentration. Mage (1998) conducted analysis using the PTEAM data and showed that the  
10 average person in PTEAM (Riverside, CA in the fall) was exposed to > 75% of ambient  $PM_{2.5}$   
11 and > 64% of ambient  $PM_{10}$ . Mage et al. (1999) used an algorithm to fill in missing data and  
12 outliers to analyzed data sets and show that variation in daily personal exposures for subjects  
13 with similar activity patterns and no ETS exposure are driven by variation in ambient PM  
14 concentrations.

### 16 **5.3.3 Factors Influencing and Key Findings on Particulate Matter** 17 **Exposures**

#### 18 **5.3.3.1 Relationship of Personal/Microenvironmental Particulate Matter with Ambient** 19 **Particulate Matter**

20 Understanding the relationship between ambient site measurements and personal exposure  
21 to PM is important for several reasons. First, it allows us to examine the extent to which  
22 ambient measurements for PM and various PM constituents can serve as surrogates for exposure  
23 to ambient PM or ambient constituents of PM in epidemiological studies. Second, it provides  
24 information that may improve surrogate exposure measurements and, hence, increase the power  
25 of epidemiologic studies. Finally, because compliance with the NAAQS is based on ambient  
26 monitoring, it can be used to understand the effect of regulation on exposures to PM and its  
27 constituents and, hence, can help link the effect of regulations to health outcomes. Many of the  
28 studies summarized in Table 5-4 have analyzed this relationship using measurements of personal  
29 PM exposures and ambient PM concentrations. Of primary interest are the PM concentrations  
30 measured in ambient, indoor, and outdoor air; personal exposure measurements; the statistical  
31 correlations between measurements; and the attenuation and/or infiltration factors developed for

1 personal exposure and indoor microenvironments. Attenuation and infiltration factors are  
2 discussed in Section 5.3.4.3.1. Information on correlation analysis is provided below.

### 3 4 **5.3.3.1.1 Types of Correlations**

5 The three types of correlation data that will be discussed in this section are longitudinal,  
6 “pooled,” and daily-average correlations. *Longitudinal correlations* are calculated when data  
7 from a study includes measurements over multiple days for each subject (longitudinal study  
8 design). Longitudinal correlations describe the temporal relationship between daily personal PM  
9 exposure or microenvironment concentration and daily ambient PM concentration for each  
10 individual subject. The longitudinal correlation coefficient,  $r$ , may differ for each subject.  
11 An analysis of the variability in  $r$  across subjects can be performed with this type of data.  
12 Typically, the median  $r$  is reported along with the range across subjects in the study. *Pooled*  
13 *correlations* are calculated when a study involves one or only a few measurements per subject  
14 and when different subjects are studied on subsequent days. Pooled correlations combine  
15 individual subject/individual day data for the correlation calculation. Pooled correlations  
16 describe the relationship between daily personal PM exposure and daily ambient PM  
17 concentration across all subjects in the study. For some studies, the multiple days of  
18 measurements for each subject were assumed to be independent (after autocorrelation and  
19 sensitivity analysis) and combined together in the correlation calculation (Ebelt et al., 2000).  
20 *Daily-average correlations* are calculated by averaging exposure across subjects for each day.  
21 Daily-average correlations then describe the relationship between the daily average exposure and  
22 daily ambient PM concentration. Cross-sectional is used to refer to both pooled and daily  
23 average correlations, so the meaning of this term must be determined from context.

24 Pooled correlations have been simulated from longitudinal data by using a random-  
25 sampling procedure to select a random day from each subject’s measurements for use in the  
26 correlation. This procedure was repeated many times, and statistics (such as the mean and  
27 standard deviation of the pooled correlation coefficient) were reported (Janssen et al., 1997,  
28 1998a, 1999c).

29 The type of correlation analysis can have a substantial effect on the resulting correlation  
30 coefficient. Mage et al. (1999) mathematically demonstrated that very low correlations between  
31 personal exposure and ambient concentrations could be obtained when people with very different

1 nonambient exposures are pooled, even though their individual longitudinal correlations are  
2 high. The longitudinal studies conducted by Tamura et al. (1996a) and Janssen et al. (1997,  
3 1998a, 1999c) determined that the longitudinal correlations between personal exposure and  
4 ambient PM concentrations were higher than the correlations obtained from a pooled data set.  
5 Wallace (2000a) reviewed a number of longitudinal studies and found that the median  
6 longitudinal correlation coefficient was higher than the pooled correlation coefficient for the  
7 same data (see Tables 1 and 2, Wallace, 2000a).

8 Mage et al. (1999) examined three longitudinal exposure data sets where several subjects  
9 were measured each day. They showed that by averaging daily exposures across subjects, daily-  
10 average correlations could be obtained. These were all higher than the median longitudinal  
11 correlations. Williams et al. (2000a,b) and Evans et al. (2000) have also reported higher  
12 correlation coefficients for daily-average correlations compared to longitudinal correlations. The  
13 higher correlations found between daily-average personal exposures and ambient PM  
14 concentrations, as opposed to lower correlations found between individual exposures and  
15 ambient PM levels, have been attributed to the statistical process of averaging (Ott et al., 2000).  
16 Personal exposures include contributions from nonambient as well as ambient PM  
17 concentrations. When several subjects are measured on the same day, the mean variability due  
18 to variations in nonambient exposures is reduced due to averaging. Therefore, the correlation  
19 between personal exposure and ambient concentrations increases as the number of subjects  
20 measured daily increases. Ott et al. (2000), using the theory on which their Random Component  
21 Superposition (RCS) model is based, predict expected correlations above 0.9 for the PTEAM  
22 study and above 0.70 for the New Jersey study (Lioy et al., 1990) if 25 subjects had been  
23 measured daily in each study.

#### 24 25 **5.3.3.1.2 Correlation Data from Personal Exposure Studies**

26 Measurement data and correlation coefficients for the personal exposure studies described  
27 in Section 5.4.2.1 are summarized in Table 5-7. All data are based on mass measurements. The  
28 studies are grouped by the type of study design, longitudinal or pooled. For each study in  
29 Table 5-7, summary statistics for the total personal PM exposure measurements are presented  
30 as well as statistics for residential indoor, residential outdoor, and ambient PM concentrations  
31 when available. The correlation coefficients ( $r$ ) between total personal PM exposures and

## Abbreviations used:

Avg. = Averaging (time)

Conc. = Concentration

CV = Cardiovascular

d = Day

ETS = Environmental tobacco smoke

h = Hour

i-a = Indoor-ambient correlation

i-o = Indoor-outdoor correlation

L = Longitudinal correlation

Med. = Median

o-a = Outdoor-ambient correlation

P = Pooled correlation

p-i = Personal-indoor correlation

p-o = Personal-outdoor correlation

SD = Standard deviation

Stat. = Statistic

 $\bar{x}$  = Mean

## Notes:

- Sample size is for personal concentrations; indoor, outdoor and ambient sample sizes may differ.
- Correlation coefficient is for personal-residential outdoor if no ambient concentration data reported.
- See text for description of types of correlations.
- Daily-averaged correlation (values for individual subjects averaged for each day).
- Pooled correlations estimated using a Monte Carlo sampling procedure, n = 1000. If mean P is shown, then SD given; if median P is shown, then range is given.
- Obtained from a regression equation;  $r = \sqrt{R^2}$ .
- Spearman rank correlations.
- Calculated,  $r = \sqrt{R^2}$ , from R<sup>2</sup> from a mixed model regression.

1 ambient PM concentrations also are presented and classified as longitudinal or pooled  
2 correlations. When reported, *p*-values for the correlation coefficients are included. Correlation  
3 coefficients between personal, indoor, outdoor, and ambient also are reported when available.  
4

#### 5 **5.3.3.1.3 Correlations Between Personal Exposures, Indoor, Outdoor, and Ambient** 6 **Measurements**

7 Longitudinal and pooled correlations between personal exposure and ambient or outdoor  
8 PM concentrations varied considerably between study and study subjects. Most studies report  
9 longitudinal correlation coefficients that range from  $< 0$  to  $\approx 1$ , indicating that an individual's  
10 activities and residence type may have a significant effect on total personal exposure to PM.  
11 General population studies tend to show lower correlations because of the higher variation in the  
12 levels of PM generating activities. In contrast, the absence of indoor sources for the populations  
13 in several of the longitudinal studies resulted in high correlations between personal exposure and  
14 ambient PM within subjects over time for these populations. But even for these studies,  
15 correlations varied by individual depending on their activities and the microenvironments that  
16 they occupied.  
17

#### 18 **Probability Studies**

19 In the Toronto study (Pellizzari et al., 1999), pooled correlations were derived for personal,  
20 indoor, outdoor, and fixed-site ambient measurements. This study was conducted in Toronto on  
21 a probability sample of 732 participants who represented the general population of people  
22 16 years and older. The study included between 185 and 203 monitoring periods with usable  
23 PM data for personal, residential indoor, and outdoor measurements. For  $PM_{10}$  measurements,  
24 the mean concentrations were  $67.9 \mu\text{g}/\text{m}^3$  for personal,  $29.8 \mu\text{g}/\text{m}^3$  for indoor air, and  $24.3 \mu\text{g}/\text{m}^3$   
25 for outdoor air samples. For  $PM_{2.5}$ , the mean concentrations were  $28.4 \mu\text{g}/\text{m}^3$  for personal,  
26  $21.1 \mu\text{g}/\text{m}^3$  for indoor air, and  $15.1 \mu\text{g}/\text{m}^3$  for outdoor air samples. A low but significant  
27 correlation ( $r = 0.23$ ,  $p < 0.01$ ) was reported between personal exposure and ambient  
28 measurements. The correlations between indoor concentrations and the various outdoor  
29 measurements of  $PM_{2.5}$  ranged from 0.21 to 0.33. The highest correlations were for outdoor  
30 measurements at the residences with the ambient measurements made at the roof site (0.88) and  
31 the other fixed site (0.82). Pellizzari et al. (1999) state that much of the difference among the  
32 data for personal/indoor/outdoor PM:

1 . . . can be attributed to tobacco smoking, since all variables reflecting smoking . . . were  
2 found to be highly correlated with the personal (and indoor) particulate matter levels, relative  
3 to other variables that were measured . . . none of the outdoor concentration data types  
4 (residential or otherwise) can adequately predict personal exposures to particulate matter.  
5 (p. 729)  
6

7 Using a Random Component Superposition (RCS) statistical model, Ott et al. (2000)  
8 calculated an attenuation factor of 0.61 for personal exposure for PM<sub>10</sub> for the Toronto study.  
9 The mean nonambient exposure component for PM<sub>10</sub> was estimated as 52.62 µg/m<sup>3</sup> with a  
10 standard deviation of 84.82 µg/m<sup>3</sup>. Although the data were available for PM<sub>2.5</sub>, similar  
11 calculations were not made.

12 PM<sub>10</sub> data from the PTEAM study were analyzed using the same approach (Ott et al.,  
13 2000). For PTEAM, an attenuation factor of 0.55 was calculated for personal exposure.  
14 Infiltration factors were calculated for each residence with an average of 0.56 and a standard  
15 deviation of 0.15. Values ranged from a minimum of 0.19 to a maximum of 0.87 showing the  
16 substantial variability that can be seen between homes depending upon the housing  
17 characteristics and operation of the HVAC system. The mean nonambient exposure component  
18 for PM<sub>10</sub> was estimated as 59 µg/m<sup>3</sup> with a standard deviation of 46 µg/m<sup>3</sup>.

19 Santos-Burgoa et al. (1998) describe a 1992 study of personal exposures and indoor  
20 concentrations to a randomly sampled population near Mexico City. The sample of 66  
21 monitored subjects included children, students, office and industrial workers, and housewives.  
22 None of the people monitored were more than 65 years old. The mean 24-h personal exposure  
23 and indoor concentrations were 97 ± 44 and 99 ± 50 µg/m<sup>3</sup>, respectively, with an  $r_{\text{Personal/Ambient}}$   
24 = 0.26 (p = 0.099). Other correlations of interest were  $r_{\text{Personal/Indoor}} = 0.47$  (p = 0.002) and  
25  $r_{\text{Indoor/Ambient}} = 0.23$  (p = 0.158). A strong statistical association was found between personal  
26 exposure and socioeconomic class (p = 0.047) and a composite index of indoor sources at the  
27 home (p = 0.039).

28 Correlation analysis for personal exposure has not yet been reported for EXPOLIS. Some  
29 preliminary results (Jantunen et al., 2000) show that in Basel and Helsinki a single ambient  
30 monitoring station was sufficient to characterize the ambient PM<sub>2.5</sub> concentration in each city.  
31 Using microenvironmental concentration data collected while the subjects were at home, at  
32 work, and outdoors, they calculated the sum of the time-weighted-averages of these data and

1 found the results closely match the personal PM<sub>2.5</sub> exposure data collected by the monitors  
2 carried by most of the subjects although a few subjects (mostly smokers) were noticeable  
3 exceptions.

#### 4 5 **Longitudinal Studies**

6 A number of longitudinal studies using a purposeful sampling design have been conducted  
7 and reported in the literature since 1996. A number of these studies (Janssen et al., 1998a,  
8 1999b, 2000; Williams et al., 2000b; Evans et al., 2000) support the previous work by Janssen  
9 et al. (1995) and Tamura et al. (1996a) and demonstrate that for individuals with little exposure  
10 to nonambient sources of PM, correlations between total PM exposure and ambient PM  
11 measurements are high. Other studies (Ebelt et al., 2000; Sarnat et al., 2000) show strong  
12 correlations for the SO<sub>4</sub><sup>-2</sup> component of PM<sub>2.5</sub> but poorer correlations for PM<sub>2.5</sub> mass. Still other  
13 studies show only weak correlations (Rojas-Bracho et al., 2000; Linn et al., 1999; Bahadori  
14 et al., 2001). Even when strong longitudinal correlations are demonstrated for individuals in a  
15 study, the variety of living conditions may lead to variations in attenuating factors or the fraction  
16 of ambient PM contributing to personal exposure. Groups with similar living conditions,  
17 especially if measurements are conducted during one season, may have similar  $\alpha$  and, therefore,  
18 very high correlations between personal exposure and ambient concentrations, even for pooled  
19 correlations. However, when studies contain subjects with homes of very different ventilation  
20 characteristics or cover more than one season, variations in  $\alpha$  can be high across subjects, thus,  
21 showing poor pooled correlations even in the absence of indoor sources.

22  
23 ***Elderly Subjects.*** Janssen et al. (2000) continued their longitudinal studies with  
24 measurements of personal, indoor, and outdoor concentrations of PM<sub>2.5</sub> for elderly subjects with  
25 doctor-diagnosed angina pectoris or coronary heart disease. Studies were conducted in  
26 Amsterdam, Holland, and Helsinki, Finland, in the winter and spring of 1998 and 1999. In the  
27 Amsterdam study with 338 to 417 observations, mean PM<sub>2.5</sub> concentrations were 24.3, 28.6, and  
28 20.6  $\mu\text{g}/\text{m}^3$  for personal, indoor, and outdoor samples, respectively. If the measurements with  
29 ETS in the home were excluded, the mean indoor concentration dropped to 16  $\mu\text{g}/\text{m}^3$ , which was  
30 lower than outdoor concentrations. In the Helsinki study, the mean PM<sub>2.5</sub> concentrations were  
31 10.8  $\mu\text{g}/\text{m}^3$  for personal, 11.0  $\mu\text{g}/\text{m}^3$  for indoor air, and 12.6  $\mu\text{g}/\text{m}^3$  outdoor air samples. The

1 authors note that for this group of subjects, personal exposure, indoor concentrations, and  
2 ambient concentrations of PM<sub>2.5</sub> were highly correlated within subjects over time. Median  
3 Pearson's correlation coefficients between personal exposure and outdoor concentrations were  
4 0.79 in Amsterdam and 0.76 in Helsinki. The median Pearson's r for the indoor/outdoor  
5 relationship was 0.85 for the Amsterdam study when homes with ETS were excluded. The  
6 correlation for indoors versus outdoors was 0.70 for all homes.

7 Results from the correlation analysis can be used to estimate infiltration factors and  
8 penetration factors for these two groups of subjects. In Amsterdam, the attenuation factor was  
9 0.43 and the infiltration factor was 0.47. Very similar results were seen in Helsinki for the  
10 attenuation factor (0.45) and the infiltration factor (0.51).

11 A series of PM personal monitoring studies involving elderly subjects was conducted in  
12 Baltimore County, MD, and Fresno, CA. The first study was a 17-day pilot (January-February  
13 1997) to investigate daily personal and indoor PM<sub>1.5</sub> concentrations, and outdoor PM<sub>2.5</sub> and  
14 PM<sub>2.5-10</sub> concentrations experienced by nonsmoking elderly residents of a retirement community  
15 located near Baltimore (Liao et al., 1999; Williams et al., 2000c). The 26 residents were aged  
16 65 to 89 (mean = 81), and 69% of them reported a medical condition such as hypertension or  
17 coronary heart disease. In addition, they were quite sedentary: on average, less than 5 h day<sup>-1</sup>  
18 were spent on ambulatory activities. Because most of the residents ate meals in a communal  
19 dining area, the average daily cooking time in the individual apartments was only 0.5 h  
20 (range = 0 to 4.5 h). About 96% of the residents' time was spent indoors (Williams et al.,  
21 2000c). Personal monitoring, conducted for five subjects, yielded longitudinal correlation  
22 coefficients between ambient concentrations and personal exposure ranging from 0.00 to 0.90.

23 The Baltimore main study and the Fresno study were conducted using similar monitoring  
24 techniques and study design. Concentrations measured in these studies are summarized in  
25 Table 5-8. For PM<sub>2.5</sub>, personal exposure and indoor air concentrations are similar for all three  
26 studies even though outdoor air concentrations for Fresno in the spring are only half of those  
27 measured for Fresno in the winter and for Baltimore. This result is presumably due to high  
28 penetration efficiencies in the spring in Fresno when the weather was warm and participants kept  
29 the windows and doors of their homes open. These data also show that even when correlations  
30 are high, the use of an ambient monitor as a surrogate for exposure in epidemiologic studies can  
31 bias the strength of the health effect found due to differing exposure levels.

**TABLE 5-8. MEAN CONCENTRATION FOR PM MASS REPORTED FOR THE BALTIMORE (Williams et al., 2000a,b,c) AND THE FRESNO (Evans et al., 2000) STUDIES**

Study	PM <sub>2.5</sub> Concentration (µg/m <sup>3</sup> )			PM <sub>10</sub> Concentration (µg/m <sup>3</sup> )		
	Personal	Indoors	Outdoors	Personal	Indoors	Outdoors
Baltimore	13.0 ± 4.2	10.5 ± 4.9	22.0 ± 12.0	—	13.5 ± 6.3	30.0 ± 13.7
Fresno-Winter	13.3 ± 5.9	9.7 ± 5.0	20.5 ± 13.4	—	15.1 ± 4.1	28.2 ± 15.9
Fresno-Spring	11.1 ± 2.8	8.0 ± 1.8	10.1 ± 3.2	37.3	16.7 ± 3.1	28.7 ± 6.6

1            Calculated correlation coefficients are summarized in Tables 5-9 and 5-10. In Table 5-9,  
2 results for Baltimore show excellent daily average correlations for both PM<sub>2.5</sub> and PM<sub>10</sub>. These  
3 results primarily represent the behavior of fine-particle regional sulfate for a group of  
4 participants who have few indoor or personal sources. However, even for this group, there was a  
5 wide range of individual correlation coefficients. The Fresno data, on the other hand, shows  
6 much poorer daily average correlations. Of special note are the poorer correlations for the  
7 ambient to outdoor residential monitors. This could be due to the higher concentrations of nitrate  
8 in the samples. In addition, the residential site may have been influenced by highway traffic.

**TABLE 5-9. DAILY-AVERAGE CORRELATION COEFFICIENTS REPORTED FOR THE BALTIMORE (Williams et al., 2000a,b,c) AND THE FRESNO (Evans et al., 2000) STUDIES**

Study	PM <sub>2.5</sub> r <sup>2</sup>			PM <sub>10</sub> r <sup>2</sup>
	Ambient/Outdoor	Personal/Ambient	Personal/Indoors	Ambient/Outdoor
Baltimore	0.92	0.80 (0.14-0.80) <sup>a</sup>	0.98 (0.20-0.99) <sup>a</sup>	0.89
Fresno-Winter	0.48	—	—	0.48
Fresno-Spring	0.53	0.70	0.77	0.61

<sup>a</sup>Range for individual participants.

**TABLE 5-10. REGRESSION ANALYSIS REPORTED FOR INDOOR/OUTDOOR RELATIONSHIPS FOR PM<sub>2.5</sub> IN THE BALTIMORE (Williams et al., 2000a,b,c) AND FRESNO (Evans et al., 2000) STUDIES**

Study	Daily Average			Individual		
	r <sup>2</sup>	slope	Intercept (µg/m <sup>3</sup> )	r <sup>2</sup>	slope	Intercept (µg/m <sup>3</sup> )
Baltimore	0.92	0.39	1.5	0.73 ± 0.16	0.43 ± 0.15	0.9 ± 2.6
Fresno-Winter	0.86	nr	nr	0.55 ± 0.25	0.25 ± 0.17	4.4 ± 3.2
Fresno-Spring	0.56	nr	nr	0.39 ± 0.21	0.49 ± 0.38	3.0 ± 3.7

1           The correlation analysis in Table 5-10 shows correlation coefficients as well as the slope  
2 (infiltration factor) and the intercept (indoor concentration due to nonambient sources) for the  
3 Baltimore and Fresno studies. These data show strongest correlations for Baltimore where there  
4 are very low indoor concentrations from nonambient sources. Correlations are not as strong for  
5 Fresno, where there are higher concentrations from nonambient sources. The infiltration factors  
6 for Baltimore and Fresno-Spring are very similar at approximately 0.5. The infiltration factors  
7 for Fresno-Winter are considerably lower.

8  
9           **Subjects with COPD.** Linn et al. (1999) describe a 4-day longitudinal assessment of  
10 personal PM<sub>2.5</sub> and PM<sub>10</sub> exposures (on alternate days) in 30 COPD subjects aged 56 to 83.  
11 Concurrent indoor and outdoor monitoring was conducted at their residences. This study  
12 occurred in the summer and autumn of 1996 in the Los Angeles area. PM<sub>10</sub> data from the nearest  
13 fixed-site monitoring station to each residence also was obtained. Pooled correlations for  
14 personal exposure to outdoor measurements gave R<sup>2</sup> values of 0.26 and 0.22 for PM<sub>2.5</sub> and PM<sub>10</sub>,  
15 respectively. Correlations of day-to-day changes in PM<sub>2.5</sub> and PM<sub>10</sub> measured outside the homes  
16 and correlated with concurrent PM<sub>10</sub> measurements at the nearest ambient monitoring location  
17 gave R<sup>2</sup> values of 0.22 and 0.44, respectively. Correlations of day to day changes in PM mass  
18 measured indoors correlated with outdoor measurements at the homes gave R<sup>2</sup> values of 0.27 and  
19 0.19 for PM<sub>10</sub> and PM<sub>2.5</sub>.

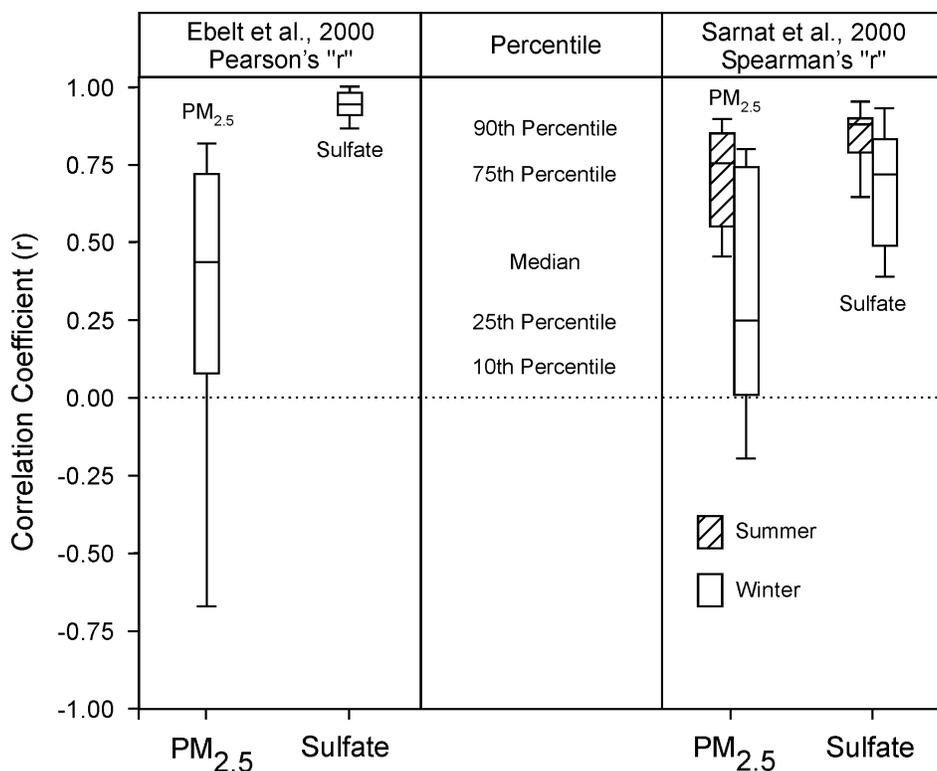

20           Personal, indoor, and outdoor PM<sub>2.5</sub>, PM<sub>10</sub>, and PM<sub>2.5-10</sub> correlations were reported by  
21 Rojas-Bracho et al. (2000) for a study conducted in Boston, MA, on 18 individuals with COPD.  
22 Both the mean and median personal exposure concentrations were higher than the indoor

1 concentrations, which were higher than outdoor concentrations for all three PM measurement  
2 parameters. Geometric mean indoor/outdoor ratios were  $1.4 \pm 1.9$  for  $PM_{10}$ ,  $1.3 \pm 1.8$  for  $PM_{2.5}$ ,  
3 and  $1.5 \pm 2.7$  for  $PM_{2.5-10}$ . Median longitudinal  $R^2$ s between personal exposure and ambient PM  
4 measurements were 0.12 for  $PM_{10}$ , 0.37 for  $PM_{2.5}$  and 0.07 for  $PM_{2.5-10}$ . The relationship between  
5 the indoor and outdoor concentrations was strongest for  $PM_{2.5}$ , with a median  $R^2$  of 0.55 and  
6 11 homes having significant  $R^2$  values. For  $PM_{10}$ , the median  $R^2$  value was 0.25, with significant  
7 values for eight homes. Only five homes had significant indoor/outdoor associations for  $PM_{2.5-10}$ ,  
8 with an insignificant median  $R^2$  value of 0.04. The poor correlations for  $PM_{10-2.5}$  are a result of  
9 poorer penetration efficiencies, higher decay rates, and spatial inhomogeneities.

10 Bahadori et al. (2001) report a pilot study of the PM exposure of 10 nonrandomly chosen  
11 COPD patients in Nashville, TN, during the summer of 1995. Each subject alternately carried a  
12 personal  $PM_{2.5}$  or  $PM_{10}$  monitor for a 12-h daytime period (8 am to 8 pm) for 6 consecutive days.  
13 These same pollutants were monitored simultaneously indoors and outdoors at their homes.  
14 All of the homes were air-conditioned and had low air exchange rates (mean =  $0.57 \text{ h}^{-1}$ ), which  
15 may have contributed to the finding that mean indoor  $PM_{2.5}$  was 66% of the mean ambient  $PM_{2.5}$ .  
16 This can be contrasted with the PTEAM study in Riverside, CA, where no air conditioners were  
17 in use and the mean indoor  $PM_{2.5}$  was 98% of the mean ambient  $PM_{2.5}$  (Clayton et al., 1993).  
18 Data sets were pooled for correlation analysis. Resulting pooled correlations between personal  
19 and outdoor concentrations were  $r = 0.09$  for  $PM_{2.5}$  and  $r = -0.08$  for  $PM_{10}$ .

#### 21 **5.3.3.1.4 Personal Exposure to Sulfate Compared to Personal Exposure to Ambient** 22 **Particulate Matter**

23 A study conducted in Vancouver involving sixteen COPD patients aged 54 to 86 reported  
24 low median longitudinal ( $r = 0.48$ ) and pooled ( $r = 0.15$ ) correlation coefficients between  
25 personal exposures and ambient concentrations of  $PM_{2.5}$  (Ebelt et al., 2000). However, the mean  
26 correlation between personal exposures to sulfate and ambient concentrations of sulfate was  
27 much higher ( $r = 0.96$ ). Because there are typically minimal indoor sources of sulfate, the  
28 relationship between ambient concentrations and personal exposures to sulfate would not be  
29 weakened by variability in an indoor-generated sulfate component as for example in the case of  
30  $PM_{2.5}$  for which there are many primary indoor sources as well as some secondary indoor  
31 sources. Correlations of ambient concentrations versus personal exposures for  $PM_{2.5}$  and sulfate  
32 are compared in Figure 5-3.

**Figure 5-3. Comparison of correlation coefficients for longitudinal analyses of personal exposure versus ambient concentrations for individual subjects for PM<sub>2.5</sub> and sulfate.**

1 Another study, conducted in Baltimore, MD, involved 15 nonsmoking adult subjects  
 2 (> 64 years old) who were monitored for 12 days during Summer 1998 and Winter 1999 (Sarnat  
 3 et al., 2000). All subjects (nonrandom selection) were retired, physically healthy, and lived in  
 4 nonsmoking private residences. Each residence, except one, was equipped with central  
 5 air-conditioning; however, not all residences used air-conditioning throughout the summer. The  
 6 average age of the subjects was 75 years ( $\pm$  6.8 years). Sarnat et al. (2000) reported higher  
 7 longitudinal and pooled correlations for PM<sub>2.5</sub> during summer than winter. Similar to Ebelt et al.  
 8 (2000), Sarnat et al. (2000) reported stronger associations between personal exposure to SO<sub>4</sub><sup>-2</sup>  
 9 and ambient concentrations of SO<sub>4</sub><sup>-2</sup> than for total personal PM<sub>2.5</sub> exposure and ambient PM<sub>2.5</sub>  
 10 concentrations. The ranges of correlations are shown in Figure 5-1 along with similar data from  
 11 Ebelt et al. (2000).

1           The higher correlation coefficients and the narrower range of the correlation coefficient for  
2 sulfate suggest that removing indoor-generated and personal activity PM from total personal PM  
3 would result in a higher correlation with ambient concentrations. If, as discussed in 5.3.4.3.1,  
4 there are no indoor sources, a personal exposure measurement for sulfate gives the ambient  
5 exposure of sulfate; the ratio of personal sulfate to ambient sulfate gives the attenuation  
6 coefficient on an individual, daily basis; and the attenuation coefficient times the ambient  $PM_{2.5}$   
7 concentration gives the individual, daily values of ambient  $PM_{2.5}$  exposures (Wilson et al., 2000).  
8 This technique applies only to the nonvolatile components of fine PM, as measured by  $PM_{2.5}$ .  
9 It requires that the sulfate concentration be large enough so that it can be measured with  
10 reasonable accuracy. It does not require that sulfate be correlated with  $PM_{2.5}$  or the non-sulfate  
11 components of  $PM_{2.5}$  because the sulfate data is used to estimate the attenuation coefficient not  
12  $PM_{2.5}$ . The technique does require that there be minimal indoor sources of sulfate, as indicated  
13 by a near-zero intercept for the regression, and that the size distribution of  $PM_{2.5}$  and sulfate be  
14 similar.

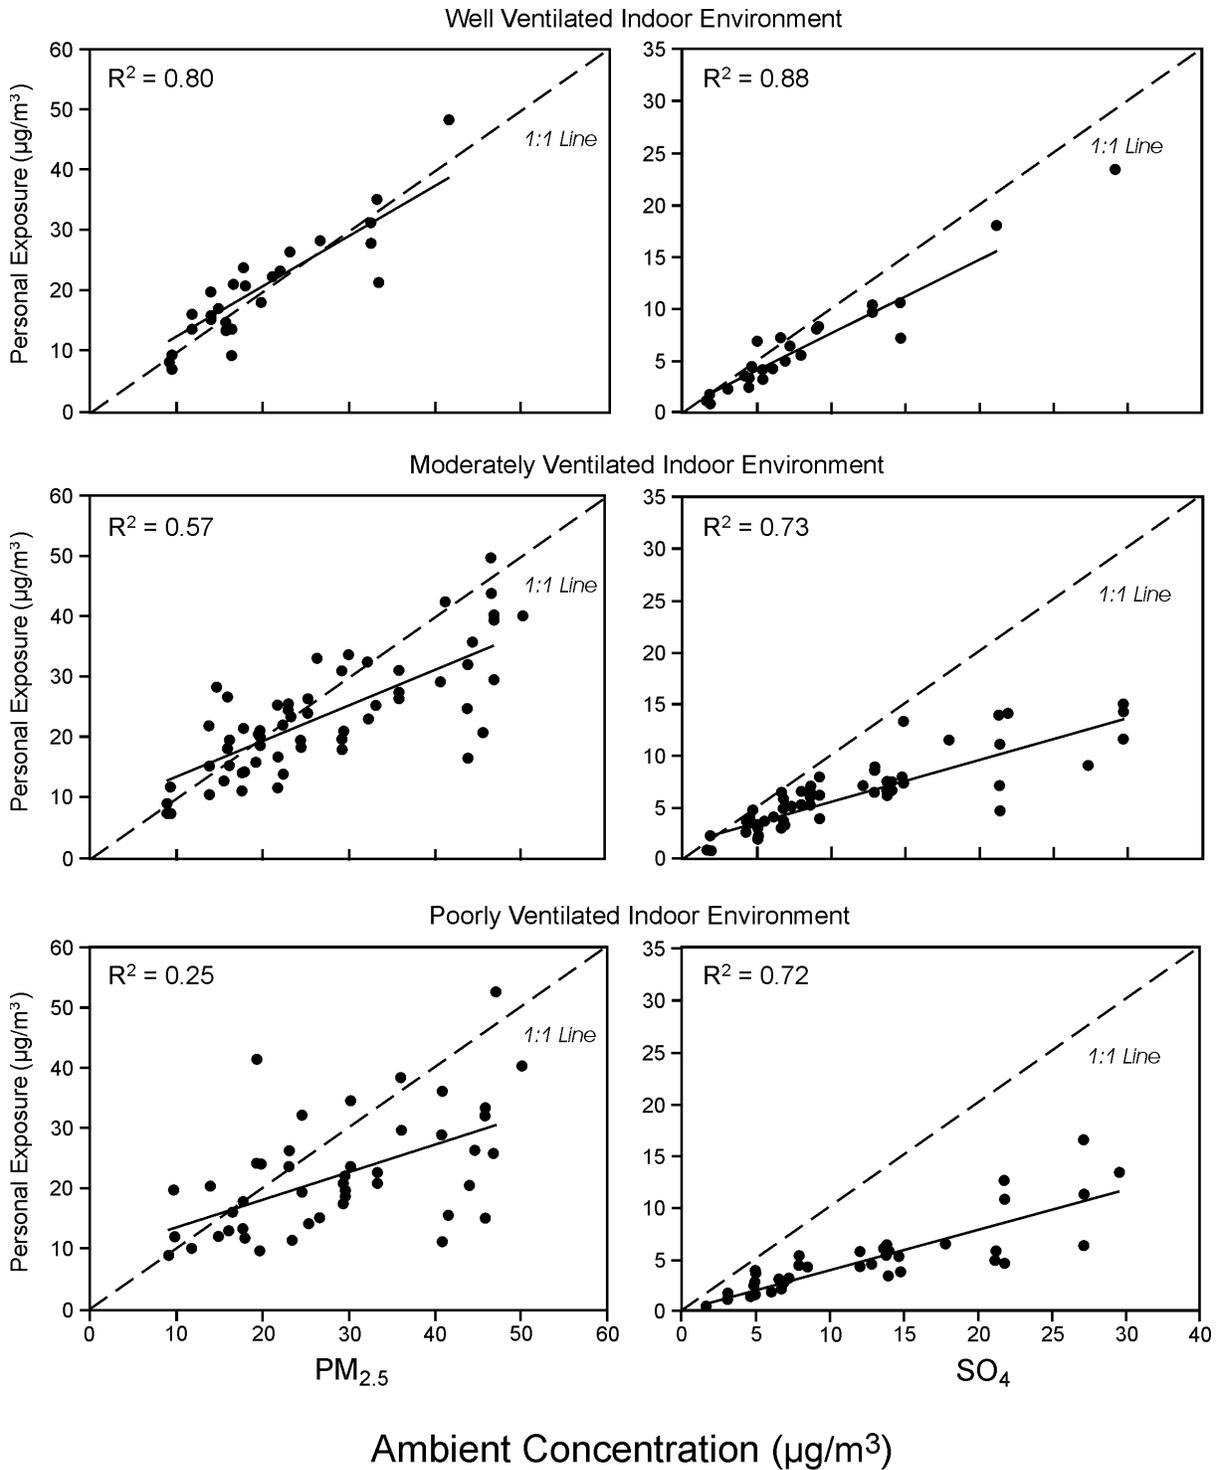

15           Sarnat et al. (2001) subsequently extended the Baltimore study to include 20 older adults,  
16 21 children, and 15 individuals with COPD for a total of 56 subjects. In both studies (Sarnat  
17 et al., 2000, 2001), they used their personal and ambient sulfate data to estimate the ambient  
18  $PM_{2.5}$  exposure. They used this information in mixed-model analysis (mixed models account for  
19 differences among individual subjects), but did not report correlations between ambient  $PM_{2.5}$   
20 exposure and ambient  $PM_{2.5}$  concentrations based on the pooled data set. However, Sarnat et al.  
21 (2001) did report slopes from the mixed model analyses. The t-statistic for the slope of ambient  
22 exposure versus ambient concentration as compared to total personal exposure versus ambient  
23 concentration increased from 9.96 to 11.12 (total exposure vs. ambient concentration) for the  
24 summer period and from 4.36 to 19.88 (ambient exposure vs. ambient concentration) for the  
25 winter period.

26           The study conducted by Sarnat et al. (2000) also illustrates the importance of ventilation on  
27 personal exposure to PM. During the summer, subjects recorded the ventilation status of every  
28 visited indoor location (e.g., windows open, air-conditioning use). As a surrogate for the air  
29 exchange rate, personal exposures were classified by the fraction of time the windows were open  
30 while a subject was in an indoor environment ( $F_v$ ). Sarnat et al. (2000) report regression  
31 analyses of personal exposure on ambient concentration for  $PM_{2.5}$  and for sulfate for each of the

1 three ventilation conditions (Figure 5-4). The correlation between personal exposure and  
2 ambient concentration is higher for sulfate than for PM<sub>2.5</sub>, presumably because PM<sub>2.5</sub> has indoor  
3 sources as well as ambient sources but sulfate has only ambient sources. As expected, the  
4 improvement is better for the lower ventilation conditions because under these conditions the  
5 ambient concentration is larger. For the lowest ventilation condition, R<sup>2</sup> improves from 0.25 to  
6 0.72.

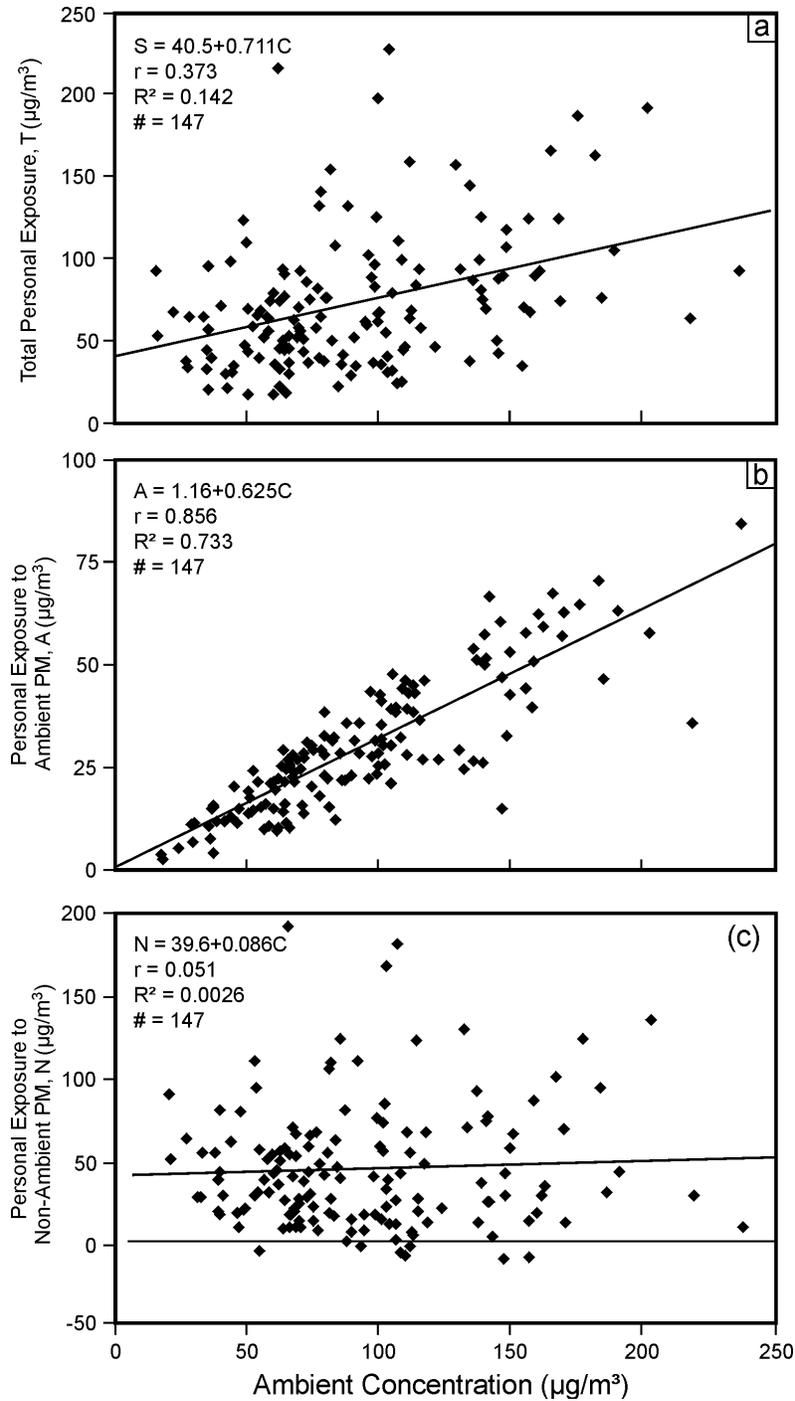

#### 7 8 **5.3.3.1.5 Personal Exposure to Ambient and Nonambient Particulate Matter**

9 The utility of treating personal exposure to ambient PM, A, and personal exposure to  
10 nonambient PM, N, as separate and distinct components of total personal exposure to PM, T,  
11 was pointed out by Wilson and Suh (1997). The PTEAM study measured, in addition to indoor,  
12 outdoor, and personal PM<sub>10</sub>, the air exchange rate for each home and collected information on  
13 the time spent in various indoor and outdoor microenvironments. This information is available  
14 for 147 12-h daytime periods. With this information and statistically estimated values of *P* and  
15 *k*, it is possible to estimate the daytime A and N as described in Section 5.2.4.3. Various  
16 examples of this information have been reported (Mage et al., 1999; Wilson et al., 2000).  
17 Graphs showing the relationships between ambient concentration and the various components of  
18 personal exposure (T, A, and N) are shown in Figure 5-5. The correlation coefficient for the  
19 pooled data set improves from  $r = 0.377$  for T versus C (Figure 5-5a) to  $r = 0.856$  for A versus C  
20 (Figure 5-5b) because of the removal of the N, which, as shown in Figure 5-5c, is highly variable  
21 and independent of C. The correlation between A and C is less than 1.0 because of the  
22 day-to-day variation in the  $\alpha$  of each individual. The regression of T on C gives  $\bar{\alpha} = 0.711$   
23 and  $\bar{N} = 81.6 \mu\text{g}/\text{m}^3$ . The regression of A on C gives  $\bar{\alpha} = 0.625$ . The regression of N on C  
24 gives  $\bar{N} = 79.2 \mu\text{g}/\text{m}^3$ . The finite intercept in the regression with A must be attributed to bias or  
25 error in some of the measurements. No reported studies, other than PTEAM, have provided the  
26 quantity of data on individual, daily values of T, C, C<sub>i</sub>, and *a* that are required to conduct an  
27 analysis comparable to that shown in Figure 5-5. It should be noted that the PTEAM study was  
28 conducted in southern California in the fall, when houses were open and air exchange rates were  
29 high and relatively uniform. These are best case conditions for showing high correlations  
30 between ambient site measurements and personal correlations. Such high correlations are not  
31 usually found and would not be expected with lower and more variable air exchange rates.

**Figure 5-5. Regression analyses of aspects of daytime personal exposure to  $\text{PM}_{10}$  estimated using data from the PTEAM study. (a) Total personal exposure to PM,  $T$ , regressed on ambient concentration,  $C$ . (b) Personal exposure to ambient PM,  $A$  regressed on  $C$ . (c) Personal exposure to nonambient PM,  $N$  regressed on  $C$ .**

Source: Data taken from Clayton et al. (1993). Adapted from Mage et al. (1999) and Wilson et al. (2000).

1           The RCS model introduced by Ott et al. (2000) presents a modeling framework to  
2 determine the average contribution of ambient PM<sub>10</sub> and indoor-generated PM<sub>10</sub> to average  
3 personal exposures in large urban metropolitan areas. The model has been tested using personal,  
4 indoor, and outdoor PM<sub>10</sub> data from three urban areas (Riverside, CA; Toronto; and Phillipsburg,  
5 NJ). Results suggest that it is possible to separate the average ambient and nonambient PM  
6 contributions to personal exposures on a community-wide basis. However, as discussed in the  
7 paper, the authors make some assumptions that require individual consideration in each-city  
8 specific application of the model for exposure or health effects investigations. Primarily,  
9 housing factors, air-conditioning, seasonal differences, and complexities in time-activity profiles  
10 specific to the cohort being studied have to be taken into account prior to adopting the model to a  
11 given situation. Finally, this and other available exposure-based analyses presented here do not  
12 yet predict the relative contribution of indoor and outdoor PM to particle mass burden to the lung  
13 as a function of human activities and different microenvironmental sources and concentrations of  
14 PM and its co-pollutants.

### 16 **5.3.3.2 Factors That Affect Relationships Between Personal Exposure and Ambient PM**

17           A number of factors will affect the relationship between personal exposure and PM  
18 measured at ambient-site community monitors. Spatial variability in outdoor  
19 microenvironmental concentrations and variations in penetration into indoor microenvironments  
20 will influence the relationship to ambient PM. Air exchange rates and decay rates in indoor  
21 microenvironments will influence the relationship to both ambient and total PM whereas  
22 personal activities will influence the relationship to total PM but not ambient PM. Information  
23 on these effects is presented in detail in the following sections.

#### 25 **5.3.3.2.1 Spatial Variability and Correlations Over Time**

26           Chapter 3, Section 3.2.3, presents information on the spatial variability of PM mass and  
27 chemical components at fixed-site ambient monitors; for purposes of this chapter, this spatial  
28 variability is called an “ambient gradient.” The data presented in Section 3.2.3 indicate that  
29 ambient gradients of PM and its constituents exist in urban areas to a greater or lesser degree.  
30 This gradient and any that may exist between a fixed-site monitor and the outdoor  
31 microenvironments near where people live, work, and play obviously affects exposure. The

1 purpose of this section is to review the available data on ambient monitor-to-outdoor  
2 microenvironmental concentration gradients or relationships that have been measured by  
3 researchers since 1996. These analyses below are, in general, consistent with the previous  
4 studies covered in the 1996 PM AQCD. A few outdoor-to-outdoor monitoring studies also are  
5 included to highlight relationships among important microenvironment categories. To assess  
6 spatial variability or gradients, the spatial correlations in the data are usually analyzed.  
7 However, it should be noted that high temporal correlation between two monitoring locations  
8 does not imply low spatial variability or low ambient gradients. High temporal correlation  
9 between two sites indicates that changes in concentrations at one site can be estimated from data  
10 at another site.

11 In a paper on the EXPOLIS-EAS study, Oglesby et al. (2000) conclude that in Basel,  
12 Switzerland little spatial variability exists between PM levels measured at fixed site monitors  
13 and the participants' outdoor microenvironments. The authors report a high correlation between  
14 home outdoor PM<sub>2.5</sub> levels (48-h measurements beginning and ending at 8:00 a.m.) and the  
15 corresponding 24-h average PM<sub>4</sub> (time-weighted values calculated from midnight to midnight)  
16 measured at a fixed monitoring station (n = 38, r<sub>sp</sub> = 0.96, p < 0.001). They considered each  
17 home outdoor monitor as a temporary fixed monitor and concluded that "the PM<sub>2.5</sub> level  
18 measured at home outdoors . . . represents the fine particle level prevailing in the city of Basel  
19 during the 48-h measuring period."

20 In a study conducted in Helsinki, Finland, Buzorius et al. (1999) concluded that a single  
21 monitor may be used to adequately describe the temporal variations in concentration across the  
22 metropolitan area. Particle size distributions were measured using a differential mobility particle  
23 sizer (DMPS; Wintlmayer) coupled with a condensation particle counter (CPC TSI 3010, 3022)  
24 at four locations including the official air monitoring station, which represented a "background"  
25 site. The monitoring period varied between 2 weeks and 6 months for the sites, and data were  
26 reported for 10-min and 1-, 8-, and 24-h averages. As expected, temporal variation decreased as  
27 the averaging time increased. The authors report that particle number concentration varied in  
28 magnitude with local traffic intensity. Linear correlation coefficients computed for all possible  
29 site-pairs and averaging times showed that the correlation coefficient improved with increasing  
30 averaging time. Using wind speed and direction vectors, lagged correlations were calculated and  
31 were generally higher than the "raw" data correlations. Weekday correlations were higher than

1 weekend correlations as “traffic provides relatively uniform spatial distribution of particulate  
2 matter” (p. 565). The authors conclude that, even for time periods of 10 min and 1 h, sampling  
3 at one station can describe temporal variations across relatively large areas of the city with a  
4 correlation coefficient  $> 0.7$ .

5 Dubowsky et al. (1999) point out that, although the variation of  $PM_{2.5}$  mass concentration  
6 across a community may be small, there may be significant spatial variations of specific  
7 components of the total mass on a local scale. An example is given of a study of concentrations  
8 of polycyclic aromatic hydrocarbons (PAH) at three indoor locations in a community:  
9 (1) an urban site, (2) a semi-urban site 1.6 km away, and (3) a suburban site located further  
10 away. The authors found the geometric mean PAH concentrations at these three locations varied  
11 respectively as 31:19:8  $ng/m^3$  and suggest that the local variations in traffic density were  
12 responsible for this gradient. Note that these concentrations are 1,000 times lower than the total  
13 PM mass concentration so that such a small gradient would not be detectable for total  $PM_{2.5}$  mass  
14 measurements on the order of 25  $\mu g m^{-3}$ .

15 The Total Human Environmental Exposure Study (THEES) reported by Waldman et al.  
16 (1991) measured indoor, outdoor, and personal benzo(a)pyrene (BaP) levels and found that the  
17 outdoor BaP was the same at all outdoor sites across the three sampling periods. This study  
18 showed the seasonal differences versus BaP levels and exposures due to indoor and outdoor  
19 sources and individual activities.

20 Leaderer et al. (1999) monitored 24-h  $PM_{10}$ ,  $PM_{2.5}$ , and sulfates during the summers of  
21 1995 and 1996 at a regional site in Vinton, VA (6 km from Roanoke, VA). One similar 24-h  
22 measurement was made outdoors at residences in the surrounding area at distances ranging from  
23 1 km to  $> 175$  km from the Vinton site, at an average separation distance of 96 km. The authors  
24 reported significant correlations for  $PM_{2.5}$  and sulfates between the residential outdoor values  
25 and those measured at Vinton on the same day. In addition, the mean values of the regional site  
26 and residential site  $PM_{2.5}$  and sulfates showed no significant differences in spite of the large  
27 distance separations and mountainous terrain intervening in most directions. However, for the  
28 concentrations of  $PM_{2.5-10}$  estimated as  $PM_{10}-PM_{2.5}$ , no significant correlation among these sites  
29 was found ( $n = 30$ ;  $r = -0.20$ ).

30 Lillquist et al. (1998) found no significant gradient in  $PM_{10}$  concentrations in Salt Lake  
31 City, UT, when levels were low, but a gradient existed when levels were high.  $PM_{10}$

1 concentrations were measured outdoor at three hospitals using a Minivol 4.01 sampler  
2 (Airmetrics, Inc.) operating at 5 L min<sup>-1</sup> and at the Utah Department of Air Quality (DAQ)  
3 ambient monitoring station located between 3 and 13 km from the hospitals for a period of about  
4 5 mo.

5 Pope et al. (1999) monitored ambient PM<sub>10</sub> concentrations in Provo, UT (Utah Valley),  
6 during the same time frame the following year and reported nearly identical concentrations at  
7 three sites separated by 4 to 12 km. Pearson correlation coefficients for the data were between  
8 0.92 and 0.96. The greater degree of variability in the Salt Lake City PM<sub>10</sub> data relative to the  
9 Provo data may be related to the higher incidence of wind-blown crustal material in Salt Lake  
10 City. Pope et al. (1999) reported that increased adverse health effects in the Utah Valley were  
11 associated with stagnation and thermal inversions trapping anthropogenically derived PM<sub>10</sub>;  
12 whereas, no increases in adverse health effects were observed when PM<sub>10</sub> levels were increased  
13 during events of wind blown crustal material.

14 Väkevä et al. (1999) found significant vertical gradients in submicron particles existed in  
15 an urban street canyon of Lahti, Finland. Particle number concentrations were measured using a  
16 TSI screen diffusion battery and a condensation particle counter at 1.5 and 25 m above the street  
17 at rooftop level. The authors found a fivefold decrease in concentration between the two  
18 sampling heights and attributed the vertical gradient to dilution and dispersion of pollutants  
19 emitted at street level.

20 White (1998) suggests that the higher random measurement error for the coarse PM  
21 fraction compared to the error for the fine PM fraction may be responsible for a major portion of  
22 the apparent greater spatial variability of coarse ambient PM concentration compared to fine  
23 ambient PM concentration in a community (e.g., Burton et al., 1996; Leaderer et al., 1999).  
24 When PM<sub>2.5</sub> and PM<sub>10</sub> are collected independently, and the coarse fraction is obtained by  
25 difference ( $PM_{2.5-10} = PM_{10} - PM_{2.5}$ ), the expected variance in the coarse fraction is influenced by  
26 the variances of the PM<sub>10</sub> and PM<sub>2.5</sub> measurements. When a dichotomous sampler collects PM<sub>2.5</sub>  
27 and PM<sub>2.5-10</sub> on two separate filters, the coarse fraction also is expected to have a larger error than  
28 the fine fraction. There is a possible error caused by loss of mass below the cut-point size and a  
29 gain of mass above the cut-point size that is created by the asymmetry of the product of the  
30 penetration times PM concentration about the cut-point size. Because a dichotomous PM

1 sampler collects coarse mass using an upper and lower cut-point, it is expected to have a larger  
2 variance than for fine mass collected using only one cut-point.

3 Wilson and Suh (1997) conclude that  $PM_{2.5}$  and  $PM_{10}$  concentrations are correlated more  
4 highly across Philadelphia than are  $PM_{2.5-10}$  concentrations. Ambient monitoring data from 1992  
5 to 1993 was reviewed for  $PM_{2.5}$ ,  $PM_{2.5-10}$ , and  $PM_{10}$ , as well as for  $PM_{2.5}$  and  $PM_{2.5-10}$  dichotomous  
6 data for 212 site-years of information contained in the AIRS database (U.S. Environmental  
7 Protection Agency, 2000). The authors also observed that  $PM_{10}$  frequently was correlated more  
8 highly with  $PM_{2.5}$  than with  $PM_{2.5-10}$ . The authors note that  $PM_{2.5}$  constitutes a large fraction of  
9  $PM_{10}$  and that this is the likely reason for the strong agreement between  $PM_{2.5}$  and  $PM_{10}$ . Similar  
10 observations were made by Keywood et al. (1999) in six Australian cities. The authors reported  
11 that  $PM_{10}$  was more highly correlated with  $PM_{2.5}$  than with coarse PM ( $PM_{2.5-10}$ ) suggesting that  
12 “variability in  $PM_{10}$  is dominated by variability in  $PM_{2.5}$ .”

13 Lippmann et al. (2000) examined the site-to-site temporal correlations in Philadelphia  
14 (1981 to 1994) and found the ranking of median site-to-site correlation was  $O_3$  (0.83),  $PM_{10}$   
15 (0.78), TSP (0.71),  $NO_2$  (0.70), CO (0.50), and  $SO_2$  (0.49). The authors explain that  $O_3$  and a  
16 fraction of TSP and  $PM_{10}$  (e.g., sulfate) are secondary pollutants that would tend to be distributed  
17 more uniformly spatially within the city than primary pollutants such as CO and  $SO_2$  which are  
18 more likely to be influenced by local emission sources. Lippman et al. (2000) conclude “Thus,  
19 spatial uniformity of pollutants may be due to area-wide sources, or to transport (e.g., advection)  
20 of fairly stable pollutants into the urban area from upwind sources. Relative spatial uniformity  
21 of pollutants would therefore vary from city to city or region to region.”

22 Goswami et al. (2002) used data collected at outdoor monitors of homes in a large  
23 exposure study in Seattle, WA to analyze the spatial variability of outdoor  $PM_{2.5}$  concentrations.  
24 The day-to-day variability between sites was 10 times higher than the spatial variability between  
25 sites. However, differences between sites was sufficient to potentially contribute to  
26 measurement error. An examination of the spatial characteristics of the monitoring sites showed  
27 that the most representative monitoring sites were located at elevations of 80-120 m above sea  
28 level and at distances of 100-300 m from the nearest arterial road.

1 **5.3.3.2.2 Physical Factors Affecting Indoor Microenvironmental Particulate Matter**  
2 **Concentrations**

3 Several physical factors affect ambient particle concentrations in the indoor  
4 microenvironment including air exchange, penetration, and particle deposition. Combined, these  
5 factors are critical variables that describe ambient particle dynamics in the indoor  
6 microenvironments and, to a large degree, significantly affect an individual’s personal exposure  
7 to ambient particles while indoors. The relationship between the concentrations of ambient  
8 particles outdoors,  $C$ , and ambient particles that have infiltrated indoors,  $C_{ai}$ , is given by  
9

10 
$$C_{ai} / C = Pa / (a + k), \quad (5-14)$$

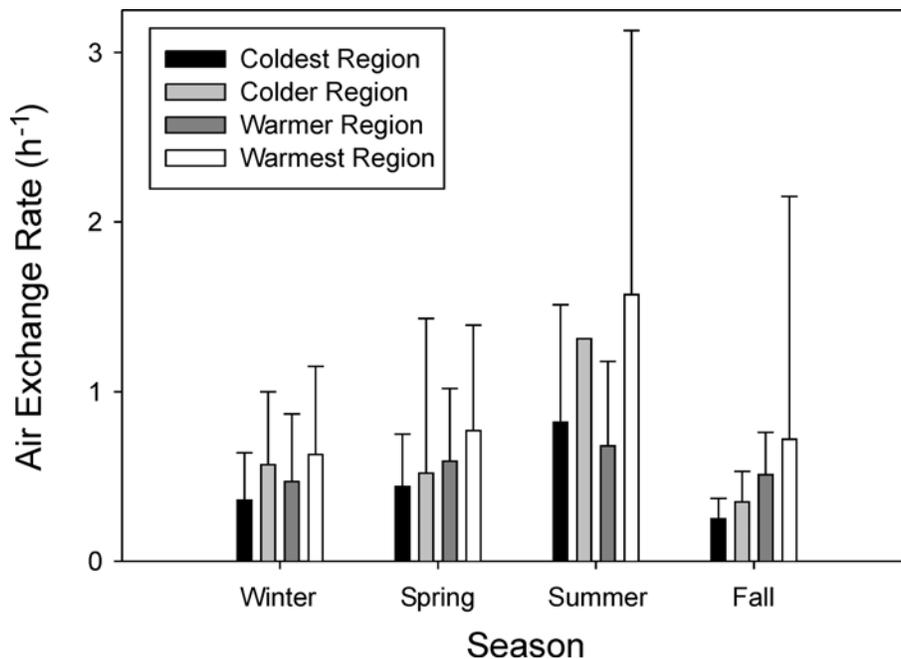

11  
12 where  $P$  is the penetration factor;  $a$  is the air exchange rate; and  $k$  is the particle deposition rate.  
13 (As discussed in Section 5.3.2.3.1, use of this model assumes equilibrium conditions and  
14 assumes that all variables remain constant.) Particle penetration is a dimensionless quantity that  
15 describes the fraction of ambient particles that effectively penetrates the building shell. “Air  
16 exchange” is a term used to describe the rate at which the indoor air in a building or residence is  
17 replaced by outdoor air. The dominant processes governing particle penetration are air exchange  
18 and deposition of particles as they traverse through cracks and crevices and other routes of entry  
19 into the building. Although air exchange rates have been measured in numerous studies, very  
20 few field data existed prior to 1996 to determine size-dependent penetration factors and particle  
21 deposition rates. All three parameters ( $P$ ,  $a$ , and  $k$ ) may vary substantially depending on  
22 building type, region of the country, and season. In the past several years, researchers have  
23 made significant advancements in understanding the relationship between particle size and  
24 penetration factors and particle deposition rates. This section will highlight the studies that have  
25 been conducted to better understand physical factors affecting indoor particle dynamics.  
26

27 **Air Exchange Rates**

28 The air exchange rate,  $a$ , in a residence varies depending on a variety of factors, including  
29 geographical location, age of the building, the extent to which window and doors are open, and  
30 season. Murray and Burmaster (1995) used measured values of  $a$  from households throughout  
31 the United States to describe empirical distributions and to estimate univariate parametric

1 probability distributions of air exchange rates. Figure 5-6 shows the results classified by season  
 2 and region. In general,  $a$  is highest in the warmest region and increases from the coldest to the  
 3 warmest region during all seasons. Air exchange rates also are quite variable within and  
 4 between seasons, as well as between regions (Figure 5-6). Data from the warmest region in  
 5 summer should be viewed cautiously as many of the measurements were made in Southern  
 6 California in July when windows were more likely to be open than in other areas of the country  
 7 where air-conditioning is used. Use of air-conditioning generally results in lowering air  
 8 exchange rates. In a separate analysis of these data, Koontz and Rector (1995) suggested that a  
 9 conservative estimate for air exchange in residential settings would be  $0.18 \text{ h}^{-1}$  (10<sup>th</sup> percentile)  
 10 and a typical air exchange would be  $0.45 \text{ h}^{-1}$  (50<sup>th</sup> percentile).

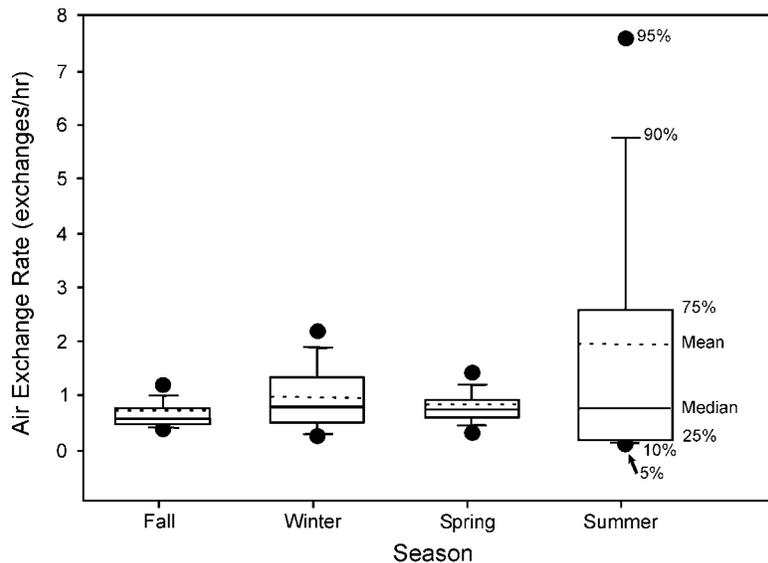

11  
 12

**Figure 5-6. Air exchange rates measured in homes throughout the United States. Climatic regions are based on heating-degree days: Coldest region  $\geq 7000$ , Colder region = 5500 to 6999, Warmer region = 2500 to 4999, and Warmest region  $\leq 2500$  heating-degree days.**

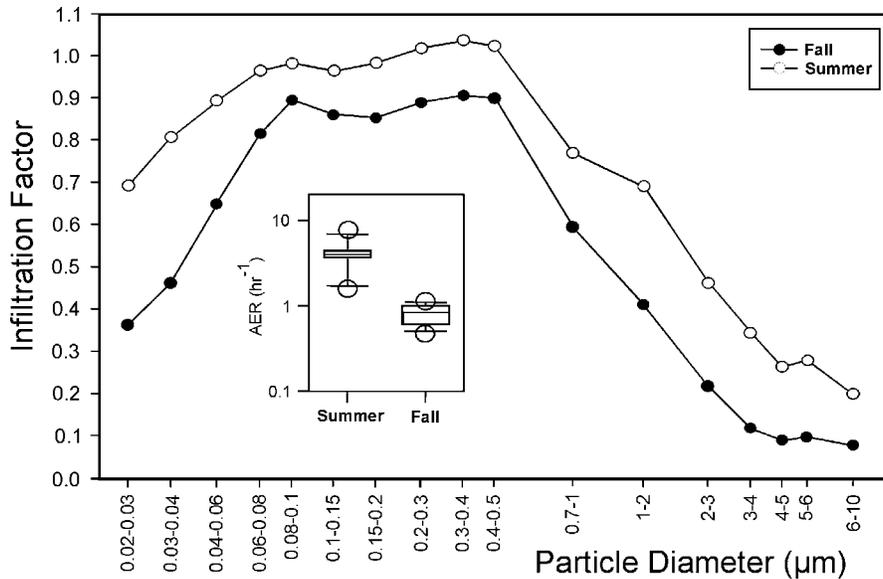

Source: Adapted from Murray and Burmaster (1995).

1            These data provide reasonable experimental evidence that *a* varies by season in locations  
2 with distinct seasons. As a result, infiltration of ambient particles may be more efficient during  
3 warmer seasons when windows are likely to be opened more frequently and air exchange rates  
4 are higher. This suggests that the fraction of ambient particles present in the indoor  
5 microenvironment would be greater during warmer seasons than colder seasons. For example, in  
6 a study conducted in Boston, MA, participants living in non-air-conditioned homes kept the  
7 windows closed except during the summer (Long et al., 2000). This resulted in higher and more  
8 variable air exchange rates in summer than during any other season (Figure 5-7). During  
9 nighttime periods when indoor sources are negligible, the indoor/outdoor concentration ratio or  
10 infiltration factor may be used to determine the relative contribution of ambient particles in the  
11 indoor microenvironment. Particle data collected during this study were used to determine the  
12 indoor/outdoor concentration ratios by particle size (Figure 5-8). For these nine homes in  
13 Boston the fraction of ambient particles penetrating indoors was higher during summer when air  
14 exchange rates were higher than during fall when air exchange rates were lower (Long et al.,  
15 2001a).  
16

Source: Long et al. (2001a).

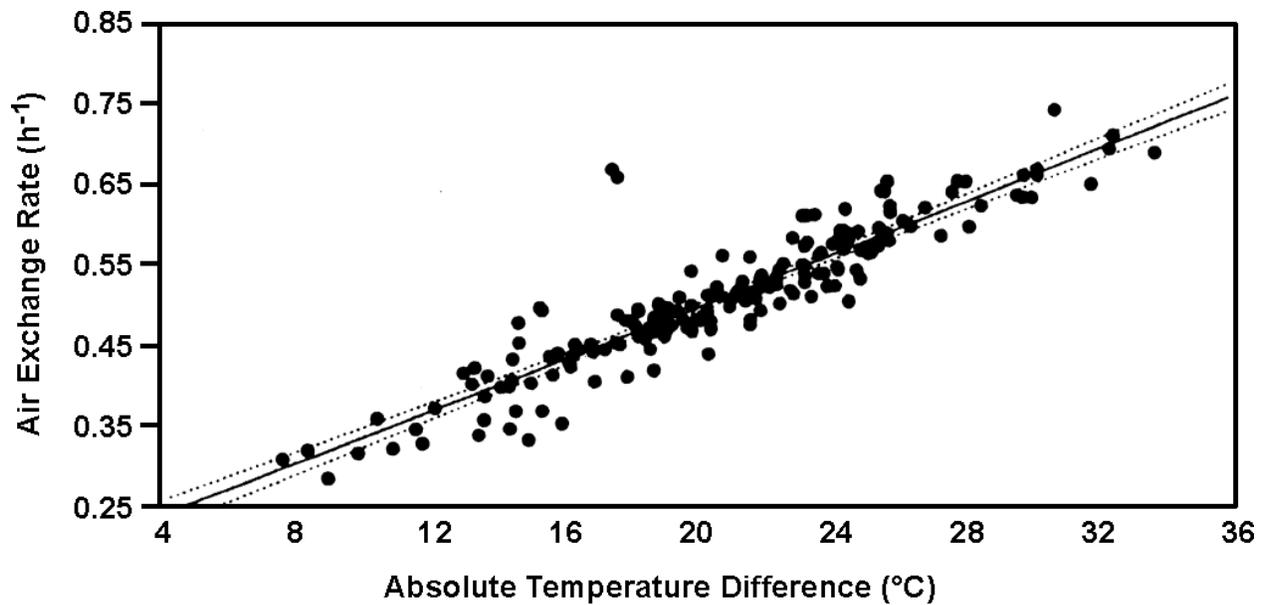

1 Wallace et al. (2002) conducted a year-long investigation of air rates in an occupied house  
 2 to establish the effects of temperature, wind velocity, use of exhaust fans, and window-opening  
 3 behavior. Air exchange rates were calculated by periodically injecting a tracer gas ( $\text{SF}_6$ ) into the  
 4 return air duct and measuring the concentration in 10 indoor locations sequentially every minute  
 5 by a gas chromatograph equipped with an electron capture detector. Temperature and relative  
 6 humidity were measured outdoors and in multiple indoor locations. Wind speed and direction in  
 7 the horizontal plane were also measured. Use of the thermostat-controlled attic fan was recorded  
 8 automatically. Indoor temperatures increased from 21 °C in winter to 27 °C in summer.  
 9 Windows were open only a few percent of the time in winter but more than half the time in  
 10 summer. About 4600 hour-long average air exchange rates were calculated from the measured  
 11 tracer gas decay rates. The mean (SD) rate was 0.65 (0.56)  $\text{h}^{-1}$ . Tracer gas decay rates in  
 12 different rooms were very similar, ranging only from 0.62 to 0.67  $\text{h}^{-1}$ , suggesting that conditions  
 13 were well mixed throughout the year. The strongest influence on air change rates was opening  
 14 windows, which could increase the rate to as much as 2  $\text{h}^{-1}$  for extended periods, and up to 3  $\text{h}^{-1}$

1 for short periods of a few hours. The use of the attic fan also increased air change rates by  
2 amounts up to 1 h<sup>-1</sup>. Use of the furnace fan had no effect on air change rates (ducts were all  
3 inside the house). A clear effect of indoor-outdoor temperature difference ( $\Delta T$ ) could be  
4 discerned. However, wind speed and direction were found to have very little influence on air  
5 change rates at the house where the measurements were made.

6 The air exchange rate,  $a$ , is a critical parameter in determining the fraction of ambient PM  
7 found indoors and the extent of build-up of indoor PM due to indoor sources. Wallace et al.  
8 (2002) provide a brief review of the existing literature on the theory and measurement of air  
9 exchange rates. Open windows and frequent opening of doors lead to higher values of  $a$ .  
10 However, many homes are kept closed for heating in winter and air-conditioning in summer.  
11 Windows may or may not be opened during moderate weather conditions. In some areas,  
12 however, heating or air-conditioning may not be required and ventilation by open windows may  
13 be more frequent. Thus,  $a$  may vary geographically with climate. However, wind speed and  
14 direction were found to have very little influence on air exchange rates at the house where  
15 measurements were made. The variation of  $a$  with  $\Delta T$ , as shown in Figure 5-9, is given by  $a$   
16 (h<sup>-1</sup>) = 0.176 + 0.0162  $\Delta T$  (°C). Thus, an increase of 10 °C in  $\Delta T$  would lead to an increase in  $a$   
17 of 0.164 h<sup>-1</sup>, almost a doubling of the value of  $a$  for no indoor/outdoor temperature difference  
18 and no open windows or forced ventilation.

19 The observation of a minimal effect of wind speed on  $a$  is an important finding. If  $a$  were  
20 strongly dependent on wind speed, especially at low wind speeds, there might be a correlation  
21 between the indoor-generated PM found indoors and the ambient concentration outdoors. Such a  
22 correlation could lead to a confounding of the relationship of ambient PM with health outcomes  
23 by indoor-generated PM. Wallace et al. (2002) suggest that “the generally tighter construction  
24 of homes and the use of vapor barriers may have reduced the effect of wind speed and direction  
25 on residential air change rates compared to earlier studies.”

26 Wind speed might be expected to have a larger effect on  $a$  in a home with open windows.  
27 Under conditions of large  $a$ , the ambient infiltrated indoors PM concentration will be a large  
28 fraction of the outdoor PM and the two concentrations will be highly correlated. However, the  
29 indoor-generated PM concentration will be kept low by the high  $a$  so a significant correlation  
30 between ambient PM concentrations and indoor-generated PM concentrations would not be  
31 likely. The observed lack of a strong wind effect on  $a$  in closed houses (Wallace et al., 2002;

**Figure 5-9. Regression of air exchange rate on absolute indoor-outdoor temperature difference. Overnight values (midnight-8 a.m.) in winter (January-March 2000).  $a$  (h<sup>-1</sup>) = 0.176 (0.011 SE) + 0.0164 (0.0005)  $\Delta T$  (°C) ( $N = 183$ ,  $R^2 = 0.82$ ).**

1 Howard-Reed et al., 2002) and the observed lack of correlation between ambient PM  
 2 concentrations and indoor-generated PM concentrations indicate that the possibility of  
 3 correlation of ambient and indoor-generated PM concentrations can be discounted.

4

### 5 **Particle Deposition Rates and Penetration Factors**

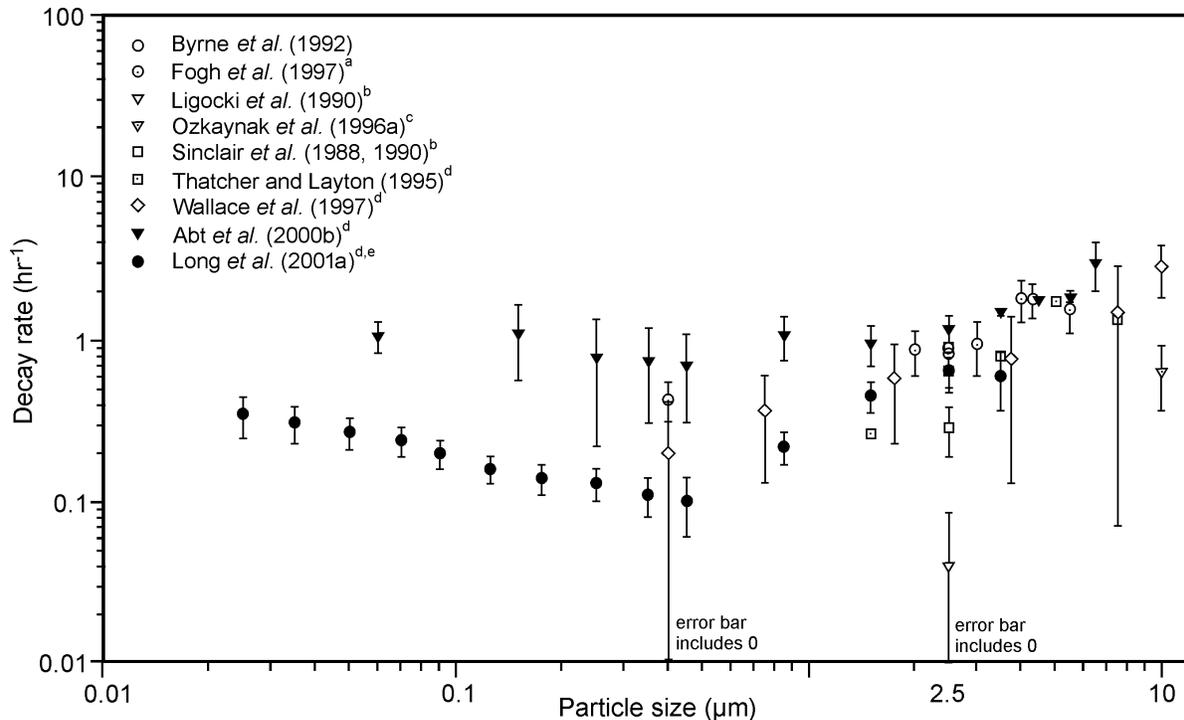

6 Physical factors affecting indoor particle concentrations including particle deposition rates,  
 7  $k$ , and penetration factors,  $P$ , are possibly the most uncertain and variable quantities. Although  $k$   
 8 can be modeled with some success, direct measurements are difficult, and results often vary  
 9 from study to study. Particle deposition rates vary considerably depending on particle size  
 10 because of the viscous drag of air on the particles hindering their movement to varying degrees.  
 11 The nature and composition of particles also affect deposition rates. Surface properties of  
 12 particles, such as their electrostatic properties, can have a significant influence on deposition  
 13 rates. In addition, thermophoresis can also affect  $k$ , but probably to a lesser degree in the indoor  
 14 microenvironment because temperatures generally vary over a small range. Combined, these

1 effects can produce order of magnitude variations in  $k$  between particles of different size and, in  
2 the case of electrophoresis and thermophoresis, particles of the same size.

3 Particle penetration efficiency into indoor microenvironments depends on particle size and  
4 air exchange rates. Penetration varies with particle size because of the size-dependent deposition  
5 of particles caused by impaction, interception, and diffusion of particles onto surfaces as they  
6 traverse through cracks and crevices. Penetration also is affected by air exchange rates. When  
7 air exchange rates are high,  $P$  approaches unity because the majority of ambient particles have  
8 less interaction with the building shell. In contrast, when air exchange rates are low,  $P$  is  
9 governed by particle deposition as particles travel through cracks and crevices.

10 Significant advancements have been made in the past few years to better characterize  
11 particle deposition rates and penetration factors. Several new studies, including two in which  
12 semi-continuous measurements of size distributions were measured indoors and outdoors, have  
13 produced new information on these quantities, which are key to understanding the contributions  
14 of ambient PM to indoor PM concentrations (Equation 5-7).

15 Studies involving semi-continuous measurements of indoor and outdoor particle size  
16 distributions have been used to estimate  $k$  and  $P$  as a function of particle size (Vette et al., 2001;  
17 Long et al., 2001a; Abt et al., 2000b). These studies each demonstrated that the indoor/outdoor  
18 concentration ratios ( $C_{\text{air}}/C$  in Equation 5-9) were highest for accumulation mode particles and  
19 lowest for ultrafine and coarse-mode particles. Various approaches were used to estimate size-  
20 specific values for  $k$  and  $P$ . Vette et al. (2001) and Abt et al. (2000b) estimated  $k$  by measuring  
21 the decay of particles at times when indoor levels were significantly elevated. Vette et al. (2001)  
22 estimated  $P$  using measured values of  $k$  and indoor/outdoor particle measurements during  
23 nonsource nighttime periods. Long et al. (2001a) used a physical-statistical model, based on  
24 Equation 5-12, to estimate  $k$  and  $P$  during nonsource nighttime periods. The results for  $k$   
25 reported by Long et al. (2001a) and Abt et al. (2000b) are compared with other studies in  
26 Figure 5-10. Although not shown in Figure 5-10, the results for  $k$  obtained by Vette et al. (2001)  
27 were similar to the values of  $k$  reported by Abt et al. (2000b) for particle sizes up to 1  $\mu\text{m}$ .  
28 Results for  $P$  by Long et al. (2001a) show that penetration was highest for accumulation-mode  
29 particles and decreased substantially for coarse-mode particles (Figure 5-11). The results for  
30  $P$  reported by Vette et al. (2001) show similar trends, but are lower than those reported by Long  
31 et al. (2001a). This likely is because of lower air exchange rates in the one Fresno, CA, test

<sup>a</sup> Decay Rates represent Summary Estimates from the four houses examined.

<sup>b</sup> Decay rates are based on sulfate and are presented as < 2.5 μm. Estimates were computed using a surface-to-volume ratio of 2 m<sup>-1</sup> (Koutrakis *et al.*, 1992).

<sup>c</sup> Data represents PM<sub>2.5</sub>.

<sup>d</sup> Particle sizes are the midpoint of the ranges examined.

<sup>e</sup> Decay rates presented are estimates of k for nightly average data from all nine study homes.

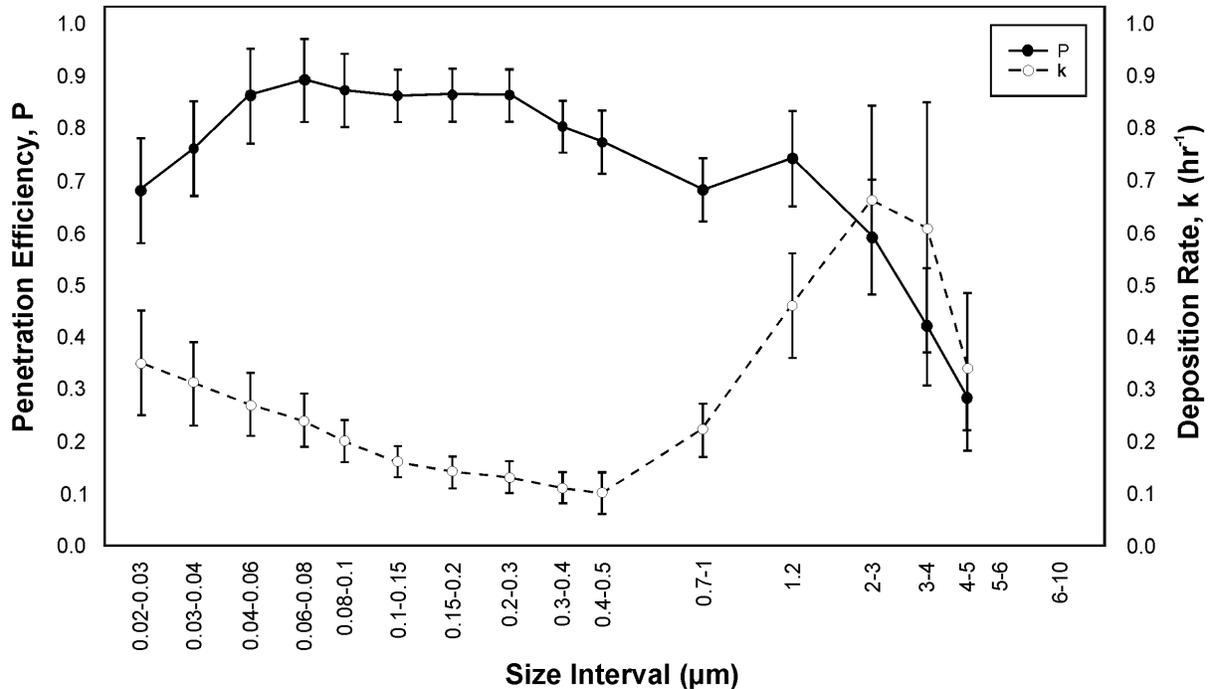

<sup>f</sup> Decay rates are theoretically modeled deposition values for smooth indoor surfaces and homogeneous and isotropically turbulent air flow. Presented curves assume typical room dimensions (3 m x 4 m x 5 m) and a friction velocity of 1.0 cm/s.

**Figure 5-10. Comparison of deposition rates from Long et al., 2001a with literature values (from Abt et al., 2000b). Error bars represent standard deviations for same-study estimates.**

1 home ( $a \approx 0.5 \text{ h}^{-1}$ ; Vette et al., 2001) than in the nine test homes in Boston, MA, study ( $a > 1 \text{ h}^{-1}$ ;  
 2 Long et al., 2001a). These data for  $P$  and  $k$  illustrate the role that the building shell may provide  
 3 in increasing the concentration of particles because of indoor sources and reducing the  
 4 concentration of indoor particles from ambient sources especially for homes with low air  
 5 exchange rates.

6

1            Several other studies have investigated particle loss as a function of particle size. The  
 2 penetration of particles across building envelopes has been modeled for several sizes of idealized  
 3 rectangular cracks (Liu and Nazaroff, 2001). Particles of 0.1 to 1.0  $\mu\text{m}$  diameter had penetration  
 4 efficiencies near 1.0. Supermicron and ultrafine particles were removed to a greater degree by  
 5 gravitational settling and Brownian diffusion. Thatcher et al. (2002) conducted an experimental  
 6 study of the effects of room furnishings and air speed on particle deposition rates indoors. The  
 7 deposition loss rate ( $k$ ) increased by as much as a factor of 2.6 in going from a bare room (35  $\text{m}^2$   
 8 surface area) to a fully furnished room (12  $\text{m}^2$  additional surface area) with the greatest increase  
 9 seen for the smallest particles. Air speed increases from  $< 5$  to 19  $\text{cm/s}$  increased the deposition  
 10 rates by factors of 1.3 to 2.4 with greater effects on large particles than small particles. The  
 11 authors state that, “The significant effect of particle size and room conditions on deposition loss

1 rates argues against using a single first-order loss-rate coefficient to represent deposition for  
2 integrated mass measurements (PM<sub>2.5</sub> or PM<sub>10</sub>).” Riley et al. (2002) have modeled the  
3 infiltration of particles into two building types: offices and residences. They developed  
4 representative values of  $P$ ,  $k$ , and ventilation-system filter efficiencies for particle sizes from  
5 0.001 to 10  $\mu\text{m}$ . They then used a typical rural and urban outdoor size distribution and  
6 calculated predicted indoor concentrations for number, surface area, and volume distributions.

### 8 **Compositional Differences Between Indoor-Generated and Ambient Particulate Matter**

9 Wilson et al. (2000) discuss the differences in composition between particles from indoor  
10 and outdoor sources. They note that, because of the difficulty in separating indoor PM into  
11 ambient and nonambient PM, there is little direct experimental information on the composition  
12 differences between the two. Although experimental data are limited, Wilson et al. (2000)  
13 suggest the following.

14  
15 Photochemistry is significantly reduced indoors; therefore, most secondary sulfate [ $\text{H}_2\text{SO}_4$ ,  
16  $\text{NH}_4\text{HSO}_4$ , and  $(\text{NH}_4)_2\text{SO}_4$ ] and nitrate ( $\text{NH}_4\text{NO}_3$ ) found indoors come from ambient sources.  
17 Primary organic emissions from incomplete combustion may be similar, regardless of the  
18 source. However, atmospheric reactions of polyaromatic hydrocarbons and other organic  
19 compounds produce highly oxygenated and nitrated products, so these species are also of  
20 ambient origin. Gasoline, diesel fuel, and vehicle lubricating oil all contain naturally present  
21 metals or metal additives. Coal and heavy fuel oil also contain more metals and nonmetals,  
22 such as selenium and arsenic, than do materials such as wood or kerosene burned inside  
23 homes. Environmental tobacco smoke (ETS), however, with its many toxic components, is  
24 primarily an indoor-generated pollutant.

25  
26 Particles generated indoors may have different chemical and physical properties than those  
27 generated by anthropogenic ambient sources. Siegmann et al. (1999) have demonstrated that  
28 elemental carbon in soot particles generated indoors has different properties than in those  
29 generated outdoors by automotive or diesel engines. In the United States, combustion-product  
30 PM in the ambient/outdoor air generally is produced by burning fossil fuels (e.g., coal, gasoline,  
31 fuel oil) and wood; whereas combustion-product PM from indoor sources is produced by  
32 biomass burning (e.g., tobacco, wood, foods, etc.). However, some indoor sources of PM (such  
33 as cigarette smoking, meat cooking, and coal burning) occur both indoors and outdoors and may

1 constitute an identifiable portion of measured ambient PM (Cha et al., 1996; Kleeman and Cass,  
2 1998).

### 4 **Indoor Air Chemistry**

5 Gas- and aerosol-phase chemical reactions in the indoor microenvironment are responsible  
6 for secondary particle formation and modification of existing particles. This process could be  
7 complex and may influence the interpretation of exposures to indoor generated particles in  
8 instances when particles are generated by outdoor gases reacting with gases generated or  
9 released indoors to produce fresh particles. For example, homogeneous gas phase reactions  
10 involving ozone and terpenes (specifically d-limonene,  $\alpha$ -terpinene, and  $\alpha$ -pinene) have been  
11 identified as an important source of submicron particles (Weschler and Shields, 1999). Terpenes  
12 are present in several commonly available household cleaning products, and d-limonene has  
13 been identified in more than 50% of the buildings monitored in the Building Assessment and  
14 Survey Evaluation (BASE) study (Hadwen et al., 1997). Long et al. (2000) found that when  
15 PineSol (primary ingredient is  $\alpha$ -pinene) was used indoors, indoor  $PM_{2.5}$  mass concentrations  
16 increased from 11 to 32  $\mu\text{g m}^{-3}$  (indoor ozone concentrations unknown, but ambient ozone  
17 concentrations were 44 to 48 ppb). Similarly, a 10-fold increase in number counts of 0.1 to  
18 0.2  $\mu\text{m}$  particles was observed in an experimental office containing supplemented d-limonene  
19 and normally encountered indoor ozone concentrations ( $< 5$  to 45 ppb), resulting in an average  
20 increase in particle mass concentration of 2.5 to 5.5  $\mu\text{g m}^{-3}$  (Weschler and Shields, 1999). Ozone  
21 appears to be the limiting reagent as particle number concentration varied proportionally to  
22 ozone concentrations (Weschler and Shields, 1999). Other studies showed similar results (e.g.,  
23 Jang and Kamens, 1999; Wainman et al., 2000). Such particles, if toxic, would represent an  
24 increased health risk due to ambient air pollution. However, the concentration would depend on  
25 the ambient  $O_3$  concentration, the  $O_3$  infiltration factor, and the indoor generation rate of  
26 terpenes. Because the concentration of the resulting particles would not be expected to be  
27 correlated with ambient PM on an individual or population basis, it seems more appropriate to  
28 consider indoor-reaction particles as part of nonambient exposure.

## 1 **Indoor Sources of Particles**

2 The major sources of indoor PM in nonsmoking residences and buildings include  
3 suspension of PM from bulk material, cooking, cleaning, and the use of combustion devices such  
4 as stoves and kerosene heaters. Human and pet activities also lead to PM detritus production  
5 (from tracked-in soil, fabrics, skin and hair, home furnishings, etc.) that is found ubiquitously in  
6 house dust deposited on floors and other interior surfaces. House dust and lint particles may be  
7 resuspended indoors by agitation (cleaning) and turbulence (HVAC systems, human activities,  
8 etc.). Ambient particles that have infiltrated into the indoor microenvironments also may be  
9 resuspended after deposition to indoor surfaces. Typically, resuspension of particles from any  
10 source involves coarse particles ( $> 1 \mu\text{m}$ ); particles with smaller diameters are not resuspended  
11 efficiently. On the other hand, cooking produces both fine and coarse mode particles whereas  
12 combustion sources typically produce ultrafine particles.

13 Environmental tobacco smoke (ETS) is also a major indoor source of PM. It is, however,  
14 beyond the scope of this chapter to review the extensive literature on ETS. A number of articles  
15 provide source-strength information for cigarette or cigar smoking (e.g., Daisey et al., 1998 and  
16 Nelson et al., 1998).

17 A study conducted on two homes in the Boston metropolitan area (Abt et al., 2000a)  
18 showed that indoor PM sources predominate when air exchange rates were  $< 1 \text{ h}^{-1}$ , and outdoor  
19 sources predominate when air exchange rates were  $\geq 2 \text{ h}^{-1}$ . The authors attributed this to the fact  
20 that when air exchange rates were low ( $< 1 \text{ h}^{-1}$ ), particles released from indoor sources tend to  
21 accumulate because particle deposition is the mechanism governing particle decay and not air  
22 exchange. Particle deposition rates are generally  $< 1 \text{ h}^{-1}$ , especially for accumulation-mode  
23 particles. When air exchange rates were higher ( $\geq 2 \text{ h}^{-1}$ ), infiltration of ambient aerosols and  
24 exfiltration of indoor-generated aerosols occur more rapidly, reducing the effect of indoor  
25 sources on indoor particle levels. The study also confirmed previous findings that the major  
26 indoor sources of PM are cooking, cleaning, and human activity. They discuss the size  
27 characteristics of these ubiquitous sources and report the following.

28  
29 The size of the particles generated by these activities reflected their formation processes.  
30 Combustion processes (oven cooking, toasting, and barbecuing) produced fine particles and  
31 mechanical processes (sauteing, frying, cleaning, and movement of people) generated coarse  
32 particles. These activities increased particle concentrations by many orders of magnitude  
33 higher than outdoor levels and altered indoor size distributions. (Abt et al., 2000a; p. 43)

1 They also note that variability in indoor PM for all size fractions was greater than for outdoor  
2 PM, especially for short averaging times (2 to 33 times higher).

3 In a separate study conducted in nine nonsmoking homes in the Boston area, Long et al.  
4 (2000) concluded that the predominant source of indoor fine particles was infiltration of outdoor  
5 particles and that cooking activities were the only other significant source of fine particles.  
6 Coarse particles, however, had several indoor sources, such as cooking, cleaning, and various  
7 indoor activities. This study also concluded that more than 50% of the particles (by volume)  
8 generated during indoor events were ultrafine particles. Events that elevated indoor particle  
9 levels were found to be brief, intermittent, and highly variable, thus requiring the use of  
10 continuous instrumentation for their characterization. Because the concentration of ultrafine  
11 particles will be greater near the source (they will grow in size into the accumulation mode as  
12 they age), the personal cloud for ultrafine particles may be higher than for accumulation mode  
13 particles if the person is nearer the source than the indoor monitor. Table 5-11 provides  
14 information on the mean volume mean diameter (VMD) for various types of indoor particle  
15 sources. The differences in mean VMD confirm the clear separation of source types and suggest  
16 that there is very little resuspension of accumulation-mode PM. In addition, measurements of  
17 organic and elemental carbon indicated that organic carbon had significant indoor sources  
18 whereas elemental carbon was primarily of ambient origin.

19 Vette et al. (2001) found that resuspension was a significant indoor source of particles  
20  $> 1 \mu\text{m}$ . Concentrations of fine particles were not affected by resuspension. Figure 5-12 shows  
21 the diurnal variability in the indoor/outdoor aerosol concentration ratio from an unoccupied  
22 residence in Fresno. The study was conducted in the absence of common indoor particle sources  
23 such as cooking and cleaning. The data in Figure 5-12 show the mean indoor/outdoor  
24 concentration ratio for particles  $> 1 \mu\text{m}$  increased dramatically during daytime hours. This  
25 pattern was consistent with indoor human activity levels. In contrast, the mean indoor/outdoor  
26 concentration ratio for particles  $< 1 \mu\text{m}$  (ultrafine and accumulation-mode particles) remain  
27 fairly constant during both day and night.

28 Wallace and Howard-Reed (2002) used three instruments (SMPS, APS, and Climet) to  
29 measure ultrafine, fine, and coarse particles in an inhabited residence for 18 months. They  
30 confirm the observations of Abt et al. (2000a) and Long et al. (2000) that indoor sources  
31 primarily generate ultrafine and coarse particles. Wallace and Howard-Reed report that, "Indoor

**Figure 5-12. Mean hourly indoor/outdoor particle concentration ratio from an unoccupied residence in Fresno, CA, during spring 1999.**

Source: Vette et al. (2001).

1 sources affecting ultrafine particle concentrations were observed 22% of the time, and sources  
 2 affecting fine and coarse particle concentrations were observed 12 and 15% of the time,  
 3 respectively . . . Indoor sources, such as cooking with natural gas, and simple physical activities,  
 4 such as walking, accounted for a majority (50-90%) of the ultrafine and coarse particle  
 5 concentrations, whereas outdoor sources were more important for accumulation-mode particles  
 6 between 0.1 and 1  $\mu\text{m}$  in diameter.”

7

8 **5.3.3.2.3 Time/Activity Patterns**

9 Total exposure to PM is the sum of various microenvironmental exposures that an  
 10 individual encounters during the day and will depend on the microenvironments occupied.  
 11 As discussed previously, PM exposure in each microenvironment is the sum of exposures from

1 ambient PM (in outdoor and indoor microenvironments), indoor-generated PM and indoor  
2 reaction PM. In addition, there is exposure to PM generated by personal activities that is  
3 determined by the personal activities that the individual conducts while in those  
4 microenvironments. As mentioned before, PM exposures and their components are variable  
5 across the population; thus, each are distributions rather than point estimates. A thorough  
6 analysis of these distributions would require a comprehensive sensitivity and uncertainty  
7 analysis.

8 Determining microenvironments and activities that contribute significantly to human  
9 exposure begins with establishing human activity pattern information for the general population,  
10 as well as subpopulations. Personal exposure and time-activity pattern studies have shown that  
11 different populations have varying time-activity patterns and, accordingly, different personal PM  
12 exposures. Both characteristics will vary greatly as a function of age, health status, ethnic group,  
13 socioeconomic status, season, and region of the country. Collecting detailed time activity data  
14 can be very burdensome on participants but is clearly valuable in assessing human exposure and  
15 microenvironments. For modeling purposes, human activity data frequently come from general  
16 databases that are discussed below.

17 The gathering of human activity information, often called “time-budget” data, started in the  
18 1920s; however, their use for exposure assessment purposes only began to be emphasized in the  
19 1980s. Many of the largest U.S. human activity databases have been consolidated by EPA’s  
20 National Exposure Research Laboratory’s (NERL) into one comprehensive database containing  
21 more than 22,000 person-days of 24-h activity known as the Consolidated Human Activity  
22 Database, or CHAD (Glen et al., 1997; McCurdy et al., 2000). The information in CHAD is  
23 accessible for constructing population cohorts of people with diverse characteristics that are  
24 useful for analysis and modeling (McCurdy, 2000). See Table 5-2 for a summary listing of  
25 human activity studies in CHAD. Most of the databases in CHAD are available elsewhere,  
26 including the National Human Activity Pattern Survey (NHAPS), California’s Air Resources  
27 Board (CARB), and the University of Michigan’s Institute for Survey Research data sets.

28 Although CHAD provides a very valuable resource for time and location data, there is little  
29 information on PM-generating personal activities. In addition, very few of the time-activity  
30 studies have collected longitudinal data within a season or over multiple seasons. Such  
31 longitudinal data are important in understanding potential variability in activities and how they

1 affect correlations between PM exposure and ambient site measurements for both total PM and  
2 PM of ambient origin.

### 4 **5.3.3.3 Effect of Ambient Sources on Exposures to Particulate Matter**

5 Different sources may generate ambient PM with different aerodynamic and chemical  
6 characteristics, which may, in turn, result in different health responses. Thus, to fully understand  
7 the relationship between PM exposure and health outcomes, exposure from different sources  
8 should be identified and quantified. Source apportionment techniques provide a method for  
9 determining personal exposure to PM from specific sources. Daily contributions from sources  
10 that have no indoor component can be used as tracers to generate exposure estimates for ambient  
11 PM of similar aerodynamic size or directly as exposure surrogates in epidemiological analyses.  
12 The most recent EPA PM Research Needs Document (U. S. Environmental Protection Agency,  
13 1998) recommended use of source apportionment techniques to determine daily time-series of  
14 source categories for use in community, time-series epidemiology.

15 A number of epidemiologic studies (discussed more fully in Chapter 8) have evaluated  
16 relationships between health outcomes and sources of particulate matter determined from  
17 measurements at a community monitor. These studies suggest the importance of examining  
18 sources and constituents of indoor, outdoor, and personal PM. For example, Özkaynak and  
19 Thurston (1987) evaluated the relationship between PM sources and mortality in 36 Standard  
20 Metropolitan Statistical Areas (SMSAs). Particulate matter samples from EPA's Inhalable  
21 Particle (IP) Network were analyzed for  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  by automated colorimetry, and elemental  
22 composition was determined with X-ray fluorescence (XRF). Mass concentrations from five PM  
23 source categories were determined from multiple regression of absolute factor scores on the  
24 mass concentration: (1) resuspended soil, (2) auto exhaust, (3) oil combustion, (4) metals, and  
25 (5) coal combustion.

26 In another study, Mar et al. (2000) applied factor analysis to evaluate the relationship  
27 between PM composition (and gaseous pollutants) in Phoenix. In addition to daily averages of  
28  $\text{PM}_{2.5}$  elements from XRF analysis, they included in their analyses organic and elemental carbon  
29 in  $\text{PM}_{2.5}$  and gaseous species emitted by combustion sources ( $\text{CO}$ ,  $\text{NO}_2$ , and  $\text{SO}_2$ ). They  
30 identified five factors classified as (1) motor vehicles, (2) resuspended soil, (3) vegetative  
31 burning, (4) local  $\text{SO}_2$ , and (5) regional sulfate. Additionally, Laden et al. (2000) applied

1 specific rotation factor analysis to particulate matter composition (XRF) data from six eastern  
2 cities (Ferris et al., 1979). Fine PM was regressed on the recentered scores to determine the  
3 daily source contributions. Three main sources were identified (1) resuspended soil (Si);  
4 (2) motor vehicle (Pb); and (3) coal combustion (Se).

5 Source apportionment or receptor modeling has been applied to the personal exposure data  
6 to understand the relationship between personal and ambient sources of particulate matter.  
7 Application of source apportionment to ambient, indoor, and personal PM composition data is  
8 especially useful in sorting out the effects of particle size and composition. If a sufficient  
9 number of samples are analyzed with sufficient compositional detail, it is possible to use  
10 statistical techniques to derive source category signatures, to identify indoor and outdoor source  
11 categories, and to estimate their contribution to indoor and personal PM.

12 Positive Matrix Factorization (PMF) has been applied to the PTEAM database by  
13 Yakovleva et al. (1999). The authors utilize mass and XRF elemental composition data from  
14 indoor and outdoor PM<sub>2.5</sub> and personal, indoor, and outdoor PM<sub>10</sub> samples. PMF is an advance  
15 over ordinary factor analysis because it allows measurements below the quantifiable limit to be  
16 used by weighting them by their uncertainty. This effectively increases the number of species  
17 that can be used in the model. The factors used by the authors correspond to general source  
18 categories of PM, such as outdoor soil, resuspended indoor soil, indoor soil, personal activities,  
19 sea-salt, motor vehicles, nonferrous metal smelters, and secondary sulfates. PMF, by identifying  
20 the various source factors and apportioning them among the different monitor locations  
21 (personal, indoor, and outdoor), was able to estimate the contribution of resuspended indoor dust  
22 to the personal cloud (15% from indoor soil and 30% from resuspended indoor soil). Factor  
23 scores for these items then were used in a regression analysis to estimate personal exposures  
24 (Yakovleva et al., 1999).

25 The most important contributors to PM<sub>10</sub> personal exposure were indoor soil, resuspended  
26 indoor soil, and personal activities; these accounted for approximately 60% of the mass  
27 (Yakovleva et al., 1999). Collectively, they include personal cloud PM, smoking, cooking, and  
28 vacuuming. For both PM<sub>2.5</sub> and PM<sub>10</sub>, secondary sulfate and nonferrous metal operations  
29 accounted for another 25% of PM mass. Motor vehicle exhausts, especially from vehicles  
30 started inside attached garages, accounted for another 10% of PM mass. The PTEAM study was

1 conducted in Riverside, CA in the fall of 1990. Yakovleva et al. (1999) caution that their results  
2 may not apply to other geographic areas, seasons of the year, or weather conditions.

3 Simultaneous measurement of personal ( $PM_{10}$ ) and outdoor measurements ( $PM_{2.5}$  and  
4  $PM_{10}$ ) were evaluated as a three-way problem with PMF, which allowed for differentiation of  
5 source categories based on their variation in time and type of sample, as well as their variation in  
6 composition. By use of this technique, it was possible to identify three sources of coarse-mode,  
7 soil-type PM. One was associated with ambient soil, one with indoor soil dispersed throughout  
8 the house, and one with soil resulting from the personal activity of the subject.

9 Two other source apportionment models have been applied to ambient measurement data  
10 and can be used for the personal exposure studies. The effective variance weighted Chemical  
11 Mass Balance (CMB) receptor model (Watson et al., 1984, 1990, 1991) solves a set of linear  
12 equations that incorporate the uncertainty in the sample and source composition. CMB requires  
13 the composition of each potential source of PM and the uncertainty for the sources and ambient  
14 measurements. Source apportionment with CMB can be conducted on individual samples;  
15 however, composition of each of the sources of PM must be known. An additional source  
16 apportionment model, UNMIX (Henry et al., 1994) is a multivariate source apportionment  
17 model. UNMIX is similar to PMF, but does not explicitly use the measurement uncertainties.  
18 Because measurement uncertainties are not used, only species above the detection limit are  
19 evaluated in the model. UNMIX provides the number of sources and source contributions and  
20 requires a similar number of observations as PMF.

21 The Yakovleva et al. (1999) study demonstrates that source apportionment techniques also  
22 could be very useful in determining parameters needed for exposure models and for determining  
23 exposure to ambient PM. Exposure information, similar to that obtained in the PTEAM study,  
24 but including other PM components useful for definition of other source categories (e.g.,  
25 elemental [EC] and organic carbon [OC]; organic tracers for elemental carbon from diesel  
26 vehicle exhaust, gasoline vehicle exhaust, and wood combustion; nitrate; Na, Mg, and other  
27 metal tracers; and gas-phase pollutants) would be useful as demonstrated in the use of EC/OC  
28 and gas-phase pollutants by Mar et al. (2000).

### 5.3.3.4 Correlations of Particulate Matter with Other Pollutants

Correlations between ambient concentrations and between ambient concentrations and personal exposures for PM and other pollutants are of importance in understanding possible confounding in epidemiological studies as will be discussed more fully in Chapter 9. The available information from exposure studies is presented in this section. Several epidemiologic studies have included the gaseous pollutants CO, NO<sub>2</sub>, SO<sub>2</sub>, and O<sub>3</sub> along with PM<sub>10</sub> or PM<sub>2.5</sub> in the analysis of the statistical association of health responses with pollutants. In a recent study, the personal exposure to O<sub>3</sub> and NO<sub>2</sub> was determined, as well as that to PM<sub>2.5</sub> and PM<sub>2.5-10</sub> for a cohort 15 elderly subjects in Baltimore, MD, although measured personal exposures to O<sub>3</sub>, NO<sub>2</sub>, and SO<sub>2</sub> were below their respective level of detection (LOD) for 70% of the samples. Spearman correlations for 14 subjects in summer and 14 subjects in winter are given in Table 5-12 for relationships between personal PM<sub>2.5</sub> and ambient concentrations of PM<sub>2.5</sub>, PM<sub>2.5-10</sub>, O<sub>3</sub>, and NO<sub>2</sub>. In contrast to ambient concentrations, neither personal exposure to total PM<sub>2.5</sub> nor PM<sub>2.5</sub> ambient origin was correlated significantly with personal exposures to the co-pollutants, PM<sub>2.5-10</sub>, nonambient PM<sub>2.5</sub>, O<sub>3</sub>, NO<sub>2</sub>, and SO<sub>2</sub>. Personal-ambient associations for PM<sub>2.5-10</sub>, O<sub>3</sub>, NO<sub>2</sub>, and SO<sub>2</sub> were similarly weak and insignificant. Based on these results, Sarnat et al. (2000) conclude that the potential for confounding of PM<sub>2.5</sub> by O<sub>3</sub>, NO<sub>2</sub>, or PM<sub>10-2.5</sub> appears to be limited, because, despite significant correlations observed among ambient pollutant concentrations, the correlations among personal exposures were low.

Sarnat et al. (2001) further evaluated the role of gaseous pollutants in particulate matter epidemiology by extending the measurements taken on the earlier adult cohort of 20 individuals in Baltimore by including additional PM and gaseous pollutant measurements that were collected during the same 1998-1999 period from 15 individuals with COPD and from 21 children, 24-h average personal exposures for PM<sub>2.5</sub>, O<sub>3</sub>, SO<sub>2</sub> and NO<sub>2</sub>, and corresponding ambient concentrations for PM<sub>2.5</sub>, O<sub>3</sub>, SO<sub>2</sub>, NO<sub>2</sub> and CO for all 56 subjects were collected over 12 consecutive days. Results from correlation and regression analysis of the personal and ambient data showed that personal PM<sub>2.5</sub> and personal gaseous pollutant exposures were generally not correlated. The analysis also showed that ambient PM<sub>2.5</sub> concentrations had significant associations with personal PM<sub>2.5</sub> exposures in both seasons. On the other hand, ambient gaseous pollutant concentrations were not correlated with their corresponding personal exposure concentrations. However, ambient gaseous concentrations were found to be strongly

**TABLE 5-12. CORRELATIONS BETWEEN PERSONAL PM<sub>2.5</sub> AND AMBIENT POLLUTANT CONCENTRATIONS<sup>1</sup>**

Source: Sarnat et al. (2000).

1 associated with personal PM<sub>2.5</sub> exposures, suggesting that ambient gaseous concentrations for O<sub>3</sub>,  
2 NO<sub>2</sub>, SO<sub>2</sub> are acting as surrogates, as opposed to confounders of PM<sub>2.5</sub> in the estimation of PM  
3 health effects based on multi-pollutant models. This study did not measure personal CO and did  
4 not find a significant association between summertime ambient CO and personal PM<sub>2.5</sub>  
5 (a significant winter-time association, however, was found).

6 Personal EC and SO<sub>4</sub><sup>-2</sup> were also measured during the winter for the cohort of COPD  
7 patients only. The analysis of this subset of the data showed that personal SO<sub>4</sub><sup>-2</sup> was  
8 significantly and negatively associated with ambient O<sub>3</sub> and SO<sub>2</sub>, and personal EC was  
9 significantly associated with ambient O<sub>3</sub>, NO<sub>2</sub>, and CO. The authors interpret these findings as  
10 suggesting that O<sub>3</sub> is primarily a surrogate for secondary particle exposures whereas ambient CO  
11 and NO<sub>2</sub> are primarily surrogates for particles from traffic. Sarnat et al. (2001) caution that these  
12 findings were from only one location and various physical and personal factors, such as  
13 ventilation, time spent outdoors, and household characteristics could affect the strength of the  
14 reported associations for certain individuals and cohorts even though the qualitative results  
15 found are unlikely to change.

16 A newly developed Roll-Around System (RAS) was used to evaluate the hourly  
17 relationship between gaseous pollutants (CO, O<sub>3</sub>, NO<sub>2</sub>, SO<sub>2</sub>, and VOCs) and PM (Chang et al.,  
18 2000). Exposures were characterized over a 15-day period for the summer and winter in  
19 Baltimore, based on scripted activities to simulate activities performed by older adults (65+  
20 years of age). Spearman rank correlations were reported for PM<sub>2.5</sub>, O<sub>3</sub>, CO, and toluene for both  
21 the summer and winter. The correlations are given for each microenvironment in Table 5-13:  
22 indoor residence, indoor other, outdoor near roadway, outdoor away from road, and in vehicle.  
23 No significant relationships (p < 0.05) were found between hourly PM<sub>2.5</sub> and O<sub>3</sub>. Significant  
24 relationships were found between hourly PM<sub>2.5</sub> and CO: indoor residence, winter; indoor other,  
25 summer and winter; and outdoor away from roadway, summer. Significant relationships also  
26 were found between hourly PM<sub>2.5</sub> and toluene: indoor residence, winter; indoor other, winter;  
27 and in vehicle, winter. The significant relationships between CO and PM<sub>2.5</sub> in the winter may be  
28 caused by reduced air exchange rates that could allow them to accumulate (Chang et al., 2000).  
29 Although no significant correlation was found between in vehicle PM<sub>2.5</sub> and CO, toluene, which  
30 is a significant component of vehicle exhaust (Conner et al., 1995), was significantly correlated  
31 to PM<sub>2.5</sub> in the winter.

Source: Chang et al. (2000).

1 emissions, there was no significant correlation between “commuting PM<sub>10</sub>” and any of the  
 2 substances (Carrer et al., 1998).

3 Carrer et al. (1998) present data on the correlations among microenvironmental and  
 4 personal PM<sub>10</sub> exposures and concentrations and selected environmental chemicals monitored  
 5 simultaneously (using methods not described). These chemicals were nitrogen oxides (NO<sub>x</sub>),  
 6 carbon monoxide (CO), and total volatile organic compounds (TVOC), benzene, toluene, xylene,  
 7 and formaldehyde. The Kendall  $\tau$  correlation coefficient was used; only results significant at  
 8  $p < 0.05$  are mentioned here. Significant associations were found only between the following  
 9 pairs of substances ( $\tau$  shown in parentheses): personal PM<sub>10</sub> (24 h) and NO<sub>x</sub> (0.34), CO (0.34),  
 10 TVOC (0.18), toluene (0.19), and xylene (0.26); office PM<sub>10</sub> and NO<sub>x</sub> (0.31); home PM<sub>10</sub> and  
 11 NO<sub>x</sub> (0.24), CO (0.24), toluene (0.17), and xylene (0.25). Even though most of these chemicals  
 12 are associated with motor vehicular emissions, there was no significant correlation between  
 13 commuting PM<sub>10</sub> and any of the substances.

14

## **5.4 SUMMARY OF PARTICULATE MATTER CONSTITUENT DATA**

### **5.4.1 Introduction**

Atmospheric PM contains a number of chemical constituents that may be of significance to human exposure and health effects. These constituents may be either components of the ambient particles or bound to the surface of particles. They may be elements, inorganic species, or organic compounds. A limited number of studies have collected data on concentrations of elements, acidic aerosols, and PAHs in ambient, personal, and microenvironmental PM samples. However, there have not been extensive analyses of the constituents of PM in personal or microenvironmental samples. Data from relevant studies are summarized in this section. The summary does not address bacteria, bioaerosols, viruses, or fungi (e.g., Owen et al., 1992; Ren et al., 1999).

### **5.4.2 Monitoring Studies That Address Particulate Matter Constituents**

Relevant studies published in recent years that have measured the constituents of PM in personal or microenvironmental samples are summarized in Tables 5-11 and 5-12 for personal exposure measurements of PM and microenvironmental samples, respectively. Studies that measured both personal and microenvironmental samples are included in Table 5-11.

The largest database on personal, microenvironmental, and outdoor measurements of PM elemental concentrations is the PTEAM study (Özkaynak et al., 1996b). The results are highlighted in the table and discussed below. The table shows that a number of studies have measured concentrations of elements (by XRF), organic carbon (OC), various indicators of elemental carbon (EC), aerosol acidity, sulfate, ammonia, and nitrate. Additionally, a number of studies have measured PAHs, both indoors and outdoors. Other than the PAHs, there are few data on organic constituents of PM.

### **5.4.3 Key Findings**

#### **5.4.3.1 Correlations of Personal and Indoor Concentrations with Ambient Concentrations of Particulate Matter Constituents**

The elemental composition of PM<sub>10</sub> in personal samples was measured in the PTEAM study, the first probability-based study of personal exposure to particles. A number of important observations made from the PTEAM data collected in Riverside, CA, are summarized by

1 Özkaynak et al. (1996b). Population-weighted daytime personal exposures averaged  
2  $150 \pm 9 \mu\text{g}/\text{m}^3$  compared to concurrent indoor and outdoor concentrations of  $95 \pm 6 \mu\text{g}/\text{m}^3$ . The  
3 personal exposure measurements suggested that there was a “personal cloud” of particles  
4 associated with personal activities. Daytime personal exposures to 14 of the 15 elements  
5 measured in the samples were considerably greater than concurrent indoor or outdoor  
6 concentrations; sulfur was the only exception.

7 The PTEAM data also showed good agreement between the concentrations of the elements  
8 measured outdoors in the backyard of the residences with the concentrations measured at the  
9 central site in the community. The agreement was excellent for sulfur. Although the particle  
10 and element mass concentrations were higher in personal samples than for indoor or outdoor  
11 samples, a nonlinear mass-balance method showed that the penetration factor was nearly 1 for all  
12 particles and elements.

13 Similarly to the PTEAM results, recent measurements of element concentrations in  
14 NHEXAS showed elevated concentrations of As and Pb in personal samples relative to indoor  
15 and outdoor samples (Clayton et al., 1999b). The elevated concentrations of As and Pb were  
16 consistent with elevated levels of  $\text{PM}_{50}$  in personal samples (median particle exposure of  
17  $101 \mu\text{g}/\text{m}^3$ ) as compared to indoor concentrations ( $34.4 \mu\text{g}/\text{m}^3$ ). There was a strong association  
18 between personal and indoor concentrations and indoor and outdoor concentrations for both As  
19 and Pb. However, there were no central site ambient measurements for comparison to the  
20 outdoor or indoor measurements at the residences.

21 Manganese (Mn) concentrations were measured in  $\text{PM}_{2.5}$  samples collected in Toronto  
22 (Crump, 2000). The mean  $\text{PM}_{2.5}$  Mn concentrations were higher outdoors than indoors.  
23 However, the outdoor concentrations measured at the participants’ homes were lower than those  
24 measured at two fixed locations. Crump (2000) suggested that the difference in the  
25 concentrations may have been because the fixed locations were likely closer to high-traffic areas  
26 than were the participants’ homes.

27 Studies of acidic aerosols and gases typically measure strong acidity ( $\text{H}^+$ ),  $\text{SO}_4^{-2}$ ,  $\text{NH}^{+4}$ , and  
28  $\text{NO}^{-3}$ . The relationship between the concentrations of these ions and the relationship between  
29 indoor and outdoor concentrations have been addressed in a number of studies during which  
30 personal samples, microenvironmental, and outdoor samples have been collected, as shown in  
31 Tables 5-14 and 5-15. Key findings from these studies include the following:

**TABLE 5-14. STUDIES THAT HAVE MEASURED PARTICULATE MATTER CONSTITUENTS IN PERSONAL EXPOSURE SAMPLES**

PM Constituent	Study Name/Reference	Study Location	Population Size/No. of Samples	Summary of Results
Elements	PTEAM/Özkaynak et al. (1996b)	Riverside, CA	178 adults	Outdoor air was the major source for most elements indoors, providing 70 to 100% of the observed indoor concentrations for 12 of the 15 elements. Correlation coefficients for central monitoring site versus outdoor at the residences were 0.98 for sulfur and 0.5 to 0.9 for other elements (except copper).
As and Pb	NHEXAS/Clayton et al. (1999b)	EPA Region 5	167 samples	Personal As and Pb levels higher than indoor or outdoor levels. No community ambient site for comparison.
Mn	Pellizzari et al. (1998, 1999); Clayton et al. (1999a); Crump (2000)	Toronto	925 personal samples	Mean PM <sub>2.5</sub> Mn higher outdoors than indoors. But PM <sub>2.5</sub> Mn concentrations higher at two fixed locations than at participants' homes.
Acid Aerosol Constituents	Sarnat et al. (2000)	Baltimore, MD	20 adults	High correlations between personal and ambient sulfate measurements in summer and winter.
	Brauer et al. (1989)	Boston, MA	—	Personal exposures to aerosol strong acidity slightly lower than concentrations measured at stationary site.
	Suh et al. (1992)	Uniontown, PA	24 children for 2 days	Personal exposures to H <sup>+</sup> and SO <sub>4</sub> <sup>-2</sup> lower than outdoor levels, but higher than indoor microenvironmental levels; personal NH <sub>4</sub> <sup>+</sup> and NO <sub>3</sub> <sup>-</sup> higher than indoor or outdoor levels.
	Suh et al. (1993a,b)	State College, PA	47 children	Results similar to Uniontown, PA, study.
	Suh et al. (1994)			Results indicate strong neutralization of acidity indoors.
PAHs	Waldman and Liang (1993); Waldman et al. (1990)	Georgia and New Jersey	Hospital, daycares	Indoor sulfate levels were 70 to 100% of outdoor levels. Indoor ammonia levels 5- to 50-times higher than outdoors. Indoors, acid aerosols were largely neutralized.
	Zmirou et al. (2000)	Grenoble, France	38 adults	Ambient air concentrations close to traffic emissions were 1.1- to 3.5-times higher than personal exposure concentrations.
Individual Particle Analyses by CCSEM	Conner et al. (2001)	Baltimore, MD Same study locations for both	3 sets of indoor-outdoor-personal filters, > 2000 particles/filter	CCSEM was used to identify individual particles and classify them by most likely sources.
Trace Elemental analyses by XRF	Landis et al. (2001)		19 days with P, I, A for 10 elderly retirees	P and A highly correlated for PM <sub>2.5</sub> and sulfates. P and A not significantly correlated for soil and trace element oxides.
Elemental analysis by HR-ICP-MS	Kinney et al. (2002)	New York City, NY	46 student volunteers, 1 week in summer and winter, PM <sub>2.5</sub>	29 PM constituents were measured. Most were similar for P, I and O suggesting Outdoor sources dominant.

**TABLE 5-15. STUDIES THAT HAVE MEASURED PARTICULATE MATTER CONSTITUENTS IN MICROENVIRONMENTAL SAMPLES**

PM Constituent	Study Name/Reference	Study Location	Population Size/No. of Samples	Summary of Results
Acid Aerosol Constituents	Jones et al. (2000)	Birmingham, England	12 residences	Sulfate I/O ratios ranged from 0.7 to 0.9 for three PM size fractions.
	Patterson and Eatough (2000)	Lindon, UT	One school	Ambient sulfate, SO <sub>2</sub> , nitrate, soot, and total particle number showed strong correlations with indoor exposure although ambient PM <sub>2.5</sub> mass was not a good indicator of total PM <sub>2.5</sub> exposure.
	Leaderer et al. (1999)	Virginia and Connecticut	232 homes	The regional ambient air monitoring site provided a reasonable estimate of indoor and outdoor sulfate at nonsmokers homes. I/O sulfate ratio of 0.74 during summer. Ammonia concentrations were an order of magnitude higher indoors than outdoors. Nitrous acid levels higher indoors than outdoors.
	Brauer et al. (1990)	Boston, MA	11 homes	Outdoor levels of H <sup>+</sup> , SO <sub>2</sub> , HNO <sub>3</sub> , and SO <sub>4</sub> <sup>-2</sup> exceeded indoor levels in winter and summer. I/O ratios of H <sup>+</sup> lower than I/O ratios of SO <sub>4</sub> <sup>-2</sup> indicated neutralization of the acidity by ammonia.
PAHs	Chuang et al. (1999)	Durham, NC	24 homes	Measurements with continuous monitor; PAH levels generally higher indoors than outdoors.
	Dubowsky et al. (1999)	Boston, MA	3 buildings	PAHs indoors attributable to traffic, cooking, and candle-burning.
	Sheldon et al. (1993a,b)	Placerville and Roseville, CA	280 homes	Mass balance model used to estimate source strengths for PAH sources such as smoking, wood-burning and cooking.
PAHs and phthalates	PTEAM/Özkaynak et al. (1996b), Sheldon et al. (1993c)	Riverside, CA	120 homes	12-h I/O ratios for particulate-phase PAHs ranged from 1.1 to 1.4 during the day and 0.64 to 0.85 during night. The concentrations of phthalates and the number of samples with detectable phthalates were higher indoors than outdoors.

- 1 • Acid aerosol concentrations measured at the residences in the Uniontown, PA, study were significantly different from those measured at a fixed ambient site located 16 km from the community. However, Leaderer et al. (1999) reported that the regional ambient air monitoring site in Vinton, VA, provided a reasonable estimate of indoor and outdoor sulfate measurements during the summer at homes without tobacco combustion.
- 2 • Approximately 75% of the fine aerosol indoors during the summer was associated with outdoor sources based on I/O sulfate ratios measured in the Leaderer et al. (1999) study.
- 3 • Personal exposures to strong acidity ( $H^+$ ) were lower than corresponding outdoor levels measured in studies by Brauer et al. (1989, 1990) and Suh et al. (1992). However, the personal exposure levels measured by Suh et al. (1992) were higher than the indoor microenvironmental levels.
- 4 • Personal exposures to  $NH_4^+$  and  $NO_3^-$  were reported by Suh et al. (1992) to be lower than either indoor or outdoor levels.

5 Personal exposures to  $SO_4^{-2}$  were also lower than corresponding outdoor levels, but higher  
6 than the indoor microenvironmental levels (Suh et al., 1992; 1993a,b) as shown in Table 5-16.

7 The fact that the personal and indoor  $H^+$  concentrations were substantially lower than  
8 outdoor concentrations suggests that a large fraction of aerosol strong acidity is neutralized by  
9 ammonia. Ammonia is emitted in relatively high concentrations in exhaled breath and sweat.  
10 The difference between indoor and outdoor  $H^+$  concentrations in the Suh et al. (1992, 1993a,b)  
11 studies was also much higher than the difference for indoor and outdoor  $SO_4^{-2}$ , indicative of  
12 neutralization of the  $H^+$ . Results of the Suh et al. (1992, 1993a,b) studies also showed  
13 substantial interpersonal variability of  $H^+$  concentrations that could not be explained by variation  
14 in outdoor concentrations.

15 Similar results for ammonia were reported by Waldman and Liang (1993). They reported  
16 that levels of ammonia in monitored institutional settings were 10- to 50- times higher than  
17 outdoors and that acid aerosols were largely neutralized. Leaderer et al. (1999) reported that  
18 ammonia concentrations during both winter and summer in residences were an order of  
19 magnitude higher indoors than outdoors, consistent with results of other studies and the presence  
20 of sources of ammonia indoors.

21 Sulfate aerosols appear to penetrate indoors effectively. Waldman et al. (1990) reported  
22 I/O ratios of 0.7 to 0.9 in two nursing care facilities and a day-care center. Sulfate I/O ratios

1 were measured for three particle size fractions in 12 residences in Birmingham, England, by  
 2 Jones et al. (2000). The sulfate I/O ratios were 0.7 to 0.9 for PM < 1.1 µm, 0.6 to 0.8 for PM  
 3 1.1 to 2.1 µm, and 0.7 to 0.8 for PM 2.1 to 10 µm. Suh et al. (1993b) reported that personal and  
 4 outdoor sulfate concentrations were highly correlated as depicted in Figure 5-13.

5 Indoor/outdoor relationships for a number of PM<sub>2.5</sub> components and related species in  
 6 Lindon, UT, during January and February of 1997 by Patterson and Eatough (2000). Outdoor  
 7 samples were collected at the Utah State Air Quality monitoring site. Indoor samples were  
 8 collected in the adjacent Lindon Elementary School. The infiltration factors, C<sub>ai</sub>/C, given by the

1 slope of the regression lines (Table 5-17), were low (0.27 for sulfate and 0.12 for  $\text{PM}_{2.5}$ ) possibly  
 2 because of removal of particles in the air heating and ventilation system. The authors concluded  
 3 that indoor  $\text{PM}_{2.5}$  mass may not always be a good indicator of exposure to ambient combustion  
 4 material due to the influence of indoor particle sources. Presumably this occurs because the  
 5 concentrations of indoor-generated particles are not well correlated with the concentrations of  
 6 ambient combustion particles. However, ambient sulfate,  $\text{SO}_2$ , nitrate, soot, and total particulate  
 7 number displayed strong correlations with indoor exposure, presumably because these species  
 8 have few indoor sources in the absence of indoor combustion. Ambient  $\text{PM}_{2.5}$  mass was not a

1 good indicator of indoor PM<sub>2.5</sub> mass exposure, presumably due to uncorrelated indoor sources of  
 2 PM<sub>2.5</sub> mass.

3 Oglesby et al. (2000) conducted a study to evaluate the validity of fixed-site fine particle  
 4 concentration measurements as exposure surrogates for air pollution epidemiology. Using 48-h  
 5 EXPOLIS data from Basel, Switzerland, they investigated the personal exposure/outdoor  
 6 concentration relationships for four indicator groups: (1) PM<sub>2.5</sub> mass, (2) sulfur and potassium  
 7 for regional air pollution, (3) lead and bromine for traffic-related particles, and (4) calcium for  
 8 crustal particles. The authors reported that personal exposures to PM<sub>2.5</sub> mass were not correlated  
 9 to corresponding home outdoor levels (n = 44, r = 0.07). In the study group reporting neither  
 10 relevant indoor sources nor relevant activities, personal exposures and home outdoor levels of

1 sulfur were highly correlated ( $n = 40$ ,  $r = 0.85$ ). These results are consistent with spatially  
2 homogeneous regional pollution and higher spatial variability of traffic and crustal materials.

3 Indoor, outdoor, and personal concentrations of  $PM_{2.5}$  mass and a variety of PM  
4 constituents were measured at an 18-story retirement facility in Towson, MD for 28, 24-hour  
5 monitoring periods during July and August 1998 (Landis et al., 2001). Indoor and outdoor  
6 measurements were made with a Versatile Air Pollutant Sampler (VAPS). Indoor, outdoor, and  
7 personal samples were made with a Personal Exposure Monitor (PEM). The VAPS  
8 (a dichotomous sampler) collected  $PM_{2.5}$  ( $15 \text{ l min}^{-1}$ ) and  $PM_{10-2.5}$  ( $2 \text{ l min}^{-1}$ ) while the PEM  
9 collected  $PM_{2.5}$  ( $2 \text{ l min}^{-1}$ ). A comparison of the VAPS and the PEM indicated that the indoor  
10 PEM collected much higher mass and more soil components than the indoor VAPS although the  
11 differences between outdoor results were smaller and not significant. These differences were  
12 attributed to there being a larger coarse particle concentration inside (and perhaps larger  
13 diameter particles) and either more particle bounce or a higher 50% cut point for the PEM.  
14 In their analysis, Landis et al. (2001) compared indoor and outdoor VAPS data and outdoor and  
15 personal PEM data.

16 As shown in Table 5-18 (PEM) and Table 5-19 (VAPS), higher correlations were found for  
17 fine-particle components of  $PM_{2.5}$  and lower correlations for coarse-particle components. Like  
18 Patterson and Eatough (2000), Landis et al. (2001) found low infiltration factors for nitrate but a  
19 reasonable correlation suggesting that fine-mode ammonium nitrate may be evaporating after it  
20 penetrates indoors. Neither sulfate nor nitrate had indoor sources.

21 Indoor and outdoor  $PM_{2.5}$  and  $PM_{10}$  mass and chemical composition were measured in  
22 13 homes (2-4 days for each home) in the Coachella Valley, a unique desert area in southern  
23 California during the winter and spring of 2000 (Geller et al., 2002). Maximum infiltration of  
24 ambient PM would be expected during this period because the mild climate minimizes the use of  
25 heating or air conditioning. Regression analysis was used to estimate  $\bar{F}_{INF}$  and  $\bar{C}_{ig}$ . Results are  
26 shown in Table 5-20. The Coachella PM is generally considered to be rich in coarse PM and  
27 epidemiological studies have associated  $PM_{10}$  (Ostro et al., 1999) and estimated  $PM_{10-2.5}$  (Ostro  
28 et al., 2000) with mortality. However, the results of Geller et al. (2002) indicate that even during  
29 periods of high air exchange rates indoor exposures would be dominated by  $PM_{2.5}$ . Geller et al.  
30 (2002) also report results for some chemical components of  $PM_{2.5}$  and  $PM_{10-2.5}$  and EC and OC in  
31  $PM_{2.5}$ . For EC,  $F_{INF}^{EC} = 0.74$ , in good agreement with  $F_{INF}^{2.5} = 0.74$ . Indoor concentrations of OC

1 were much higher than outdoor concentrations; the average indoor to outdoor ratio was 1.77.  
 2 PAHs have been measured in studies by EPA and the California Air Resources Board. PAH  
 3 results from a probability sample of 125 homes in Riverside are discussed in reports by Sheldon  
 4 et al. (1992a,b) and Özkaynak et al. (1996b). Data for two sequential 12-h samples were  
 5 reported for PAHs by ring size (3 to 7) and for individual phthalates. The results can be  
 6 summarized as follows.

- 7 • The particulate-phase 5- to 7-ring species had lower relative concentrations than the more  
 volatile 3- to 4-ring species.
- 8 • The 12-h indoor/outdoor ratios for the 5- to 7-ring species ranged from 1.1 to 1.4 during  
 the day and from 0.64 to 0.85 during the night (Sheldon et al., 1993a).
- 9 • An indoor air model used to calculate indoor “source strengths” for the PAHs showed that  
 smoking had the strongest effect on indoor concentrations.

10 Results from a larger PAH probability study in 280 homes in Placerville and Roseville, CA  
 11 (Sheldon et al., 1993a,b) were similar to the 125-home study. The higher-ring, particle-bound  
 12 PAHs had lower indoor and outdoor concentrations than the lower-ring species. For most PAHs,  
 13 the I/O ratio was greater than 1 for smoking and smoking/fireplace homes and less than 1 for  
 14 fireplace-only, wood stove, wood stove/gas heat, gas heat, and “no source” homes.

15 A study of PAHs in indoor and outdoor air was conducted in 14 inner-city and 10 rural  
 16 low-income homes near Durham, NC, in two seasons (winter and summer) in 1995 (Chuang  
 17 et al., 1999). Fine-particle-bound PAH concentrations measured with a real-time monitor were  
 18 usually higher indoors than outdoors ( $2.47 \pm 1.90$  versus  $0.53 \pm 0.58 \mu\text{g}/\text{m}^3$ ). Higher indoor

1 levels were seen in smokers' homes compared with nonsmokers' homes, and higher outdoor and  
2 indoor PAH levels were seen in urban areas compared with rural areas.

3 In a study reported by Dubowsky et al. (1999), the weekday indoor PAH concentrations  
4 attributable to traffic (indoor source contributions were removed) were  $39 \pm 25 \text{ ng/m}^3$  in a  
5 dormitory that had a high air exchange rate because of open windows and doors;  $26 \pm 25 \text{ ng/m}^3$   
6 in an apartment; and  $9 \pm 6 \text{ ng/m}^3$  in a suburban home. The study showed that both indoor and  
7 outdoor sources (especially motor vehicular traffic) contributed to indoor PAH concentrations.  
8 BaP concentrations were measured in the THEES study (Waldman et al., 1991).

9 A comprehensive analysis of the data showed considerable seasonal variability of indoor and  
10 outdoor sources and resultant changes in personal exposures to BaP.

11 The indoor and outdoor concentrations of 30 PAHs were measured in 55 nonsmoking  
12 residences in Los Angeles, CA; Houston, TX; and Elizabeth, NJ (Naumova et al., 2002). A  
13 comparison of indoor/outdoor ratios of low molecular weight PAHs (3-4 rings) and higher  
14 molecular weight PAHs (5-7 rings) indicated that indoor sources had a significant effect on  
15 indoor concentrations of 3-ring PAHs and a smaller effect on 4-ring PAHs while outdoor sources  
16 dominated the indoor concentrations of 5-7 ring PAHs.

#### 17 18 **5.4.4 Factors Affecting Correlations Between Ambient Measurements** 19 **and Personal or Microenvironmental Measurements of** 20 **Particulate Matter Constituents**

21 The primary factors affecting correlations between personal exposure and ambient air PM  
22 measurements have been discussed in Section 4.3.2. These include air exchange rates, particle  
23 penetration factors, decay rates, removal mechanisms, indoor air chemistry, indoor sources, and  
24 freshly-generated particles indoors. The importance of these factors varies for different PM  
25 constituents. For acid aerosols, indoor air chemistry is particularly important as indicated by the  
26 discussion of the neutralization of the acidity by ammonia which is present at higher  
27 concentrations indoors because of the presence of indoor sources. For SVOCs, including PAHs  
28 and phthalates, the presence of indoor sources will substantially affect the correlation between  
29 indoor and ambient concentrations (Özkaynak et al., 1996b; Sheldon et al., 1993b). Penetration  
30 factors for PM will affect correlations between indoors and outdoors for most elements, except  
31 Pb, which may have significant indoor sources in older homes. Indoor air chemistry, decay  
32 rates, and removal mechanisms may affect soot and organic carbon. Furthermore, reactions

1 between indoor and outdoor gases and particles may produce freshly generated aerosols indoors.  
2 These factors must be fully evaluated when attempting to correlate concentrations of PM  
3 constituents in ambient, personal, or indoor samplers.  
4

#### 5 **5.4.5 Limitations of Available Data**

6 The previous discussion demonstrates that there is limited data available that can be used  
7 to compare personal, microenvironmental, and ambient air concentrations of PM constituents.  
8 Because of resource limitations, PM constituents have not been measured in many studies of PM  
9 exposure. There are little data on freshly generated aerosols indoors. Although there are some  
10 data on acid aerosols, the comparisons between the personal and indoor data generally have been  
11 with outdoor measurements at the participants' residences not with community ambient air  
12 measurement sites. The relationship between personal exposure and indoor levels of acid  
13 aerosols is not clear because of the limited database. The exception is sulfate, for which there  
14 appears to be a strong correlation between indoor and ambient concentrations.

15 With the exception of PAHs, there are practically no data available with which to relate  
16 personal or indoor concentrations with outdoor or ambient site concentrations of SVOCs that  
17 may be generated from a variety of combustion and industrial sources. The relationship between  
18 exposure and ambient concentrations of particles from specific sources, such as diesel engines,  
19 has not been determined.

20 Although there is an increasing amount of research being performed to measure PM  
21 constituents in different PM size fractions, the current data are inadequate to adequately assess  
22 the relationship between indoor and ambient concentrations of most PM constituents. Additional  
23 information is also needed on PM exposures that result from outdoor vapors reacting with indoor  
24 vapors. This is a source that could also vary with outdoor PM, for example, when the outdoor  
25 vapor is ozone.

1 **5.5 IMPLICATIONS OF USING AMBIENT PARTICULATE MATTER**  
2 **CONCENTRATIONS IN TOXICOLOGICAL AND**  
3 **EPIDEMIOLOGICAL STUDIES OF PARTICULATE MATTER**  
4 **HEALTH EFFECTS**

5 **5.5.1 Toxicology**

6 Most studies of PM toxicity have used either pure chemicals or ambient PM. Indoor-  
7 generated PM differs somewhat from ambient PM in terms of sources, size, and composition.  
8 It is possible, therefore, that indoor-generated PM could have different toxicological properties.  
9 Tobacco smoke has been studied extensively; however, there is little toxicological information  
10 on PM from other indoor sources. Long et al. (2001b) have assessed the in vitro toxicity of  
11 14 paired indoor and outdoor PM<sub>2.5</sub> samples collected in 9 Boston-area homes. Bioassays were  
12 conducted using rat alveolar macrophages (AMs) and tumor necrosis factor (TNF) was measured  
13 to assess particle-induced proinflammatory responses. TNF production was found to be  
14 significantly higher in AMs exposed to indoor PM than to those exposed to outdoor PM. This  
15 result held even after normalization for endotoxin concentrations which were higher in indoor  
16 samples. The authors feel that their results “suggest that indoor-generated particles may be more  
17 bioactive than ambient particles.” PM, in its various forms, produces many types of biological  
18 effects. It seems possible that indoor PM could be more active than ambient PM for some  
19 effects and less for others.  
20

21 **5.5.2 Potential Sources of Error Resulting from Using Ambient Particulate**  
22 **Matter Concentrations in Epidemiological Analyses**

23 In this section, the exposure issues that relate to the interpretation of the findings from  
24 epidemiological studies of PM health effects are examined. This section examines the errors that  
25 may be associated with using ambient PM concentrations in epidemiological analyses of PM  
26 health effects. First, implications of associations found between personal exposure and ambient  
27 PM concentrations are reviewed. This is discussed separately in the context of either community  
28 time-series studies or long-term, cross-sectional studies of chronic effects. Next, the role of  
29 compositional and spatial differences in PM concentrations are discussed and how these may  
30 influence the interpretation of findings from PM epidemiology. Finally, using statistical  
31 methods, an evaluation of the influence of exposure measurement errors on PM epidemiological  
32 studies is presented.

1 Measurement studies of personal exposures to PM are still few and limited in spatial,  
2 temporal, and demographic coverage. Consequently, with the exception of a few longitudinal  
3 panel studies, most epidemiological studies of PM health effects rely on ambient community  
4 monitoring data giving 24-h average PM concentration measurements. Moreover, because of  
5 limited sampling for PM<sub>2.5</sub>, many of these epidemiological studies had to use available PM<sub>10</sub> or in  
6 some instances had to rely on historic data on other PM measures or indicators, such as TSP,  
7 SO<sub>4</sub><sup>-2</sup>, IP<sub>15</sub> (inhalable particles with an upper cut of 15 μm), RSP (respirable particles), COH  
8 (coefficient of haze), etc. A critical question often raised in the interpretation of results from  
9 acute or chronic epidemiological community-based studies of PM is whether the use of ambient  
10 stationary site PM concentration data influences or biases the findings from these studies.

11 If it is assumed that total personal PM exposure is responsible for observed effects, use of  
12 ambient concentrations could lead to misclassification of individual exposures and to errors in  
13 the epidemiological analysis of pollution and health data depending on the pollutant and on the  
14 mobility and lifestyles of the population studied. Ambient monitoring stations can be some  
15 distance away from the individuals and can represent only a fraction of all likely outdoor  
16 microenvironments that individuals come in contact with during the course of their daily lives.  
17 Furthermore, most individuals are quite mobile and move through multiple microenvironments  
18 (e.g., home, school, office, commuting, shopping, etc.) and engage in diverse personal activities  
19 at home (e.g., cooking, gardening, cleaning, smoking). Some of these microenvironments and  
20 activities may have different sources of PM and result in distinctly different concentrations of  
21 PM than that monitored by the fixed-site ambient monitors. Consequently, exposures of some  
22 individuals could be classified incorrectly if only ambient monitoring data are used to estimate  
23 individual level total personal PM exposures. Thus, improper assessment of exposures using  
24 data routinely collected by the neighborhood monitoring stations could conceivably lead to a  
25 bias or increase in the standard error in epidemiological analysis. Except for extremely unlikely  
26 situations, however, the bias would be expected to reduce the estimated health risk coefficient.

27 Because many individuals are typically exposed to particles in a multitude of indoor and  
28 outdoor microenvironments during the course of a day, concern about possible error introduced  
29 in the estimation of PM risk coefficients using ambient, as opposed to personal, PM  
30 measurements has received considerable attention recently from exposure analysts,  
31 epidemiologists, and biostatisticians. Some exposure analysts contend that, for community time-

1 series epidemiology to yield information on the statistical association of a pollutant with a health  
2 response, there must be an association between personal exposure to a pollutant and the ambient  
3 concentration of that pollutant because people tend to spend around 90% time indoors and are  
4 exposed to both indoor-generated and ambient-infiltrated PM (cf. Wallace, 2000b; Brown and  
5 Paxton, 1998; Ebel et al., 2000). Consequently, numerous findings reported in the  
6 epidemiological literature on significant associations between ambient PM concentrations and  
7 various morbidity and mortality health indices, in spite of the low correlations between ambient  
8 PM and concentrations and measures of personal exposure, have been described by some  
9 exposure analysts as an exposure paradox (Lachenmyer and Hidy, 2000; Wilson et al., 2000).

10 To resolve the so-called exposure paradox, several types of analyses need to be considered.  
11 The first type of analysis has to examine the correlations between ambient PM concentrations  
12 and personal exposures that are relevant to most of the existing PM epidemiological studies  
13 using either pooled, daily-average, or longitudinal exposure data. The second approach has to  
14 study the degree of correlations between the two key components of personal PM exposures (i.e.,  
15 exposures caused by ambient PM and exposures caused by nonambient PM) with ambient or  
16 outdoor PM concentrations, for each of the three types of exposure study designs. Yet, even  
17 with these two approaches, it may still be difficult to examine complex synergisms which, in  
18 some situations, may preclude simple decoupling of indoor and outdoor particles either in terms  
19 of exposure or total dose delivered to the lung. In addition, several factors that influence either  
20 the exposure or health response characterization of the subjects have to be addressed. These  
21 include such factors as

- 22 • spatial variability of PM components,
- 23 • health or sensitivity status of subjects,
- 24 • variations of PM with other co-pollutants,
- 25 • co-generation of fine and ultrafine particles from outdoor air and indoor gaseous  
pollutants,
- 26 • formal evaluation of exposure errors in the analysis of health data, and
- 27 • how the results may depend on the variations in the design of the epidemiological study.

28 To facilitate the discussion of these topics, a brief review of concepts pertinent to exposure  
29 analysis issues in epidemiology is presented.

### 1 **5.5.2.1 Associations Between Personal Exposures and Ambient Particulate Matter** 2 **Concentrations**

3 As defined in Sections 5.3 and 5.4, personal exposures to PM result from an individual's  
4 exposures to PM in many different types of microenvironments (e.g., outdoors near home,  
5 outdoors away from home, indoors at home, indoors at office or school, commuting, restaurants,  
6 malls, other public places, etc.). Total personal exposures that occur in these indoor and outdoor  
7 microenvironments can be classified as those resulting from ambient PM (ambient PM exposure  
8 includes exposure to ambient PM while outdoors and exposure while indoors to ambient PM that  
9 has infiltrated indoors) and those primarily generated by indoor sources, indoor reaction, and  
10 personal activities (nonambient PM exposure). The associations between personal exposures  
11 and ambient PM concentrations that have been reported from various personal exposure  
12 monitoring studies under three broad categories of study design, (1) longitudinal, (2) daily-  
13 average, or (3) pooled exposure studies, are summarized below.

14 In Sections 5.4.3.1.2 and 5.4.3.1.3, recent studies mainly conducted in the United States  
15 and involving children, the elderly, and subjects with COPD were reviewed, and they indicated  
16 that both intra- and inter-individual variability in the relationships between personal exposures  
17 and ambient PM concentrations were observed. A variety of different physical, chemical, and  
18 personal or behavioral factors were identified by the original investigators that seem to influence  
19 the magnitude and the strength of the associations reported.

20 For cohort studies in which individual daily health responses are obtained, individual  
21 longitudinal PM personal exposure data (including ambient and nonambient components) may  
22 provide the appropriate indicators. In this case, health responses of each individual can be  
23 associated with the total personal exposure, the ambient exposure, or the nonambient exposure of  
24 each individual. Additionally, the relationships of personal exposure indicators with ambient  
25 concentration can be investigated. In the case of community time-series epidemiology, however,  
26 it is not feasible to obtain experimental measurements of personal exposure for the millions of  
27 people over time periods of years that are needed to investigate the relationship between air  
28 pollution and infrequent health responses such as deaths or even hospital admissions. The  
29 epidemiologist must work with the aggregate number of health responses occurring each day and  
30 a measure of the ambient concentration that is presumed to be representative of the entire  
31 community. The relationship of PM exposures of the potentially susceptible groups to  
32 monitored ambient PM concentrations depends on their activity pattern and level, residential

1 building and HVAC factors (which influence the infiltration factor), status of exposure to ETS,  
2 amount of cooking or cleaning indoors, and seasonal factors, among others. For these special  
3 subgroups, average personal exposures to ambient PM are correlated well with ambient PM  
4 concentrations regardless of individual variation in the absence of major microenvironmental  
5 sources.

6 Even though both ambient and nonambient PM exposure contribute to daily baseline PM  
7 dose received by the lung, there seem to be clear differences in the relationships of ambient and  
8 nonambient PM exposure with ambient PM concentration. Various researchers have shown that  
9 nonambient PM exposure is independent of ambient PM concentration, but that ambient PM  
10 exposure is a function of ambient PM concentration. Wilson et al. (2000) explain the difference  
11 based on different temporal patterns that affect PM concentrations. “Concentrations of ambient  
12 PM are driven by meteorology and by changes in the emission rates and locations of emission  
13 sources, while concentrations of nonambient PM are driven by the daily activities of people.”  
14 Still, although nonambient PM exposure may not correlate with ambient PM concentration or  
15 ambient PM exposure, it will nevertheless add to the daily baseline dose received by the lung.  
16 An important concern, for which there is little information, is the relative biological activity of  
17 ambient and indoor generated PM both in terms of the type of toxic effect and the relative  
18 potency for a given effect.

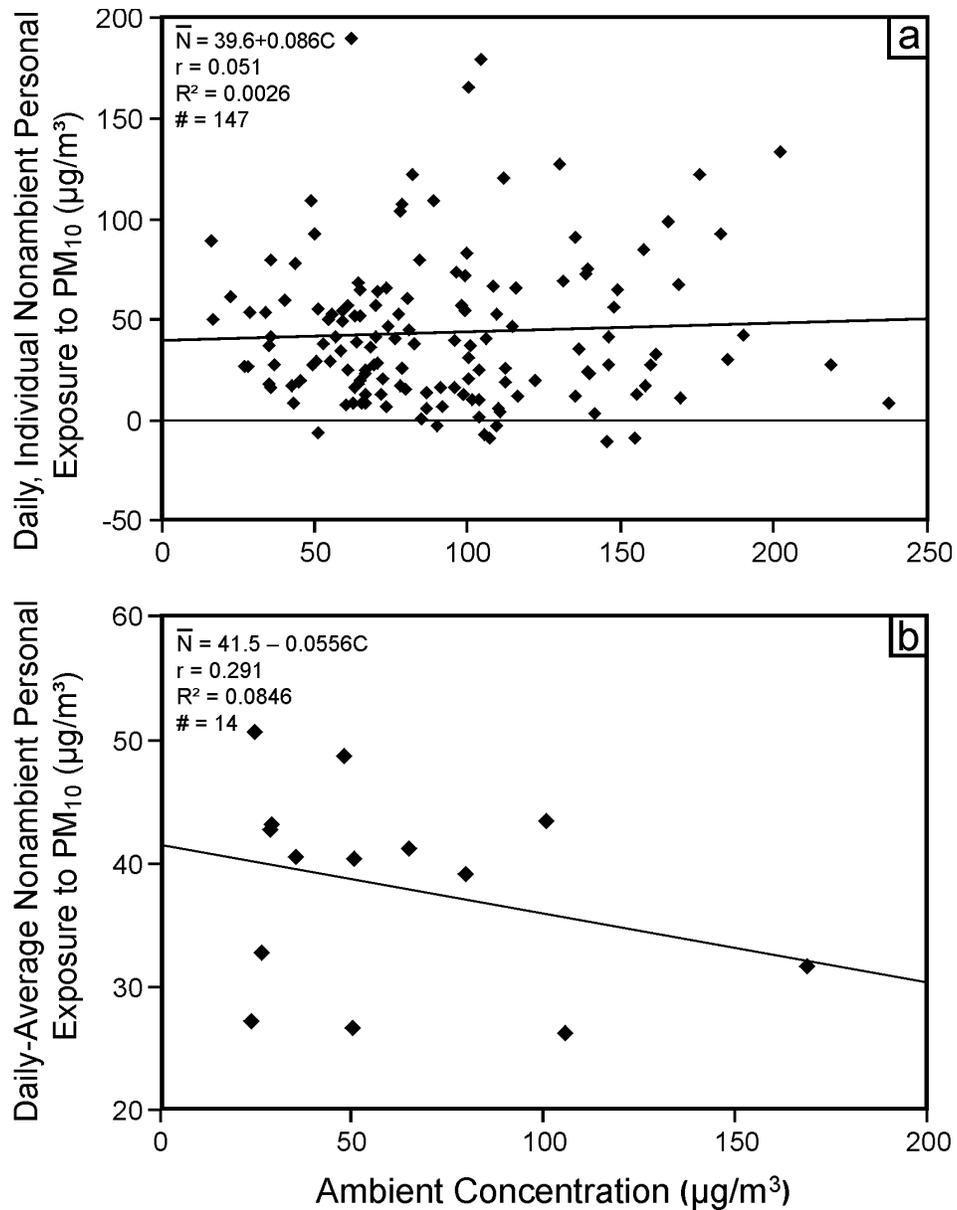

19 Ott et al. (2000) also discuss the reasons for assuming that nonambient PM exposure is  
20 independent of ambient PM exposure and ambient PM concentration. They show that the  
21 nonambient component of total personal exposure is uncorrelated with the outdoor concentration  
22 data. Ott et al. (2000) show the ambient PM exposure is similar for three population-based  
23 exposure studies: two large probability-based studies (the PTEAM study conducted in Riverside  
24 [Clayton et al., 1993; Thomas et al., 1993; Özkaynak et al., 1996a,b] and a study in Toronto  
25 [Pelizzari et al., 1999; Clayton et al., 1999a]), and a nonprobability-based study conducted in  
26 Phillipsburg (Lioy et al., 1990). Based on these three studies, they conclude that the average  
27 nonambient PM exposure and the distribution of individual, daily values of nonambient PM  
28 exposure can be treated as constant from city to city.

29 Dominici et al. (2000) examined a larger database consisting of five different PM exposure  
30 studies and concluded that nonambient PM exposure can be treated as relatively constant from  
31 city to city although their data show greater variability than the data reported by Ott (2000). The

1 constancy of nonambient PM exposure remains an open question. If daily values of nonambient  
2 PM exposure were constant, this would imply a zero correlation with ambient PM concentration.  
3 However, this hypothesis of constant individual, daily nonambient PM exposure has not been  
4 established fully because only a few studies have obtained the data needed to estimate daily,  
5 individual values of nonambient PM exposure. Although nonambient PM exposure is  
6 independent of ambient PM concentration, it may not be independent of the attenuation factor  
7 (ambient PM exposure/ambient PM concentration). Sarnat et al. (2000) show that nonambient  
8 PM exposure goes up as the ventilation rate (and attenuation factor) goes down. By comparing  
9 winter and summer regression equations Lachenmeyer and Hidy (2000) also show that as the  
10 slope, which gives the attenuation factor, decreases, the intercept, which gives the nonambient  
11 PM exposure, increases.

12 Mage et al. (1999) assume that the PM<sub>10</sub> concentration component from indoor sources  
13 (such as smoking, cooking, cleaning, burning candles, and so on) is not correlated with the  
14 outdoor concentration. They indicate that this lack of correlation is expected because people are  
15 unaware of ambient concentrations and do not necessarily change their smoking or cooking  
16 activities as outdoor PM<sub>10</sub> concentrations vary, an assumption supported by other empirical  
17 analyses of personal exposure data. For the PTEAM data set, Mage et al. (1999) have shown  
18 that individual, daily exposures to indoor-generated PM and daily ambient PM concentrations  
19 have a correlation coefficient near zero ( $R^2 = 0.005$ ). Wilson et al. (2000) have shown that  
20 individual, daily values of concentration of ambient PM which has infiltrated indoors and  
21 indoor-generated PM concentrations also have a near zero correlation ( $R^2 = 0.03$ ). Figure 5-14  
22 shows the relationship of estimated values of nonambient PM exposure with ambient PM  
23 concentrations (calculated by EPA, daily, individual values from PTEAM and daily average  
24 values for the cohort from THEES).

25 Based on these results it is reasonable to assume that ordinarily nonambient PM exposure  
26 will have little correlation with ambient PM concentration. A possible exception could be  
27 caused by indoor-reaction PM, PM formed when an ambient gas infiltrates indoors and reacts  
28 with an indoor-generated gas, i.e., the reaction of O<sub>3</sub> with terpenes from air cleaners. However,  
29 ambient O<sub>3</sub> does not appear to be highly correlated with ambient or personal PM<sub>2.5</sub> (See  
30 Table 5-12, Sarnat et al., [2000]). Additionally, not every home will use air fresheners or have  
31 the same level of terpene emissions. Hence, indoor-reaction PM concentrations would not be

**Figure 5-14. Plots of nonambient exposure to PM<sub>10</sub>, (a) daily individual daytime values from PTEAM data and (b) daily-average values from THEES data.**

Source: Data taken from (a) Clayton et al. (1993) and (b) Liroy et al. (1990).

- 1 expected to correlate with ambient PM concentrations on a community basis. Therefore, in
- 2 linear nonthreshold models of PM health effects, nonambient PM exposure is not expected to
- 3 contribute to the relative risk determined in a regression of health responses on ambient PM

1 concentration. Furthermore, in time-series analysis of pooled or daily health data, it is expected  
2 that ambient PM exposure rather than total personal PM exposure will have the stronger  
3 association with ambient PM concentration.  
4

### 5 **5.5.2.2 Role of Compositional Differences in Exposure Characterization for Epidemiology**

6 The majority of the available data on PM exposures and relationships with ambient PM  
7 have come from a few large-scale studies, such as PTEAM, or longitudinal studies on selected  
8 populations. Consequently, for most analyses, exposure scientists and statisticians had to rely on  
9  $PM_{10}$  or  $PM_{2.5}$  mass data, instead of elemental or chemical compositional information on  
10 individual or microenvironmental samples. In a few cases, researchers have examined the  
11 factors influencing indoor outdoor ratios or penetration and deposition coefficients using  
12 elemental mass data on personal, indoor, and outdoor PM data (e.g., Özkaynak et al., 1996a,b;  
13 Yakovleva et al., 1999). These results have been informative in terms of understanding relative  
14 infiltration of different classes of particle sizes and sources into residences (e.g., fossil fuel  
15 combustion, mobile source emissions, soil-derived, etc.). Clearly, in the accumulation-mode,  
16 particles associated with stationary or mobile combustion sources have greater potential for  
17 penetration into homes and other microenvironments than does crustal material. There will be  
18 variability in the chemical composition of these broad categories of source classes and also  
19 probably variations in relative toxicity. Moreover, when particles and reactive gases are present  
20 indoors in the presence of other pollutants or household chemicals, they may react to form  
21 additional or different compounds and particles with yet unknown physical, chemical, and toxic  
22 composition (Wainman et al., 2000). Thus, if indoor-generated and ambient PM were  
23 responsible for different types of health effects or had significantly different toxicities on a per  
24 unit mass basis, it would then be important that ambient and nonambient exposure should be  
25 separated and treated as different components, much like the current separation of  $PM_{10}$  into  
26  $PM_{2.5}$  and  $PM_{10-2.5}$ . These complexities in personal exposure profiles may introduce  
27 nonlinearities and other statistical challenges in the selection and fitting of concentration-  
28 response models. Unfortunately, PM health effects models have not yet been able to  
29 meaningfully consider such complexities.

30 It is important also to note that individuals spend time in places other than their homes and  
31 outdoors. Many of the interpretations reported in the published literature on factors influencing

1 personal PM<sub>10</sub> exposures, as well as in this chapter, come from the PTEAM study. The PTEAM  
2 study was conducted 10 years ago in one geographic location in California, during one season,  
3 and most residences had very high and relatively uniform air exchange rates. Non-home indoor  
4 microenvironments were not monitored directly during the PTEAM study. Commuting  
5 exposures from traffic or exposures in a variety of different public places or office buildings  
6 could not be assessed directly. Nonresidential buildings may have lower or higher ambient  
7 infiltration rates depending on the use and type of the mechanical ventilation systems employed.  
8 Because the source and chemical composition of particulate matter affecting personal exposures  
9 in different microenvironments vary by season, day-of-the-week, and time of day, it is  
10 conceivable that some degree of misclassification of exposures to PM toxic agents of concern  
11 could be introduced when health-effects models use only daily-average mass measures such as  
12 PM<sub>10</sub> or PM<sub>2.5</sub>. However, because of the paucity of currently available data on many of these  
13 factors, it is not now possible to ascertain the potential magnitude or severity of any such  
14 complex exposure missclassification problems or their potential implications for interpretation of  
15 results from PM epidemiology at this point.

### 17 **5.5.2.3 Role of Spatial Variability in Exposure Characterization for Epidemiology**

18 Chapter 3, Section 3.2.3 and Chapter 5, Section 5.3 present information on the spatial  
19 variability of PM mass and chemical components at fixed-site ambient monitors; for purposes of  
20 this chapter, this spatial variability is called an “ambient gradient.” Any gradient that may exist  
21 between a fixed-site monitor and the outdoor microenvironments near where people live, work,  
22 and play obviously affects the concentration profile actually experienced by people as they go  
23 about their daily lives.

24 However, the evidence so far indicates that PM concentrations, especially fine PM (mass  
25 and sulfate), generally are distributed uniformly in most metropolitan areas. This reduces the  
26 potential for exposure misclassification because of outdoor spatial gradients when a limited  
27 number of ambient PM monitors are used to represent population average ambient exposures in  
28 time-series or cross-sectional epidemiological studies of PM. This topic is further discussed in  
29 Section 5.6.5. However, as discussed earlier, the same assumption is not necessarily true for  
30 different components of PM such as PM<sub>10-2.5</sub> because source-specific and other spatially  
31 nonuniform pollutant emissions could alter the spatial profile of individual PM components in a

1 community. For example, particulate and gaseous pollutants emitted from motor vehicles tend  
2 to be higher near roadways and inside cars. Likewise, acidic and organic PM species may be  
3 location- and time-dependent. Furthermore, human activities are complex. If outdoor PM  
4 constituent concentration profiles are either spatially or temporally variable, it is likely that  
5 exposure misclassification errors could be introduced in the analysis of PM air pollution and  
6 health data.

### 7 8 **5.5.3 Analysis of Exposure Measurement Error Issues in Particulate Matter** 9 **Epidemiology**

10 The effects of exposure misclassification on relative risk estimates of disease using  
11 classical 2 by 2 contingency design (i.e., exposed/nonexposed versus diseased/nondiseased) have  
12 been studied extensively in the epidemiological literature. It has been shown that the magnitude  
13 of the exposure-disease association (e.g., relative risk) because of either misclassification of  
14 exposure or disease alone (i.e., nondifferential misclassification) biases the effect results toward  
15 the null; and differential misclassification (i.e., different magnitudes of disease misclassification  
16 in exposed and nonexposed populations) can bias the effect measure toward or away from the  
17 null value relative to the true measure of association (Shy et al., 1978; Gladen and Rogan, 1979;  
18 Copeland et al., 1977; Özkaynak et al., 1986). However, the extension of these results from  
19 contingency analysis design to multivariate models (e.g., log-linear regression, Poisson, logit)  
20 typically used in recent PM epidemiology has been more complicated.

#### 21 22 **5.5.3.1 Time-Series Analyses**

23 Researchers have investigated the appropriateness of using ambient PM concentration as  
24 an exposure metric and have developed a framework for analyzing measurement errors typically  
25 encountered in the analysis of time-series mortality and morbidity effects from exposures to  
26 ambient PM (cf. Zeger et al., 2000; Dominici et al., 2000; Samet et al., 2000). Use of this  
27 framework, discussed more extensively in Chapters 8 and 9, leads to the following conclusions:  
28 the deviation of an individual's personal exposure from the risk-weighted average exposure due  
29 to variations in ambient concentrations, infiltration rates, and indoor-generated PM  
30 concentrations is a Berkson error and will not bias the estimated regression coefficient ( $\beta$ , the  
31 increase in risk per unit increase in PM) in a time-series analysis of mortality as a function of  
32 ambient PM concentrations. However, the difference between the average personal exposure

1 and the true ambient concentration will bias  $\beta$ . If the daily, individual values of ambient PM  
2 exposure and nonambient PM exposure are poorly correlated and the attenuation coefficient,  $\alpha$ ,  
3 equal to the ambient PM concentration/ambient PM exposure were constant, the bias would be  
4 given by  $\beta_c = \alpha\beta_A$  where  $\beta_c$  is calculated using the ambient PM concentration,  $C$ , and  $\beta_A$  is  
5 calculated using the ambient PM exposure,  $A$ ; i.e., the risk determined from an analysis using the  
6 daily ambient PM concentrations would be lower than the risk obtained using ambient PM  
7 exposure by the factor  $\alpha$ . However,  $\beta_c$  provides the correct information on the change in health  
8 risks that would be produced by a change in ambient concentrations. However, if the daily,  
9 individual values of ambient PM exposure and nonambient PM exposure are highly correlated  
10 and the nonambient PM is toxic for the effect being studied, nonambient PM exposure will act as  
11 a confounder and could introduce substantial bias into  $\beta_c$ . Only one study has reported the  
12 association between the daily, individual values of ambient PM exposure and nonambient PM  
13 exposure. Wilson et al. (2000), in a further analysis of the PTEAM data set, found a coefficient  
14 of determination ( $R^2$ ) of 0.03 suggesting that the daily, individual values of ambient PM  
15 exposure and nonambient PM exposure are independent so that nonambient PM exposure will  
16 not confound  $\beta_c$ .

### 17 18 **5.5.3.2 Studies of Chronic Effects**

19 The Six Cities (Dockery et al., 1993) and American Cancer Society (ACS) (Pope et al.,  
20 1995) studies have played an important role in assessing the health effects from long-term  
21 exposures to particulate pollution. Even though these studies often have been considered as  
22 chronic epidemiological studies, it is not easy to differentiate the role of historic exposures from  
23 those of recent exposures on chronic disease mortality. In the Six Cities study, fine particles and  
24 sulfates were measured at the community level, and the final analysis of the database used six  
25 city-wide average ambient concentration measurements. This limitation also applies to the ACS  
26 study but has less impact because of the larger number of cities considered in that study. In a  
27 HEI-sponsored reanalysis of the Six Cities and the ACS data sets, Krewski et al. (2000)  
28 attempted to examine some of the exposure misclassification issues either analytically or through  
29 sensitivity analysis of the aerometric and health data. The HEI reanalysis project also addressed  
30 exposure measurement error issues related to the Six Cities study. For example, the inability to  
31 account for exposures prior to the enrollment of the cohort hampered accurate interpretation of

1 the relative risk estimates in terms of acute versus chronic causes. Although the results seem to  
2 suggest that past exposures are more strongly associated with mortality than recent exposures,  
3 the measurement error for long-term averages could be higher and influence these  
4 interpretations. For example, Krewski et al. (2000), using the individual mobility data available  
5 for the Six Cities cohort, analyzed the mover and nonmover groups separately. The relative risk  
6 of fine particle effects on all-cause mortality was shown to be higher for the nonmover group  
7 than for the mover group, suggesting the possibility of higher exposure misclassification biases  
8 for the movers. The issue of using selected ambient monitors in the epidemiological analyses  
9 also was investigated by the ACS and Six Cities studies reanalysis team. Krewski et al. (2000)  
10 presented the sensitivity of results to choices made in selecting stationary or mobile-source-  
11 oriented monitors. For the ACS study, reanalysis of the sulfate data using only those monitors  
12 designated as residential or urban and excluding sites designated as industrial, agricultural, or  
13 mobile did not change the risk estimates appreciably. On the other hand, application of spatial  
14 analytic methods designed to control confounding at larger geographic scales (i.e., between  
15 cities) caused changes in the particle and sulfate risk coefficients. Spatial adjustment may  
16 account for differences in pollution mix or PM composition, but many other cohort-dependent  
17 risk factors will vary across regions or cities in the United States. Therefore, it is difficult to  
18 interpret these findings solely in terms of spatial differences in pollution composition or relative  
19 PM toxicity until further research is concluded.

20 The influence of measurement errors in air pollution exposure and health effects  
21 assessments has also been examined by Navidi et al. (1999). This study developed techniques to  
22 incorporate exposure measurement errors encountered in long-term air pollution health- effects  
23 studies and tested them on the data from the University of Southern California Children's Health  
24 Study conducted in 12 communities in California. These investigators developed separate error  
25 analysis models for direct (i.e., personal sampling) and indirect (i.e., microenvironmental)  
26 personal exposure assessment methods. These models were generic to most air pollutants, but a  
27 specific application was performed using a simulated data set for studying ozone health effects  
28 on lung function decline in children. Because the assumptions made in their  
29 microenvironmental simulation modeling framework were similar to those made in estimating  
30 personal PM exposures, it is useful to consider the conclusions from Navidi et al. (1999).  
31 According to Navidi et al. (1999), neither the microenvironmental nor the personal sampler

1 method produces reliable estimates of the exposure-response slope for O<sub>3</sub> when measurement  
2 error is uncorrected. Because of nondifferential measurement error, the bias was toward zero  
3 under the assumptions made in Navidi et al. (1999) but could be away from zero if the  
4 measurement error was correlated with the health response. A simulation analysis indicated that  
5 the standard error of the estimate of a health effect increases as the errors in exposure assessment  
6 increase (Navidi et al., 1999). According to Navidi et al. (1999), when a fraction of the ambient  
7 level in a microenvironment is estimated with a standard error of 30%, the standard error of the  
8 estimate is 50% higher than it would be if the true exposures were known. It appears that errors  
9 in estimating ambient PM indoor/ambient PM outdoor ratios have much more influence on the  
10 accuracy of the microenvironmental approach than do errors in estimating time spent in these  
11 microenvironments.

12 Epidemiological studies of chronic effects, that use long-term average ambient PM  
13 concentrations as the exposure metric, generally do not address the nonambient component of  
14 personal exposure (N). However, if N contributes to the health effect being studied and the  
15 average N is different in different cities, the correlation between the average ambient PM  
16 concentration and the health effect could be reduced. In an analysis of the effect of nonambient  
17 exposure on time-series epidemiology, Dominici et al. examine nonambient exposure data from  
18 several cities and conclude that the average nonambient PM exposure varies little among cities  
19 in developed countries. Ott et al. (2000) examined estimated average and daily, individual  
20 values of nonambient exposure from three studies and concluded that both the average and the  
21 distribution of daily, individual values were similar for the three studies.

#### 22 23 **5.5.4 Conclusions from Analysis of Exposure Measurement Errors on** 24 **Particulate Matter Epidemiology**

25 Personal exposures to PM are influenced by a number of factors and sources of PM located  
26 in both indoor and outdoor microenvironments. However, PM resulting from ambient sources  
27 does penetrate into indoor environments such as residences, offices, public buildings, etc., in  
28 which individuals spend a large portion of their daily lives. The correlations between total  
29 personal exposures and ambient or outdoor PM concentrations can vary depending on the  
30 relative contributions of indoor PM sources to total personal exposures. Panel studies of both  
31 adult and young subjects have shown that, in fact, individual correlations of personal exposures  
32 with ambient PM concentrations could vary person to person, and even day to day, depending on

1 the specific activities of each person. Separation of PM exposures into two components,  
2 ambient PM and nonambient PM, would reduce uncertainties in the analysis and interpretation  
3 of PM health effects data. Nevertheless, because ambient PM is an integral component of total  
4 personal exposures to PM, statistical analyses of cohort-average exposures are strongly  
5 correlated with ambient PM concentrations when the size of the underlying population studied is  
6 large. Using the PTEAM study data, analysis of exposure measurement errors, in the context of  
7 time-series epidemiology, also has shown that errors or uncertainties introduced by using  
8 surrogate exposure variables, such as ambient PM concentrations, could lead to biases in the  
9 estimation of health risk coefficients. These then would need to be corrected by suitable  
10 calibration of the PM health risk coefficients. Correlations between the PM exposure variables  
11 and other covariates (e.g., gaseous co-pollutants, weather variables, etc.) also could influence the  
12 degree of bias in the estimated PM regression coefficients. However, most time-series  
13 regression models employ seasonal or temporal detrending of the variables, thus reducing the  
14 magnitude of this cross-correlation problem (Özkaynak and Spengler 1996).

15 Ordinarily, exposure measurement errors are not expected to influence the interpretation of  
16 findings from either the chronic or time-series epidemiological studies that have used ambient  
17 concentration data if they include sufficient adjustments for seasonality and key confounders.  
18 Clearly, there is no question that better estimates of exposures to components of PM of health  
19 concern are beneficial. Composition of PM may vary in different geographic locations and  
20 different exposure microenvironments. Compositional and spatial variations could lead to  
21 further errors in using ambient PM measures as surrogates for exposures to PM. Even though  
22 the spatial variability of PM (PM<sub>2.5</sub> in particular) mass concentrations in urban environments  
23 seems to be small, the same conclusions drawn above regarding the influence of measurement  
24 errors may not necessarily hold for all of the toxic PM components. Again, the expectation  
25 based on statistical modeling considerations is that these exposure measurement errors or  
26 uncertainties will most likely reduce the statistical power of the PM health effects analysis,  
27 making it difficult to detect a true underlying association between the correct exposure metric  
28 and the health outcome studied. However, until more data on exposures to toxic agents of PM  
29 become available, existing studies on PM exposure measurement errors must be relied on; thus,  
30 at this time the use of ambient PM concentrations as a surrogate for exposures is not expected to

1 change the principal conclusions from PM epidemiological studies that use community average  
2 health and pollution data.

## 5.6 SUMMARY OF OBSERVATIONS AND LIMITATIONS

### Exposure Definitions and Components

- 7 • Personal exposure to PM mass or its constituents results when individuals come in contact  
with particulate pollutant concentrations in locations or microenvironments that they  
frequent during a specific period of time. Various PM exposure metrics can be defined  
according to its source (i.e., ambient, nonambient) and the microenvironment where  
exposure occurs.
- 8 • Personal exposure to PM results from an individual's exposure to PM in many different  
types of microenvironments (e.g., outdoors near home, outdoors away from home, indoors at  
home, indoors at office or school, commuting, restaurants, malls, other public places, etc.).  
Thus, total daily exposure to PM for a single individual can be expressed as the sum of  
various microenvironmental exposures that the person encounters during the course of a day.
- 9 • In a given microenvironment, particles may originate from a wide variety of sources. In an  
indoor microenvironment, PM may be generated from within as a result of PM-generating  
activities (e.g., cooking, cleaning, smoking, resuspending PM from PM resulting from both  
indoor and outdoor sources that had settled out), from outside (outdoor PM entering through  
cracks and openings in the structure), and from the chemical interaction of pollutants from  
outdoor air with indoor-generated pollutants.
- 10 • The total daily exposure to PM for a single individual also can be expressed as the sum of  
contributions of ambient and nonambient PM. Nonambient PM exposure is due to PM  
generated by indoor sources, personal activities, and chemical reactions in indoor air.  
Ambient PM exposure includes exposure to ambient PM while outdoors, and ambient PM  
that has infiltrated indoors while indoors. However, within a large population, there will be  
distributions of total personal exposure and its components due to variations in human  
activities and microenvironmental concentrations and sources each individual encounters.
- 11 • Exposure models are useful tools for examining the importance of sources,  
microenvironments, and physical and behavioral factors that influence personal exposures to

PM. However, development and evaluation of population exposure models for PM and its components have been limited. Improved modeling methodologies and new model input data are needed.

12

13 **Factors Affecting Concentrations and Exposures to Particulate Matter**

- 14
- Concentrations of PM indoors are affected by several factors and mechanisms: ambient concentrations outdoors; air exchange rates; particle penetration factors; particle production from indoor sources and indoor air chemistry; and indoor particle decay rates and removal mechanisms caused by physical processes or resulting from mechanical filtration, ventilation or air-conditioning devices.
- 15
- Average personal exposures to PM mass and its constituents are influenced by microenvironmental PM concentrations and by how much time is spent by each individual in these various indoor and outdoor microenvironments. Nationwide, individuals, on average, spend nearly 90% of their time indoors (at home and in other indoor locations) and about 6% of their time outdoors.
- 16
- Personal exposures are associated with both indoor as well as outdoor sources. The personal exposure/outdoor concentration ratios present substantial intra- and inter-personal variability. This variability is due to both the presence of personal and microenvironmental sources and the varying effect of the outdoor particles on indoor environments.
- 17
- Home characteristics may be the most important factor that affects the relationship between the average population exposures and ambient concentrations. Air exchange rate seems to be an important home characteristic surrogate that can explain a large fraction of the observed inter- and intra-personal variability. One reason why longitudinal studies (many repeated measurements per person) provide stronger correlations between personal exposure and outdoor concentrations than cross-sectional studies (few repeated measurements per individual) may be because home characteristics remain the same.
- 18
- Because home characteristics constitute the most important factor affecting personal exposures, one would expect that correlations between average population exposures and outdoor concentrations will vary by season and geography.

- 1 • The relative size of personal exposure to ambient PM relative to nonambient PM depends on the ambient concentration, the infiltration rate of outdoor PM into indoor microenvironments, the amount of PM generated indoors (e.g., ETS, cooking and cleaning emissions), and the amount of PM generated by personal activity sources. Infiltration rates primarily depend on air exchange rate, size-dependent particle penetration across the building membrane, and size-dependent removal rates. All of these factors vary over time and across subjects and building types.
- 2 • The relationship between PM exposure, dose, and health outcome could depend on the concentration, composition, and toxicity of PM or PM components originating from different sources. Application of source apportionment techniques to indoor and outdoor PM<sub>2.5</sub> and personal, indoor, and outdoor PM<sub>10</sub> composition data have identified the following general source categories: outside soil, resuspended indoor soil, indoor soil, personal activities, sea-salt, motor vehicles, nonferrous metal smelters, and secondary sulfates.
- 3 • There have been only a limited number of studies that have measured the physical and chemical constituents of PM in personal or microenvironmental samples. Available data on PM constituents indicate the following:
  - personal and indoor sulfate measurements often are correlated highly with outdoor and ambient sulfate concentration measurements;
  - for acid aerosols, indoor air chemistry is particularly important because of the neutralization of the acidity by ammonia, which is present at higher concentrations indoors because of the presence of indoor sources of ammonia;
  - for SVOCs, including PAHs and phthalates, the presence of indoor sources will substantially affect the relation between indoor and ambient concentrations;
  - penetration and decay rates are functions of size and will cause variations in the attenuation factors as a function of particle size; infiltration rates will be higher for PM<sub>1</sub> and PM<sub>2.5</sub> than for PM<sub>10</sub>, PM<sub>10-2.5</sub> or ultrafine particles; and
  - indoor air chemistry may increase indoor concentrations of organic PM.
- 4 • Even though there is an increasing amount of research being performed to measure PM constituents in different PM size fractions, with few exceptions (i.e., sulfur or sulfates) the current data are inadequate to adequately assess the relationship between personal, indoor, and ambient concentrations of most PM constituents.

## 1 **Correlations Between Personal Exposures, Indoor, Outdoor, and Ambient Measurements**

- 2 • Most of the available personal data on PM measurements and information on the  
relationships between personal and ambient PM come from a few large-scale studies (e.g.,  
the PTEAM study) or the longitudinal panel studies that have been conducted on selected  
populations, such as the elderly.
- 3 • Panel and cohort studies that have measured PM exposures and concentrations typically have  
reported their results in terms of three types of correlations: (1) longitudinal, (2) pooled, and  
(3) daily-average correlations between personal and ambient or outdoor PM.
- 4 • The type of correlation analysis performed can have a substantial effect on the resulting  
correlation coefficient. Low correlations with ambient concentrations could result when  
people with very different nonambient exposures are pooled even though their individual  
personal exposures may temporally be correlated highly with ambient concentrations.
- 5 • Longitudinal and pooled correlations between personal exposure and ambient or outdoor PM  
concentrations reported by various investigators varied considerably among the different  
studies and in each study between the study subjects. Most studies report longitudinal  
correlation coefficients that range from close to zero to near one, indicating that individual's  
activities and residence type may have a significant effect on total personal exposures to PM.
- 6 • Longitudinal studies that measured sulfate found high correlations between personal and  
ambient sulfate.
- 7 • In general, probability-based population studies tend to show low pooled correlations  
because of the high differences in levels of nonambient PM-generating activities from one  
subject to another. In contrast, the absence of indoor sources for the populations in several  
of the longitudinal panel studies resulted in high correlations between personal exposure and  
ambient PM within subjects over time for these populations. However, even for these  
studies, correlations varied by individual depending on their activities and the  
microenvironments that they occupied.

10

## Potential Sources of Error Resulting from Using Ambient Particulate Matter Concentrations in Epidemiological Analyses

As yet, there is no clear consensus among exposure analysts as to how well community monitor measurements of ambient air PM concentrations represent a surrogate for personal exposure to total PM or to ambient PM.

- Measurement studies of personal exposures to PM are still few and limited in spatial, temporal, and demographic coverage. Consequently, with the exception of a few longitudinal panel studies, most epidemiological studies on PM health effects have relied on daily-average PM concentration measurements obtained from ambient community monitoring data as a surrogate for the exposure variable.
- Because individuals are exposed to particles in a multitude of indoor and outdoor microenvironments during the course of a day, concerns about error introduced in the estimation of PM risk coefficients using ambient, as opposed to personal PM measurements, have been raised.
- Total personal exposures to PM could vary from person to person, and even day to day, depending on the specific activities of each person. Separation of PM exposures into two components, ambient and nonambient PM, would reduce potential uncertainties in the analysis and interpretation of PM health effects data.
- Available data indicate that PM mass concentrations, especially fine PM, typically are distributed relatively uniformly in most metropolitan areas, thus reducing the potential for exposure misclassification because of spatial variability when a limited number of ambient PM monitors are used to represent population average ambient exposures in community time-series or long-term, cross-sectional epidemiological studies of PM.
- Even though the spatial variability of PM (in particular,  $PM_{2.5}$ ) mass concentrations in urban environments seems to be small, the same conclusions drawn above regarding the influence of measurement errors may not necessarily hold for all PM components.
- There are important differences in the relationship of ambient PM concentrations with ambient PM exposures and with nonambient PM exposures. Various researchers have shown that ambient PM exposure is a function of ambient PM concentration and that concentrations of ambient PM are driven by meteorology, by changes in source emission rates, and in locations of emission sources relative to the measurement site. However,

nonambient PM exposure is independent of ambient PM concentration because concentrations of nonambient PM are driven by the daily activities of people.

- 12
- Because personal exposures also include a contribution from ambient concentrations, the correlation between daily-average personal exposure and the daily-average ambient concentration increases as the number of subjects measured daily increases. An application of a Random Component Superposition model has shown that the contributions of ambient  $PM_{10}$  and indoor-generated  $PM_{10}$  to community mean exposure can be decoupled in modeling urban population exposure distributions.
- 13
- If linear nonthreshold models are assumed in time-series analysis of daily-average ambient PM concentrations and community health data, nonambient PM exposure is not expected to contribute to the relative risk estimates determined by regression of health responses on ambient PM concentration.
- 14
- Using the PTEAM study data, analysis of exposure measurement errors in the context of time-series epidemiology has shown that the error introduced by using ambient PM concentrations as a surrogate for ambient PM exposure biases the estimation of health risk coefficients low by the ratio of ambient PM exposure to ambient PM concentration (called the attenuation factor). However, the health risk coefficient determined using ambient PM concentrations provides the correct information on the change in health risks that would be produced by a change in ambient concentrations.
- 15
- Because sources and chemical composition of particulate matter affecting personal exposures in different microenvironments vary by season, day-of-the-week, and time of day, it is likely that some degree of misclassification of exposures to PM toxic agents of concern will be introduced when health-effects models use only daily-average mass measures such as  $PM_{10}$  or  $PM_{2.5}$ . Because of the paucity of currently available data on many of these factors, at this point it is impossible to ascertain the significance of these more complex exposure misclassification problems in the interpretation of results from PM epidemiology.
- 16
- Exposure measurement errors may depend on particle size and composition.  $PM_{2.5}$  better reflects personal exposure to PM of outdoor origin than  $PM_{10}$ . Various indicators of ultrafine particle concentrations or other components of PM may also be useful exposure indicators for epidemiological studies.

- 1
- Seasonal or temporal variations in the measurement errors and their correlations between different PM concentration measures and co-pollutants (e.g., SO<sub>2</sub>, CO, NO<sub>2</sub>, O<sub>3</sub>) could influence the error analysis results but not likely the interpretation of current findings.
- 2
- Multipollutant personal exposure studies have suggested that ambient concentrations of gaseous co-pollutants serve as surrogates of personal exposures to particles rather than as confounders. The implications for epidemiology are discussed in Chapters 8 and 9.
- 3
- Ordinarily, PM exposure measurement errors are not expected to influence the interpretation of findings from either the community time-series or long-term epidemiological studies that have used ambient concentration data if they include sufficient adjustments for seasonality and key personal and geographic confounders.
- 4
- In the context of long-term epidemiological studies, it appears that the errors introduced in estimating ambient PM indoor/ambient PM outdoor ratios have much more influence on the accuracy of the microenvironmental exposure estimation approach than do errors in estimating time spent in these microenvironments.
- 5
- To reduce exposure misclassification errors in PM epidemiology, conducting new cohort studies of sensitive populations with better real-time techniques for exposure monitoring and further speciation of indoor-generated, ambient, and personal PM mass are essential.
- 6
- Based on statistical modeling considerations, it is expected that existing PM exposure measurement errors or uncertainties most likely will reduce the statistical power of the PM health effects analysis, thus making it difficult to detect a true underlying association between the correct exposure metric and the health outcome studied.
- 7
- Although exposure measurement errors for fine particles are not expected to influence the interpretation of findings from either the community time-series or the long-term, cross-sectional epidemiological studies that have used ambient concentration data, they may underestimate the strength of the effect. Sufficient data are not available to evaluate the effect of exposure measurement error for other PM species or size fractions.

8

9

## 1 **Key Findings**

- 2 • Most people spend most of their time indoors where they are exposed to indoor-generated PM and ambient PM that has infiltrated indoors.
- 3 • Indoor-generated and ambient PM differ in sources, sizes, chemical composition, and toxicity.
- 4 • The ambient PM concentration and the indoor PM concentration can be measured by outdoor and indoor monitors. The total personal exposure can be measured by a personal exposure monitor carried by the person. However, the concentrations of indoor-generated PM and ambient PM that has infiltrated indoors and the related values of ambient and nonambient PM exposures must be estimated.
- 5 • From a regression of individual, daily values of total personal exposure on daily PM concentrations, the intercept gives the average nonambient PM exposure and the slope gives the average attenuation factor (the ratio of ambient PM exposure to ambient PM concentration).
- 6 • Similarly, from a regression of individual, daily values of indoor PM concentration on daily ambient concentrations, the intercept gives the average concentration of indoor-generated PM and the slope gives the average infiltration factor (concentrations of ambient PM that has infiltrated indoors/ambient PM concentration).
- 7 • The attenuation factor and the infiltration factor depend on the penetration coefficient, the fraction of ambient PM that penetrates through the walls, doors, windows, etc.; the deposition or removal rate, a measure of how rapidly PM within the indoor microenvironment is removed by deposition to surfaces or by filtration in a heating/cooling system; and the air exchange rate, a measure of how rapidly indoor air is replaced by outdoor air. The attenuation factor also depends on the fraction of time spent outdoors.
- 8 • The air exchange rate is an important variable for determining the concentration of ambient PM found indoors. It can be measured by release and measurement of an inert tracer gas indoors. The air exchange rate increases with opening of windows or doors or operation of window or attic fans. It also increases as the indoor/outdoor temperature difference increases. For closed homes, i.e., no open windows or doors, the air exchange rate does not appear to be a function of wind speed or direction.

- 1 • The penetration coefficient and the deposition rate can be estimated from measurements of outdoor and indoor concentrations under conditions when there are no indoor sources (night time or unoccupied home). These parameters are functions of particle size. The penetration coefficient is high and the deposition rate is low for accumulation mode particles (0.1 to 1.0  $\mu\text{m}$ ). The penetration coefficient is lower and the deposition rate is higher for ultrafine particles ( $< 0.1 \mu\text{m}$ ) and coarse mode particles ( $> 1.0 \mu\text{m}$ ). The attenuation factor and the infiltration factor are higher for particles in the accumulation mode than for ultrafine or coarse particles.
- 2 • The attenuation factor and the infiltration factor will vary as the air exchange rate and therefore will vary with season and housing characteristics. These factors will increase with increased opening of windows and doors. For closed homes, these factors will increase with an increase of the indoor/outdoor temperature difference but they do not appear to be affected by wind speed or direction.
- 3 • The regression technique is useful for finding average values of the attenuation factor and the nonambient exposure and possibly for estimating the distribution of individual, daily values of the nonambient PM exposure.
- 4 • However, individual, daily values of the ambient PM exposure, the nonambient PM exposure, and the attenuation factor are needed. These may be determined from individual, daily values of the total PM personal exposure and daily ambient PM concentrations by several techniques:
  - 5 (1) *Mass balance technique*. Direct measurement of the air exchange rate, measurement of the fraction of time spent outdoors by a diary of the subject's activity pattern, and use of the equilibrium mass balance equation for the attenuation factor with estimated values of the penetration coefficient and the deposition rate.
  - 6 (2) *Sulfate ratio technique*. Individual, daily values of the attenuation factor (for  $\text{PM}_{2.5}$ ) will be given by individual, daily values of personal exposure to sulfate / the daily ambient sulfate concentration provided there are no indoor sources of sulfate and sulfate and  $\text{PM}_{2.5}$  have similar particle size distributions.

1           (3) *Recursive technique.* Indoor-generated emissions, which tend to be episodic, can be  
2           removed from a continuous record of indoor PM concentration, allowing separation of  
3           indoor-generated PM and ambient PM that has infiltrated indoors.

4           • In pooled studies (different subjects measured on different days), individual, daily values of  
5           the total PM exposure are usually not well correlated with the daily ambient PM  
6           concentrations. In longitudinal studies (each subject measured for multiple days), individual,  
7           daily values of the total PM personal exposure and the daily ambient PM concentrations are  
8           found to be highly correlated for some, but not all subjects.

9           • Only one study has reported estimated individual, daily values of ambient and nonambient  
10          PM exposure. Individual, daily values of the total PM personal exposure and the daily  
11          ambient PM concentrations were poorly correlated. However, individual, daily values of  
12          ambient PM exposure and the daily ambient PM concentrations were highly correlated.  
13          Individual daily values of ambient and nonambient PM exposure were not well correlated.  
14          Individual daily values of nonambient PM exposure and daily ambient PM concentrations  
15          were also not well correlated.

16          • These key findings will be used in examining the implications of using the ambient PM  
17          concentration instead of the total PM personal exposure (or the ambient PM exposure) in  
18          epidemiological studies.
